(Dated: today)

Detection of a surprisingly high flux of positron annihilation radiation from the inner galaxy has motivated the proposal that dark matter is made of weakly interacting light particles (possibly as light as the electron). This scenario is extremely hard to test in current high energy physics experiments. Here, however, we demonstrate that the current value of the electron anomalous magnetic moment already has the required precision to unambiguously test the light dark matter hypothesis. If confirmed, the implications for astrophysics are far-reaching.

## I. INTRODUCTION

Many cosmological observations have shown that visible matter only represents 20% of the mass of the Universe. The remaining 80% is of unknown origin. For several decades, particle physicists have speculated that this "dark" matter was made of very heavy particles (from one to a thousand proton masses). Recently, however, the confirmation that low energy positrons are being emitted in the centre of the galaxy [1] motivated the proposal that light particle annihilations could account for the extended 511 keV line emission [2] detected since the 1970s. Dark matter would then be made of light scalars annihilating via the exchange of both a new gauge boson Z' and a heavy fermion  $F_e$ . The existence of the  $F_e$  particle would explain the morphology of the 511 keV line while the Z' would explain why dark matter represents 80% of the matter content of our universe. Both particles are very hard to test in current particle physics experiments. Therefore the question arises as to whether one can ever unambiguously test this model in the laboratory.

A few months ago, a group proposed an electron-proton scattering experiment to detect light new gauge bosons [3]. Although such an experiment certainly deserves to be done, it may not unambiguously determine the source of antimatter in the Milky Way. Indeed, not only is the Z' not directly related to the 511 keV line but there is also an alternative scenario in which the Z' is replaced by a neutral fermion N [4]. Hence, the only way to really answer the question of the light particle annihilation origin of low energy positrons in our galaxy is to directly test the existence of  $F_e$  particles. Here we present such a test.

## II. ELECTRON ANOMALOUS MAGNETIC MOMENT

With the latest observations by the SPI spectrometer on the INTEGRAL satellite, it became possible to establish that the 511 keV line (already observed by five experiments and now detected at  $16\sigma$ ) originates from electron-positron pair annihilations at rest. The rate at which these positrons are being emitted and their spatial distribution are extremely hard to explain with conventional and/or new (as yet unknown) astrophysical sources. On the other hand, both the energy and spatial distribution is suggestive of dark matter characteristics. Hence, one hypothesis is that SPI has discovered, for the

first time, evidence that dark matter is made of nonbaryonic particles.

To explain the observed morphology of the 511 keV line, dark matter must be light (a thousand to a hundred times lighter than a proton, i.e. with a mass comparable to the electron mass) and must annihilate into electron-positron pairs. The model which was first proposed relies on Z' and  $F_e$  exchanges. In the primordial universe, the Z' reduces the dark matter abundance to the observed value while the  $F_e$  provides a subdominant source of positrons. In the Milky Way, the importance of these two particles is inverted (due to the velocitydependence of the Z' exchange cross-section) and the  $F_e$  becomes the dominant source of electron-positron pairs.

Since both Z' and  $F_e$  interact with electrons, they are expected to modify the electron characteristics to some extrent. For example, the Landé factor  $g_e$  which is equal to  $g_e = 2(1+a_e)$ , with  $a_e$  the so-called anomalous magnetic moment of the electron due to QED, QCD, weak interactions, could receive two additional contributions  $\delta g_e^{Z',F} = 2a_e^{Z',F}$  with:

	$F_e$	Z'
$a_e$	$\frac{c_l c_r \ m_e}{16\pi^2 m_{F_e}}$	$\frac{z_e^2}{12\pi^2} \frac{m_e^2}{m_{Z'}^2}$
=	$5.10^{-12} \sqrt{f} \left(\frac{m_{\rm dm}}{\rm MeV}\right)$	$10^{-11} \left(\frac{z_e}{710^{-5}}\right)^2 \left(\frac{m_{Z'}}{\text{MeV}}\right)^{-2}$

where we use the expressions and values of the  $F_e$  [5, 6] and Z' exchange [7] annihilation cross-sections. The parameter f reflects the type of dark matter halo profile that fits the data. As shown in Ref. [6], it is equal to unity in the case of a Navarro-Frenk-White profile (much flatter or cuspier profiles were ruled out by this analysis).

The remarkable point is that  $a_e^F$  only depends on the morphology of the 511 keV line and is therefore constrained to lie within a narrow range of values. This enables us to make firm predictions. So far, the Z' contribution, which seems closer to the experimental value of  $(g_e - 2)$ , was always regarded as more important. Here, however, we point out that the  $F_e$  particles give the dominant contribution to the electron anomalous magnetic moment. This opens up new possibilities to test the light dark matter scenario in laboratory experiments.

The term  $a_e^{Z'}$  depends on two parameters: the mass  $m_{Z'}$  and the coupling to electron  $z_e$ . The latter varies from a minimal value  $z_e^{min,RD}$ , fixed by the relic density condition, to a maximal value  $z_e^{max,g_e-2}$ , fixed by the condition  $a_e^{Z'} = a_e^{exp}$ 

FIG. 1: Here we plotted the Z' coupling to electrons versus the Z' mass for  $m_{\rm dm} = 1$  MeV and  $(a_e^F + a_e^{Z'}) \le \delta a_{Rb06}$  (we do not plot the error bars). The allowed parameter space is represented in green. The upper region (above the magenta line) represents  $z_e$  values for which the Z' contribution to the electron anomalous magnetic moment is dominant. As one can see,  $a_e^F$  always dominates over  $a_e^{Z'}$  in the allowed region. This region shrinks towards the red line for increasing values of  $m_{\rm dm}$ .

(with  $a_e^{exp}$  the measured value of the the anomalous magnetic moment)[7]. The Z' contribution to the electron anomalous magnetic moment dominates over the  $F_e$  contribution when

$$z_e > z_e^{eq} = 4.7 \ 10^{-5} \ \sqrt{f} \ \left(\frac{m_{Z'}}{\text{MeV}}\right) \ \sqrt{\left(\frac{m_{\text{dm}}}{1 \text{MeV}}\right)}.$$

However, as we demonstrate in Fig. 1 for  $m_{\rm dm} = 1$  MeV, and varying  $m_{Z'}$  between 7 to 200 MeV, we find that  $z_e^{eq}$  is always outside the allowed range, *i.e.*  $a_e^F$  is the main extra contribution to the electron  $g_e - 2$  value. One can therefore unambiguously test the existence of  $F_e$  particles and elucidate the origin of the low energy positrons in the Milky Way by using  $g_e - 2$  measurements.

The latest measurement of the electron anomalous magnetic moment by the Harvard group in 2006 [8], using a One-Electron Quantum Cyclotron, gives  $a_e^{exp,06} = g/2 - 1 = 0.00115965218085(76)$ , with a 7.6  $10^{-13}$  uncertainty. We estimate the  $F_e$  contribution to lie between

$$a_e^F \in [5\sqrt{f} \, 10^{-12} \,, \, 1.5\sqrt{f} \, 10^{-11}],$$

using dark matter mass range derived in [9]. This is comparable to the level of precision that has been reached experimentally. This experiment is therefore sensitive enough to prove  $F_e$  interactions.

Let us now compare our estimate with the discrepancy between the  $a_e^{exp}$  experimental value and the Standard Model prediction (without light dark matter). The theoretical estimate  $a_e^{th}$  depends on one parameter: the value of the fine structure constant  $\alpha$ . Unfortunately, this is not known with the same level of precision as the electron anomalous magnetic moment but the latest (most precise) measurements of  $\alpha$  by the Caesium and Rydberg constant experiments in 2006 [10, 11] nevertheless lead to the following differences [8]:

$$\delta a_{CS06} = a_e^{th}(\alpha_{Cs06}) - a_e^{exp,06} = -7.9 \ (9.3) \ 10^{-12}$$

and

$$\delta a_{Rb06} = a_e^{th}(\alpha_{Rb06}) - a_e^{exp,06} = 1.9 (7.7) \ 10^{-12}$$

respectively. At present, this comparison only indicates that there is room for light dark matter. However, as soon as measurements of  $\alpha$  will converge and the error bars will decrease, one should be able to determine whether or not scalar particles coupled to heavy fermions  $F_e$  can be responsible for the emission of the 511 keV line in our galaxy.

Note that the relation between  $a_e^{th}$  and the fine structure constant includes calculations of QED, WEAK and QCD contributions (QED to the tenth-order [12]). The next order calculations may change the present discrepancies and even be sufficient to solve the dark matter problem.

## **III. CONCLUSION**

Using the 511 keV line properties, we have shown that the  $F_e$  contribution to the electron anomalous magnetic moment was dominant and within the reach of the present anomalous magnetic moment experiment. It is remarkable that precise measurement of the fine structure constant offers the best way to test the light dark matter scenario. Although such a test requires the experimental and computational expertise of particle physicists, the result should have a great impact on the astrophysics/astroparticle community by answering whether or not dark matter is light and has actually been discovered by SPI. A negative answer would indicate that the origin of the low energy positrons in our galaxy is of (hitherto unknown) astrophysical origin. This would in turn motivate high sensitivity point source searches as well as improved diffuse X-ray/ $\gamma$ -ray background observations.
