M odeling hom ophily and stochastic equivalence in symmetric relational data

Peter D.Ho

December 9, 2021

A bstract

This article discusses a latent variable model for inference and prediction of symmetric relational data. The model, based on the idea of the eigenvalue decomposition, represents the relationship between two nodes as the weighted inner-product of node-speci c vectors of latent characteristics. This \eigenmodel" generalizes other popular latent variable models, such as latent class and distance models: It is shown mathematically that any latent class or distance model has a representation as an eigenmodel, but not vice-versa. The practical implications of this are examined in the context of three real datasets, for which the eigenmodel has a good or better out-of-sample predictive perform ance than the other two models.

Som e key words: Factor analysis, latent class, M arkov chain M onte C arlo, social network.

1 Introduction

Let $fy_{i;j}: 1$ i < j ng denote data measured on pairs of a set of n objects or nodes. The examples considered in this article include friendships among people, associations among words and interactions among proteins. Such measurements are often represented by a sociomatrix Y, which is a symmetric n n matrix with an unde ned diagonal. One of the goals of relational data analysis is to describe the variation among the entries of Y, as well as any potential covariation of Y with observed explanatory variables $X = fx_{i;j}; 1$ i < j ng.

To this end, a variety of statistical models have been developed that describe y_{ij} as some function of node-speci c latent variables u_j and u_j and a linear predictor ${}^T x_{ij}$. In such formulations, fu₁;:::; u_n g represent across-node variation in the y_{ij} 's and represents covariation of the y_{ij} 's

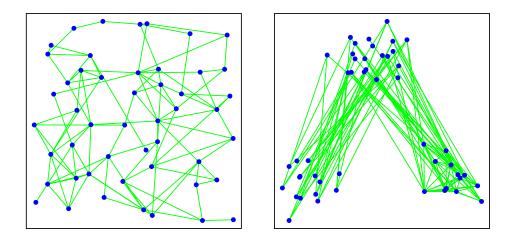

Figure 1: Networks exhibiting hom ophily (left panel) and stochastic equivalence (right panel).

with the $x_{i;j}$'s. For example, N ow icki and Snijders [2001] present a model in which each node i is assumed to belong to an unobserved latent class u_i , and a probability distribution describes the relationships between each pair of classes (see K emp et al. [2004] and A iroldi et al. [2005] for recent extensions of this approach). Such a model captures stochastic equivalence, a type of pattern offen seen in network data in which the nodes can be divided into groups such that mem bers of the sam e group have similar patterns of relationships.

An alternative approach to representing across-node variation is based on the idea of hom ophily, in which the relationships between nodes with sim ilar characteristics are stronger than the relationships between nodes having di erent characteristics. Hom ophily provides an explanation to data patterns often seen in social networks, such as transitivity (\a friend of a friend is a friend"), balance (\the enem y of m y friend is an enem y") and the existence of cohesive subgroups of nodes. In order to represent such patterns, Ho et al. [2002] present a model in which the conditional m ean of $y_{i;j}$ is a function of ${}^{0}x_{i;j}$ j μ_{i} u_jj where fu₁;:::; u_{n} g are vectors of unobserved, latent characteristics in a Euclidean space. In the context of binary relational data, such a model predicts the existence of m ore transitive triples, or \triangles," than would be seen under a random allocation of edges am ong pairs of nodes. An important assumption of this model is that two nodes with a strong relationship between them are also sim ilar to each other in terms of how they relate to other nodes: A strong relationship between them are also sim ilar to each other in terms of how they relate to other nodes: A strong relationship between is and j suggests j μ_{i} u_jj is small, but this further implies that j μ_{i} u_kj j μ_{j} u_kj and so nodes i and j are assumed to have sim ilar relationships to other nodes.

The latent classm odelofN ow icki and Snijlers [2001] and the latent distancem odelofH o et al. [2002] are able to identify, respectively, classes of nodes with similar roles, and the locational properties of the nodes. These two items are perhaps the two primary features of interest in social network and relational data analysis. For example, discussion of these concepts makes up more than halfof the 734 pages of main text in W asserm an and Faust [1994]. However, a model that can represent one feature may not be able to represent the other: Consider the two graphs in Figure 1. The graph on the left displays a large degree of transitivity, and can be well-represented by the latent distance model with a set of vectors $fu_1; \ldots; u_n g$ in two-dimensional space, in which the probability of an edge between i and j is decreasing in $ju_1 = u_j j$. In contrast, representation of the graph by a latent class model would require a large number of classes, none of which would be particularly cohesive or distinguishable from the others. The second panel of Figure 1 displays a network involving three classes of stochastically equivalent nodes, two of which (say A and B) have only across-class ties, and one (C) that has both within- and across-class ties. This graph is well-represented by a latent class model in which edges occur with high probability between pairs having one member in each of A and B or in B and C, and am ong pairs having both members in C (in models of stochastic equivalence, nodes within each class are not dimensional both members in the latent characteristics to be on the order of the class membership sizes.

M any real networks exhibit combinations of structural equivalence and hom ophily in varying degrees. In these situations, use of either the latent class or distance m odel would only be representing part of the network structure. The goal of this paper is to show that a simple statistical m odel based on the eigenvalue decom position can generalize the latent class and distance m odels: Just as any symmetric matrix can be approximated with a subset of its largest eigenvalues and corresponding eigenvectors, the variation in a sociomatrix can be represented by m odeling $y_{i;j}$ as a function of ${}^{0}x_{i;j} + u_{i}^{T}$ u_{j} , where fu_{1} ; :::; u_{n} g are node-speci c factors and is a diagonal matrix. In this article, we show mathematically and by example how this eigenmodel can represent both stochastic equivalence and hom ophily in symmetric relational data, and thus is more general than the other two latent variable m odels.

The next section motivates the use of latent variables models for relational data, and shows m athem atically that the eigenmodel generalizes the latent class and distance models in the sense that it can compactly represent the same network features as these other models but not vice-versa. Section 3 compares the out-of-sample predictive performance of these three models on three di erent datasets: a social network of 12th graders; a relational dataset on word association counts from the rst chapter of G enesis; and a dataset on protein-protein interactions. The rst two networks exhibit latent hom ophily and stochastic equivalence respectively, whereas the third shows both to some degree. In support of the theoretical results of Section 2, the latent distance and class models perform well for the rst and second datasets respectively, whereas the eigenmodel performs well for all three. Section 4 sum marizes the results and discusses som e extensions.

2 Latent variable m odeling of relational data

2.1 Justi cation of latent variable modeling

The use of probabilistic latent variable models for the representation of relational data can be motivated in a naturalway: For undirected data without covariate information, symmetry suggests that any probability modelwe consider should treat the nodes as being exchangeable, so that

for any permutation of the integers f1;:::;ng and any set of sociom atrices A. R esults of H oover [1982] and A ldous [1985, chap. 14] show that if a m odel satis es the above exchangeability condition for each integer n, then it can be written as a latent variable m odel of the form

$$y_{i;j} = h(; u_i; u_j; i; j)$$
 (1)

for i.i.d. latent variables fu_1 ;:::; u_n g, i.i.d. pair-speci c e ects $f_{i;j}$:1 i < j ng and som e function h that is sym m etric in its second and third argum ents. This result is very general-it says that any statistical m odel for a sociom atrix in which the nodes are exchangeable can be written as a latent variable m odel.

Di erence choices of h lead to di erent models for y. A general probit model for binary network data can be put in the form of (1) as follows:

where and are parameters to be estimated, and is a symmetric function, also potentially involving parameters to be estimated. Covariation between Y and an array of predictor variables X can be represented by adding a linear predictor ${}^{T}x_{i;j}$ to . Finally, integrating over ${}_{i;j}$ we obtain $Pr(y_{i;j} = 1jx_{i;j};u_i;u_j;u_j;u_j) = [+ {}^{T}x_{i;j} + (u_i;u_j)]$. Since the ${}_{i;j}$'s can be assumed to be independent, the conditional probability of Y given X and fu_1;:::;u_ng can be expressed as

$$Pr(y_{i;j} = 1; x_{i;j}; u_i; u_j) = \begin{bmatrix} + & X_{i;j} + & (u_i; u_j) \end{bmatrix}$$

$$Pr(Y ; x_i; u_1; \dots; u_n) = Y$$

$$Y$$

$$Y$$

$$y_{i;j} (1 = y_{i;j})^{y_{i;j}}$$

$$i < j$$

$$(2)$$

M any relational datasets have ordinal, non-binary m easurem ents (for example, the word association data in Section 3.2). Rather than \thresholding" the data to force it to be binary, we can make use of the full information in the data with an ordered probit version of (2):

$$\Pr(y_{i;j} = y_{j}x_{i;j}; u_{i}; u_{j}) \quad \stackrel{(y)}{_{i;j}} = \left[y_{j} + {}^{T}x_{i;j} + (u_{i}; u_{j}) \right] \quad \left[y_{j+1} + {}^{T}x_{i;j} + (u_{i}; u_{j}) \right]$$

$$\Pr(Y_{j}X_{j}; u_{1}; \dots; u_{n}) = \begin{array}{c} Y \quad \stackrel{(y_{i;j})}{_{i;j}}; \\ i < j \end{array}$$

where f $_{\rm y}$ g are parameters to be estimated for all but the lowest value y in the sample space.

2.2 E ects of nodal variation

The latent variable models described in the Introduction correspond to dimension of the symmetric function :

Latent class m odel:

(u_i;u_j) = m_{u_i,u_j} u_i 2 f1;...;K g; i2 f1;...;ng M a K K symmetric matrix

Latent distance m odel:

Latent eigenm odel:

$$(u_i;u_j) = u_i^T \quad u_j$$

 $u_i 2 R^K ; i 2 f1; :::; ng$
a K K diagonalmatrix.

Interpretations of the latent class and distance models were given in the Introduction. An interpretation of the latent eigenmodel is that each node i has a vector of unobserved characteristics $u_i = fu_{i;1}$;:::; $u_{i;K}$ g, and that similar values of $u_{i;k}$ and $u_{j;k}$ will contribute positively or negatively to the relationship between i and j, depending on whether k > 0 or k < 0. In this way, the model can represent both positive or negative hom ophily in varying degrees, and stochastically equivalent nodes (nodes with the same or similar latent vectors) m ay or m ay not have strong relationships with one another.

We now show that the eigenm odel generalizes the latent class and distance models: Let S_n be the set of n n sociom atrices, and let

$$C_{K} = fC \ 2 \ S_{n} : c_{i;j} = m_{u_{i},u_{j}}; u_{i} \ 2 \ f1; :::; K \ g; M \ a \ K \ sym \ m \ etric \ m \ atrixg;$$
$$D_{K} = fD \ 2 \ S_{n} : d_{i;j} = ju_{i} \ u_{j}; u_{i} \ 2 \ R^{K} \ g;$$
$$E_{K} = fE \ 2 \ S_{n} : e_{i;j} = u_{i}^{T} \ u_{j}; u_{i} \ 2 \ R^{K}; a \ K \ diagonal \ m \ atrixg:$$

In other words, C_K is the set of possible values of $(u_i; u_j); 1 \quad i < j \quad ng \text{ under a } K \text{ -dim} \text{ ensional}$ latent class m odel, and sim ilarly for D_K and E_K .

 E_K generalizes C_K : Let C 2 C_K and let C be a completion of C obtained by setting $c_{i;i} = m_{u_i;u_i}$. There are at most K unique rows of C and so C is of rank K at most. Since the set E_K contains all socion atrices that can be completed as a rank-K matrix, we have $C_K = E_K$. Since E_K includes matrices with n unique rows, $C_K = E_K$ unless K n in which case the two sets are equal.

 E_{K+1} weakly generalizes D_K : Let $D \ 2 \ D_K$. Such a (negative) distance matrix will generally be of full rank, in which case it cannot be represented exactly by an E 2 E_K for K < n. However, what is critical from a modeling perspective is whether or not the order of the entries of each D can be matched by the order of the entries of an E. This is because the probit and ordered probit model we are considering include threshold variables f $_{y}$: y 2 Y g which can be adjusted to accommodate monotone transformations of $(u_{i};u_{j})$. With this in mind, note that the matrix of squared distances among a set of K-dimensional vectors $fz_{1}; \ldots; z_{n}^{0} z_{n}$ $]^{T} 1^{T} + 1[z_{1}^{0} z_{1}; \ldots; z_{n}^{0} z_{n}] 2Z Z^{T}$) and so is in E_{K+2} . Furthermore, letting $u_{i} = (z_{i}; r^{2} - z_{i}^{T} z_{i}) 2 R^{K+1}$ for each $i 2 \ fl_{1}; \ldots; rg$, we have $u_{i}^{0}u_{j} = z_{i}^{0}z_{j} + \frac{p}{(r^{2} - ju_{i}f)}(r^{2} - ju_{j}f)$. For large enough r the num erical order of the num erical order of the entries of the same as that of $D \ 2 D_{K}$.

 D_K does not weakly generalize E_1 : Consider E 2 E_1 generated by = 1, $u_1 = 1$ and $u_1 = r < 1$ for i > 1. Then $r = e_{1;i_1} = e_{1;i_2} > e_{i_1;i_2} = r^2$ for all $i_1; i_2 \in 1$. For which K is such an ordering of the elements of D 2 D_K possible? If K = 1 then such an ordering is possible only if n = 3. For K = 2 such an ordering is possible for n = 6. This is because the kissing number in R^2 , or the number of non-overlapping spheres of unit radius that can simultaneously touch a central sphere of unit radius, is 6. If we put node 1 at the center of the central sphere, and 6 nodes at the centers of the 6 kissing spheres, then we have $d_{1;i_1} = d_{1;i_2} = d_{i_1;i_2}$ for all $i_1; i_2 \in 1$. We can only have $d_{1;i_1} = d_{1;i_2} > d_{i_1;i_2}$ if we remove one of the non-central spheres to allow for more room between those remaining, leaving one central sphere plus ve kissing spheres for a total of n = 6. Increasing n increases the necessary dimension of the Euclidean space, and so for any K there are n and E 2 E_1 that have entry orderings that cannot be matched by those of any D 2 D_K .

A less general positive sem ide nite version of the eigenmodel has been studied by Ho [2005], in which was taken to be the identity matrix. Such a model can weakly generalize a distance model, but cannot generalize a latent class model, as the eigenvalues of a latent class model could be negative.

3 M odel com parison on three di erent datasets

3.1 Param eter estim ation

Bayesian parameter estimation for the three models under consideration can be achieved via M arkov chain M onte C arlo (M C M C) algorithms, in which posterior distributions for the unknown quantities are approximated with empirical distributions of samples from a M arkov chain. For these algorithms, it is useful to form ulate the probit models described in Section 2.1 in terms of an additional latent variable $z_{i;j}$ norm al[${}^{0}x_{i;j}$ + ($u_i;u_j$)], for which $y_{i;j} = y$ if $_{y} < z_{i;j} < _{y+1}$. Using conjugate prior distributions where possible, the M C M C algorithm s proceed by generating a new state ${}^{(s+1)} = fZ {}^{(s+1)}$; ${}^{(s+1)}; {}^{(s+1)}; {}^{(s$

1. For each fi; jg, sam ple z_{i;j} from its (constrained norm al) full conditional distribution.

- 2. For each y 2 Y, sample v from its (norm al) full conditional distribution.
- 3. Sample from its (multivariate norm al) full conditional distribution.
- 4. Sam ple u_1 ;:::; u_n and their associated parameters:

For the latent distance model, propose and accept or reject new values of the u's with the M etropolis algorithm, and then sample the population variances of the $u_i's$ from their (inverse-gam m a) full conditional distributions.

For the latent class model, update each class variable u_j from its (multinom ial) conditional distribution given current values of Z_j ; $fu_j : j \in j$ ig and the variance of the elements of M (but marginally over M to improve mixing). Then sample the elements of M from their (norm al) full conditional distributions and the variance of the entries of M from its (inverse-gam m a) full conditional distribution.

For the latent vector model, sample each u_i from its (multivariate normal) full conditional distribution, sample the mean of the u_i 's from their (normal) full conditional distributions, and then sample from its (multivariate normal) full conditional distribution.

To facilitate comparison across models, we used prior distributions in which the level of prior variability in $(u_i;u_j)$ was similar across the three dimension of the MCMC is available at cran.r-project.org/src/contrib/Descriptions/eigenmodel.html.

3.2 Cross validation

To compare the perform ance of these three di erent models we evaluated their out-of-sample predictive perform ance under a range of dimensions (K $2 f_{3};5;10g$) and on three di erent datasets

K	Add health			G enesis			Protein interaction dist class eigen		
_	dist	class	eigen	dist	class	eigen	dist	class	eigen
3	0.82	0.64	0.75	0.62	0.82	0.82	0.83	0.79	0.88
5	0.81	0.70	0.78	0.66	0.82	0.82	0.84	0.84 0.86	0.90
10	0.76	0.69	0.80	0.74	0.82	0.82	0.85	0.86	0.90

Table 1: Cross validation results and area under the ROC curves.

exhibiting varying combinations of hom ophily and stochastic equivalence. For each combination of dataset, dimension and model we perform ed a ve-fold cross validation experiment as follows:

- 1. Random ly divide the $\frac{n}{2}$ data values into 5 sets of roughly equal size, letting $s_{i;j}$ be the set to which pair fi; jg is assigned.
- 2. For each s 2 f1;:::;5g:
 - (a) O btain posterior distributions of the model parameter conditional on $fy_{i;j} : s_{i;j} \in sg$, the data on pairs not in set s.
 - (b) For pairs fk; \lg in set s, let $\hat{y}_{k;l} = E[y_{k;l}fy_{i;j}:s_{i;j} \in sg]$, the posterior predictive m ean of $y_{k;l}$ obtained using data not in set s.

This procedure generates a sociom atrix \hat{Y} , in which each entry $\hat{y}_{i;j}$ represents a predicted value obtained from using a subset of the data that does not include $y_{i;j}$. Thus \hat{Y} is a sociom atrix of out-of-sam ple predictions of the observed data Y.

3.3 A dolescent H ealth social network

The rst dataset records friendship ties am ong 247 12th-graders, obtained from the N ational Longitudinal Study of A dolescent H ealth (www.cpc.unc.edu/projects/addhealth). For these data, $y_{i;j} = 1$ or 0 depending on whether or not there is a close friendship tie between student i and j (as reported by either i or j). These data are represented as an undirected graph in the rst panel of F igure 2. Like m any social networks, these data exhibit a good deal of transitivity. It is therefore not surprising that the best perform ing m odels considered (in terms of area under the ROC curve, given in Table 1) are the distance m odels, with the eigenm odels close behind. In contrast, the latent class m odels perform ance.

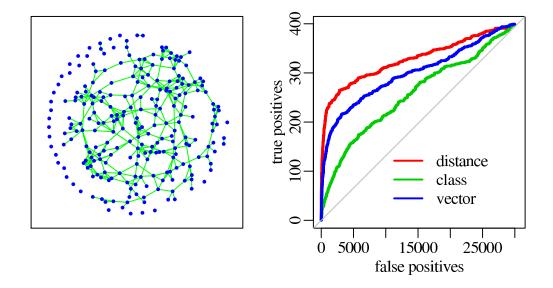

Figure 2: Social network data and unscaled ROC curves for the K = 3 m odels.

3.4 W ord neighbors in G enesis

The second dataset we consider is derived from word and punctuation counts in the st chapter of the K ing Jam es version of Genesis (www.gutenberg.org/dirs/etext05/bib0110.txt). There are 158 unique words and punctuation marks in this chapter, and for our example we take yi; to be the num ber of times that word i and word j appear next to each other (a model extension, appropriate for an asymmetric version of this dataset, is discussed in the next section). These data can be viewed as a graph with weighted edges, the unweighted version of which is shown in the rst panel of Figure 3. The lack of a clear spatial representation of these data is not unexpected, as text data such as these do not have groups of words with strong within-group connections, nor do they display much hom ophily: a given noun may appear quite frequently next to two di erent verbs, but these verbs will not appear next to each other. A better description of these data might be that there are classes of words, and connections occur between words of di erent classes. The cross validation results support this claim , in that the latent class m odel perform s much better than the distance model on these data, as seen in the second panel of Figure 3 and in Table 1. As discussed in the previous section, the eigenm odel generalizes the latent class m odel and perform s equally well. We note that param eter estim ates for these data were obtained using the ordered probit versions of the m odels (as the data are not binary), but the out-of-sam ple predictive perform ance was evaluated based on each model's ability to predict a non-zero relationship.

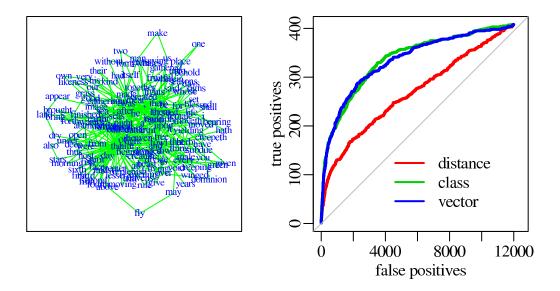

Figure 3: Relational text data from Genesis and unscaled ROC curves for the K = 3 m odels.

3.5 Protein-protein interaction data

O ur last example is the protein-protein interaction data of Butland et al. [2005], in which $y_{i;j} = 1$ if proteins i and j bind and $y_{i;j} = 0$ otherw ise. We analyze the large connected component of this graph, which includes 230 proteins and is displayed in the st panel of 4. This graph indicates patterns of both stochastic equivalence and hom ophily: Som e nodes could be described as \hubs", connecting to m any other nodes which in turn do not connect to each other. Such structure is better represented by a latent class m odel than a distance m odel. How ever, m ost nodes connecting to hubs generally connect to only one hub, which is a feature that is hard to represent with a sm all number of latent classes. To represent this structure well, we would need two latent classes per hub, one for the hub itself and one for the nodes connecting to the hub. Furtherm ore, the core of the network (the nodes with m ore than two connections) displays a good degree of hom ophily in the form of transitive triads, a feature which is easiest to represent with a distance m odel. The eigenm odel is able to capture both of these data features and perform s better than the other two m odels for any value of K considered.

4 D iscussion

Latent distance and latent class models provide concise, easily interpreted descriptions of social networks and relational data. However, neither of these models will provide a complete picture of relational data that exhibit degrees of both hom ophily and stochastic equivalence. In contrast,

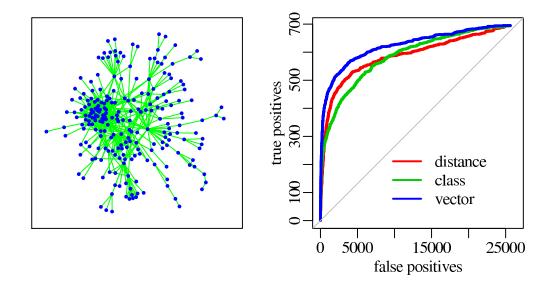

Figure 4: Protein-protein interaction data and unscaled ROC curves for the K = 3 m odels.

we have shown that a latent eigenm odel is able to represent datasets with either or both of these data patterns. This is due to the fact that the eigenm odel provides an unrestricted low-rank approximation to the sociomatrix, and is therefore able to represent a wide array of patterns in the data.

The concept behind the eigenm odel is the fam iliar eigenvalue decomposition of a symmetric matrix. The analogue for directed networks or rectangular matrix data would be a model based on the singular value decomposition, in which data $y_{i,j}$ could be modeled as depending on $u_i^T D v_j$, where u_i and v_j represent vectors of latent row and column e ects respectively. Statistical inference using the singular value decomposition for G aussian data is straightforward. A model-based version of the approach for binary and other non-G aussian relational datasets could be implemented using the ordered probit model discussed in this paper.
