Robust negative differential conductance and enhanced shot noise in transport through a molecular transistor with vibration assistance

Bing Dong, X. L. Lei, and N. J. M. Horing,

Abstract— In this paper, we analyze vibration-assisted sequential tunneling (including current-voltage characteristics and zerofrequency shot noise) through a molecular quantum dot with two electronic orbitals asymmetrically coupled to the internal vibration. We employ rate equations for the case of equilibrated phonons, and strong Coulomb blockade. We find that a system with a strongly phonon-coupled ground state orbital and weakly phonon-coupled excited state orbital exhibits strong negative differential conductance; and it also shows super-Poissonian current noise. We discuss in detail the reasons and conditions for the appearance of negative differential conductance.

I. INTRODUCTION

N a nanoelectromechanical system, mechanical motion can affect electrical transport and vice versa. [1] This has stimulated a large body of experimental [2]-[8] and theoretical [9]-[19] work concerning phonon-assisted resonant tunneling through a quantum dot (OD) with strong coupling to an internal vibrational (phonon) mode (IVM), since tunneling of a single electron may induce a displacement of the mobile mechanical structure (which can be used as a prototype of a nanoscale displacement sensor). On the other hand, the vibration of an adsorbed molecule can induce a change of tunneling current, providing a mechanism for sensing its adsorption and its identification. Current progress in nanotechnology has facilitated the fabrication of single-electron tunneling devices using molecules, for instance, a single $C_{60(140)}$ molecule and carbon nanotubes (CNTs). In particular, CNTs are ideal systems for designing electromechanical devices since they have a small diameter, a low mass, hence a strong electronphonon coupling (EPC) constant, and more importantly a relatively high quality factor, up to 10^4 .

Recent experimental studies of a long suspended CNT sample connected to two electrodes has revealed the appearance of negative differential conductance (NDC) at the onset of each phonon-assisted current step. [8] Theoretically, several previous calculations have been carried out for a system of a single level coupled to the phonon mode, and have revealed that the combined effect of low vibrational dissipation, i.e. an unequilibrated phonon (hot phonon), and strongly asymmetric tunnel-couplings to the left and right electrodes is responsible for the appearance of NDC at an appropriate EPC strength. [9], [15], [16], [20] However, this NDC in the single-orbital system is quite weak and can be destroyed easily by a dissipative environment [20], and even by applying an ac-bias voltage. [21] Nonetheless, it is desirable to search for a strong and robust NDC property in such transistors by tailoring material parameters for possible application in functional devices.

Our recent work has examined unequilibrated vibrationassisted tunneling through a molecular OD with two electronic orbitals having asymmetric couplings to the electrodes, with both strongly interacting with an IVM. [20] We found a strong NDC and correspondingly enhanced current noise due to a trapping effect, and we analyzed in detail the influence of the unequilibrated vibration on its appearance. On the other hand, Nowack and Wegewijs have considered vibration-assisted tunneling through a two-level QD with asymmetric couplings to an IVM. [17] Their results display strong NDC through a competition between different Franck-Condon (FC) tailored tunneling processes of the two levels, which is completely robust even against strong relaxation of the vibration. In this paper, we further investigate tunneling in this two-orbital system with asymmetric couplings to the vibration in the equilibrated vibration condition, focusing on the reasons and conditions for the appearance of strong NDC, as well as its corresponding zero-frequency shot noise. We find that the current noise is always greatly enhanced (having a giant Fano factor) for this kind of system.

The outline of this paper is as follows. In Sec. II, we describe the model system that we study. We also exhibit the rate equations in a number-resolved form at high temperature to describe phonon-assisted resonant tunneling in the limit of strong relaxation (equilibrated phonon). In Sec. III, we then investigate in detail the vibration-assisted transport and shot noise properties of a molecular two-orbital QD. Finally, a brief summary is given in Sec. IV.

II. MODEL AND RATE EQUATIONS

Here we consider a generic model, as shown in Fig. 1, for a molecular QD with two spinless levels, one as the highestoccupied molecular orbital (HOMO), ε_1 , and the other as the lowest-unoccupied molecular orbital (LUMO), ε_2 , coupled to two electrodes, left (L) and right (R), and also linearly coupled to an IVM of the molecule having frequency ω_0 with respective coupling strengths λ_1 and λ_2 . The model Hamiltonian is

$$H = H_{leads} + H_{mol} + H_T, \tag{1a}$$

Bing Dong and X.L. Lei are with the Department of Physics, Shanghai Jiaotong University, 1954 Huashan Road, Shanghai 200030, China.

N.J.M. Horing is with the Department of Physics and Engineering Physics, Stevens Institute of Technology, Hoboken, New Jersey 07030, USA.

with

$$H_{leads} = \sum_{\eta, \mathbf{k}} \varepsilon_{\eta \mathbf{k}} c_{\eta \mathbf{k}}^{\dagger} c_{\eta \mathbf{k}}, \qquad (1b)$$

$$H_{mol} = \sum_{j=1,2} \varepsilon_j c_j^{\dagger} c_j + U n_1 n_2 + \omega_0 a^{\dagger} a + \sum_{j=1,2} \lambda_j c_j^{\dagger} c_j (a^{\dagger} + a), \quad (1c)$$

$$H_T = \sum_{\eta, \mathbf{k}, j} (V_{\eta j} c_{\eta \mathbf{k}}^{\dagger} c_j + \text{H.c.}), \qquad (1d)$$

where $c_{\eta \mathbf{k}}^{\dagger}$ ($c_{\eta \mathbf{k}}$) is the creation (annihilation) operator of an electron with momentum k, and energy $\varepsilon_{\eta k}$ in lead η ($\eta =$ L, R, and $c_i^{\mathsf{T}}(c_i)$ is the corresponding operator for a spinless electron in the *j*th level of the QD (j = 1, 2). U denotes interdot Coulomb interaction and $n_j = c_j^{\dagger} c_j$ is the electron number operator in level j. In this paper, we consider strong Coulomb repulsion, $U \to \infty$, which suppresses simultaneous occupation of the two orbitals. a^{\dagger} (a) is phonon creation (annihilation) operator for the IVM. λ_i represents the EPC constant of an electron in level j; $V_{\eta j}$ describes the tunnelcoupling between electron level j and lead η . We use units with $\hbar = k_B = e = 1$ throughout the paper. In addition, it is worth noting that we do not consider the EPC-induced coupling between the two MO's in the Hamiltonian, Eq. (1c), because it is much weaker than the coupling of a single MO.

Fig. 1. Schematic diagram of the model system.

It is well-known that the electron-phonon interaction term in Eq. (1c) can be eliminated by a canonical transformation, [22] $\widetilde{H} = e^{S}He^{-S}$, with $S = (g_1n_1 + g_2n_2)(a^{\dagger} - a)$ $(g_j = \lambda_j/\omega_0)$, leading to a renormalization of the energy parameters, $\tilde{\varepsilon}_j =$ $\varepsilon_j - g_j \lambda_j$, and of the tunnel-coupling, $V_{\eta j} = V_{\eta j} \exp[g_j(a^{\dagger} +$ a)]. The transformed Hamiltonian is

$$\widetilde{H}_{mol} = \sum_{j} \widetilde{\varepsilon}_{j} c_{j}^{\dagger} c_{j} + \widetilde{U} n_{1} n_{2} + \omega_{0} a^{\dagger} a,$$
 (2a)

$$\widetilde{H}_T = \sum_{\eta, \mathbf{k}, j} (\widetilde{V}_{\eta j} c_{\eta \mathbf{k}}^{\dagger} c_j + \text{H.c.}), \qquad (2b)$$

with $\widetilde{U} = U - 2 \frac{\lambda_1 \lambda_2}{\omega_0}$. In this paper, we consider the case of strong relaxation of the IVM. In this situation, the vibration is always in an equilibrated state during tunneling processes, i.e., the excited phonon relaxes very quickly due to strong dissipation, before the next electronic tunneling event takes place. As a result, in this strongly Coulomb-interacting two-level QD system, we

have ρ_{00} , ρ_{11} , and ρ_{22} denoting probabilities for the electronic states: zero-electrons in the dot (0), single-electron occupation in the HOMO (1) or the LUMO (2), respectively.

In the weak tunneling regime and high temperature approximation, $\Gamma_{\eta j} \ll T, \omega_0$ ($\Gamma_{\eta j}$ is the tunneling rate between lead η and level j, and T is the temperature), we have established generic rate equations for these electron occupation probabilities including the role of phonon-assisted resonant tunneling in the eqilibrated phonon condition employing a quantum Langevin equation approach. [20] In order to employ MacDonald's formula for calculating shot noise [23], [24], we write these rate equations in a number-resolved form:

$$\dot{\rho}_{00}^{(l)} = \Gamma_{L1}^{-} \rho_{11}^{(l)} + \Gamma_{L2}^{-} \rho_{22}^{(l)} + \Gamma_{R1}^{-} \rho_{11}^{(l-1)} + \Gamma_{R2}^{-} \rho_{22}^{(l-1)} - (\Gamma_{1}^{+} + \Gamma_{2}^{+}) \rho_{00}^{(l)}, \qquad (3a)$$

$$\dot{\rho}_{11}^{(l)} = \Gamma_{L1}^{+} \rho_{00}^{(l)} + \Gamma_{R1}^{+} \rho_{00}^{(l+1)} - \Gamma_{1}^{-} \rho_{11}^{(l)}, \tag{3b}$$

$$\dot{\rho}_{22}^{(l)} = \Gamma_{L2}^+ \rho_{00}^{(l)} + \Gamma_{R2}^+ \rho_{00}^{(l+1)} - \Gamma_2^- \rho_{22}^{(l)}, \tag{3c}$$

where $\rho_{jj}^{(l)}(t)$ represents the electron occupation probability at time t together with l electrons arriving at the right lead due to tunneling events. Obviously, $\rho_{jj}(t) = \sum_{l} \rho_{jj}^{(l)}(t)$. The electronic tunneling rates are defined as

$$\Gamma_{j}^{+} = \sum_{\eta} \Gamma_{\eta j}^{+} = \sum_{\eta} \Gamma_{\eta j} \sum_{n} \mathcal{L}_{n}^{j} f_{\eta} (\tilde{\epsilon}_{j} + n\omega_{0}),$$
(4a)

$$j = \sum_{\eta} \prod_{\eta j} \prod_{n j} \Gamma_{\eta j} \sum_{n} \mathcal{L}_{n}^{j} [1 - f_{\eta}(\widetilde{\epsilon}_{j} - n\omega_{0})], \qquad (4b)$$

$$\mathcal{L}_{n}^{j} = e^{-g_{j}^{2}(2n_{B}+1)}e^{n\omega_{0}/2T}\mathcal{I}_{n}(2g_{j}^{2}\sqrt{n_{B}(n_{B}+1)}),(4c)$$

where $f_{\eta}(\epsilon) = [1 + e^{(\epsilon - \mu_{\eta})/T}]^{-1}$ is the Fermi-distribution function of lead η (μ_{η} is the chemical potential of lead η), $n_B = (e^{\omega_0/T} - 1)^{-1}$ is the Bose distribution function and $\mathcal{I}_n(x)$ is the *n*th Bessel function of complex argument.

The current flowing through the system can be evaluated by the time rate of change of electron number in the right lead as

$$I = \dot{N}_R(t) = \frac{d}{dt} \sum_l l P^{(l)}(t) \Big|_{t \to \infty},$$
(5)

where

$$P^{(l)}(t) = \sum_{n} [\rho_{00}^{(l)}(t) + \rho_{11}^{(l)}(t) + \rho_{22}^{(l)}(t)]$$
(6)

is the total probability of transferring l electrons into the right lead by time t. The zero-frequency shot noise with respect to the right lead is similarly defined in terms of $P^{(l)}(t)$ as well: [20], [23], [24]

$$S(0) = 2\frac{d}{dt} \left[\sum_{l} l^2 P^{(l)}(t) - (tI)^2 \right] \Big|_{t \to \infty}.$$
 (7)

To evaluate S(0), we define an auxiliary function $G_{ij}^{\eta}(t)$ as

$$G_{jj}(t) = \sum_{l} l \rho_{jj}^{(l)}(t),$$
(8)

whose equations of motion can be readily deduced employing the number-resolved QREs, Eqs (3a)-(3c), in matrix form: $\dot{\boldsymbol{G}}(t) = \mathcal{M}\boldsymbol{G}(t) + \mathcal{G}\boldsymbol{\rho}(t)$ with $\boldsymbol{G}(t) = (G_{00}, G_{11}, G_{22})^T$ and $\boldsymbol{\rho}(t) = (\rho_{00}, \rho_{11}, \rho_{22})^T$. Applying the Laplace transform to these equations yields

$$\boldsymbol{G}(s) = (s\boldsymbol{I} - \mathcal{M})^{-1}\mathcal{G}\boldsymbol{\rho}(s), \qquad (9)$$

where $\rho(s)$ is readily obtained by applying the Laplace transform to its equations of motion with the initial condition $\rho(0) = \rho_{st}$ (ρ_{st} denotes the stationary solution of the rate equations). Due to the inherent long-time stability of the physical system under consideration, all real parts of nonzero poles of $\rho(s)$ and $G^{\eta}(s)$ are negative definite. Consequently, the divergent terms arising in the partial fraction expansions of $\rho(s)$ and $G^{\eta}(s)$ as $s \to 0$ entirely determine the large-t behavior of the auxiliary functions, i.e. the zero-frequency shot noise, Eq. (7). This scheme facilitates evaluation of the zero-frequency shot noise as a function of bias-voltage for equilibrated-vibration-assisted tunneling through a molecular QD.

III. RESULTS AND DISCUSSIONS

In this section, we proceed with numerical calculations of the current I, the zero-frequency Fano factor F = S(0)/2I for the two-orbital model. We set the symmetric tunnel-couplings as $\Gamma_{L1} = \Gamma_{R1} = \Gamma_{L2} = \Gamma_{R2} = 0.01\omega_0$, take a weak EPC constant of the excited level, $g_2 = 0.1$, with the energy gap between the LUMO and HOMO as $\Delta = \tilde{\varepsilon}_2 - \tilde{\varepsilon}_1 = \omega_0/2$, in our calculations (Here, several values of g_1 are employed). Throughout the paper, the energy of IVM, ω_0 , is chosen as the energy unit, and we set the temperature as $T=0.05\omega_0$ unless otherwise indicated and assume that the bias voltage Vis applied symmetrically, $\mu_L = -\mu_R = V/2$. We have checked our parameter choices by comparing with the experimental data. [2], [8] Our numerical calculations yield the maximum current through the molecule as $I_{\rm max} \sim 0.5\Gamma$ (see below), and the experimental result is about $I_{\rm max} \sim 100$ pA, therefore we obtain $\Gamma \sim 1 \,\mu \text{eV}$, which is nearly $\sim 0.01 \omega_0$ since the characteristic energy ω_0 of the oscillation is found to be \sim 0.5 meV for the experimental setup of Sapmaz, et al. [8]

Figure 2 exhibits the calculated results. For comparison, we also plot the corresponding results of the single-level QD (which has only the ground orbital involved in transport) in Fig. 2(a,b). It is clearly evident that for the single-level system, the strong coupling between electronic and vibrational degrees of freedom induces a significant current suppression at low bias voltage due to a *phonon-modified tunneling rate*, and the noise is always sub-Poissonian, albeit the current is also largely suppressed by the strong EPC. Interestingly, it is seen that the current noise has an oscillatory feature with an approximate period of $V = 2.0\omega_0$, if $\tilde{\varepsilon}_1 \neq \pm n\omega_0/2$ (*n* is an integer), which can be explained based on Eqs. (3a)-(4c). For the sake of simplicity, we assume low temperature, T = 0, in the following analysis.

To start, we consider a system with $|\tilde{\varepsilon}_1| < \omega_0/2$, for example, $\tilde{\varepsilon}_1 = -0.25\omega_0$. Within the bias voltage window $0.5\omega_0 < V < 1.5\omega_0$, we have the tunneling-in rate, $x' = \Gamma_L^+ = \Gamma_{L1}\mathcal{L}_0^1$, and the tunneling-out rate, $x = \Gamma_R^- = \Gamma_{R1}\mathcal{L}_0^1$ ($\Gamma_R^+ = \Gamma_L^- = 0$). This is equivalent to a single-level QD

Fig. 2. Current I (a,c) and Fano factor F = S(0)/2I (b,d) vs. the bias voltage for a single-level system, $\tilde{\varepsilon}_1/\omega_0 = -0.25$ (a,b), and for a two-level system, $\tilde{\varepsilon}_1/\omega_0 = -0.25$, $\Delta/\omega_0 = 1/2$, $g_2 = 0.1$ (c,d), with various values of g_1 . Inset: Fano factor vs. bias voltage for the single-level system with $g_1 = 2.5$ and various energies of the QD level, $\tilde{\varepsilon}_1 = 0$ (solid line), -0.25 (dashed line), -0.5 (dotted line), and -0.75 (dotted-dashed line).

with symmetric tunnel-couplings under large bias voltage. Its typical Fano factor is $F_1 = 1/2$. However, when the bias voltage becomes $1.5\omega_0 < V < 2.5\omega_0$, the n = 1 channel is open, which leads to $x' = \Gamma_L^+ = \Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$ but still has $x = \Gamma_R^- = \Gamma_{R1}\mathcal{L}_0^1$. The equivalent model changes to an asymmetric single-level system with a Fano factor given by

$$F_2 = \frac{x'^2 + x^2}{(x' + x)^2} < 1.$$
(10)

If the bias voltage increases further to $2.5\omega_0 < V < 3.5\omega_0$, Γ_R^- becomes equal to Γ_L^+ again and the Fano factor changes back to 1/2. Therefore, because of the specific forms of the phonon-assisted tunneling rates, Eqs. (4b) and (4c), the single-level QD varies between two equivalent models, the symmetric model and asymmetric one, with increasing bias voltage, which generates the oscillatory feature of the Fano factor. Similarly, it is easy to verify that a system with $\tilde{\varepsilon}_1 = 0$ always corresponds to the symmetric model with a constant Fano factor, $F_1 = 1/2$.

A system with $|\tilde{\varepsilon}_1| \geq \omega_0/2$ always corresponds to the asymmetric model, whose noise exhibits step structure only if $|\tilde{\varepsilon}_1| = n\omega_0/2$ (*n* is a positive integer), but it is oscillatory otherwise, as shown in the inset of Fig. 2(b). Here, for illustration, we take $\tilde{\varepsilon}_1 = -0.5\omega_0$ and $-0.75\omega_0$ as examples. Their zero-temperature tunneling rates are listed in Table I for three different bias voltages. It is obvious that the rates of tunneling-in and -out, x' and x, of the system with $\tilde{\varepsilon}_1 =$ $-0.5\omega_0$ experience a simultaneous increase with increasing bias voltage, leading to a step-down of the current noise; but their increases become out of phase with respect to bias voltage for a system with $\tilde{\varepsilon}_1 = -0.75\omega_0$: the tunneling-in rate (x') suffers an increase first and the tunneling-out rate (x) remains unchanged from $V = 2.0\omega_0$ to $3.0\omega_0$, then x increases at $V = 4.0\omega_0$, which generates an oscillation of the noise [Eq. (10)].

In the case of a single-level QD, there is no NDC and no super-Poissonian noise. However, the situation is different for two-level systems. We find a strong NDC and a huge Fano factor ($F \sim 100$ for $g_1 = 2.5$) with $\tilde{\varepsilon}_1 = -0.25\omega_0$, $\Delta = \omega_0/2$, and $g_1 > 1.0$, as shown in Figs. 2(c,d). Actually, we find from Fig. 3 that no NDC occurs only when $\tilde{\varepsilon}_1 = \pm n\omega_0/2$ between $-1.5\omega_0 < \tilde{\varepsilon}_1 < 1.0\omega_0$.

Fig. 3. The differential conductance, $dI/dV(\tilde{\varepsilon}_1, V)$ for $g_1 = 2.5, g_2 = 0.1$, and $\Delta = \omega_0/2$ at $T = 0.05\omega_0$.

This peculiar feature can be understood from the biasvoltage-dependent electron occupation probabilities. For a system with $\tilde{\varepsilon}_1 = -0.25\omega_0$ [Fig. 4(a)], considering increasing bias voltage up to $0.5\omega_0$, the excited orbital (LUMO) starts to be occupied and then contributes to current. When the bias voltage arrives at $1.0\omega_0$, only two states, 1_0 and 2_0 (i_n denotes the *n*-phonon-assisted tunneling channel of orbital *i*), are involved at the bias voltage window with respective symmetric tunneling rates, $x = \Gamma_{L1}^+ = \Gamma_{R1}^- = \Gamma_{L1}\mathcal{L}_0^1 \ll \Gamma_{L1}$ and $y = \Gamma_{L2}^+ = \Gamma_{R2}^- = \Gamma_{L1}\mathcal{L}_0^2 \approx \Gamma_{L1}$ (due to $g_2^2 \ll$ $1 \ll g_1^2$). This situation is equivalent to a two-level QD with symmetric tunnel-couplings under a large bias voltage at zero temperature, as indicated in Fig. 5(a). Thus, we have attained the maximum value of ρ_{11} ($\rho_{11} \simeq \rho_{00} \simeq \rho_{22} \simeq 1/3$) and the current and Fano factor are given by

$$I_a = \frac{x+y}{3}\Gamma_{L1}, \tag{11}$$

$$F_a = \frac{2(x^2 + y^2) + xy}{9xy}, \qquad (12)$$

respectively. From Eq. (12), we obtain the huge Fano factor (due to $x \ll y$), $F_a \simeq 2y/9x \simeq 114$. If the bias voltage increases further, for example to $1.5\omega_0$, the tunneling channel 1_1 is in alignment with the Fermi energy of the left lead. As a result, an electron in the QD prefers to re-occupy the ground orbital, which causes a suppression of current due to its stronger EPC constant than that of the excited orbital, $g_1 \gg g_2$. In this case, the zero-temperature equivalent model is depicted in Fig. 5(b), where tunneling through the ground orbital becomes asymmetric, $x' = \Gamma_{L1}^+ = \Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1) >$

$$\rho_{11} = \frac{x'}{x'+2x} > \rho_{22} = \rho_{00} = \frac{x}{x'+2x}, \quad (13)$$

$$I_b = \frac{x(x'+y)}{x'+2x} \Gamma_{L1} < I_a,$$
(14)

$$F_b = \frac{2x'(y^2 + x^2 - xy) + y(x'^2 + 2x^2)}{y(x' + 2x)^2}.$$
 (15)

It should be noted that if the bias voltage increases further to $2.5\omega_0 < V < 3.5\omega_0$, the system changes back to the symmetric model (a) with a stronger tunneling rate, $x = \Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$.

Fig. 4. (a,b) Electron occupation probabilities, (c) current *I*, and (d) Fano factor *F* vs. the bias voltage for the two-level system with $\Delta/\omega_0 = 0.5$ and $g_1 = 2.5$. (a) is plotted for $\tilde{\epsilon}_1/\omega_0 = -0.25$; (b-c) are for $\tilde{\epsilon}_1/\omega_0 = -0.5$ (thick lines), 0 (thin red lines), and -0.75 (thin blue lines).

Fig. 5. Schematic diagram of two equivalent models for a two-orbital system. The arrows denote the directions of electron tunneling.

Similar to the single-orbital QD, if the energy of the ground orbital is zero, $\tilde{\varepsilon}_1 = 0$, the system always corresponds to the equivalent model (a). As a result, it exhibits step structures in the electron occupation probabilities [Fig. 4(b)] and current [Fig. 4(c)]. However, a system with $|\tilde{\varepsilon}_1| \ge \omega_0/2$ is always equivalent to model (b): (1) if $|\tilde{\varepsilon}_1| = n\omega_0/2$, electron occupation probabilities also exhibit step structures because of simultaneous increases of x' and x (Table I) with increasing bias voltage. Correspondingly, no NDC occurs in its current; (2) On the contrary, if $|\tilde{\varepsilon}_1| \ne n\omega_0/2$, the tunneling-in rate

TABLE I TUNNELING RATES, $x' = \Gamma_{L1}^+$ and $x = \Gamma_{R1}^-$, of the ground orbital with $\tilde{\varepsilon}_1 = -0.5\omega_0$ and $-0.75\omega_0$ at $V/\omega_0 = 2.0, 3.0,$ and 4.0, respectively, at zero-temperature.

		$V/\omega_0 = 2.0$	3.0	4.0
$\widetilde{\varepsilon}_1 = -0.5\omega_0$	x'	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1 + \mathcal{L}_2^1)$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1 + \mathcal{L}_2^1)$
	x	$\Gamma_{L1}\mathcal{L}_0^1$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$
$\widetilde{\varepsilon}_1 = -0.75\omega_0$	x'	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1 + \mathcal{L}_2^1)$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1 + \mathcal{L}_2^1)$
	x	$\Gamma_{L1}\mathcal{L}_0^1$	$\Gamma_{L1}\mathcal{L}_0^1$	$\Gamma_{L1}(\mathcal{L}_0^1 + \mathcal{L}_1^1)$

x' increases first with increasing bias voltage, which means that an electron has a greater opportunity to enter the ground orbital, i.e., ρ_{11} increases. With further bias voltage increase, the tunneling-out rate x also increases, leading to a decrease of ρ_{11} . Therefore, this system also exhibits oscillatory behavior in its electron occupation probabilities, and thus exhibits an NDC feature in its current. The noise in all these cases is still super-Poissonian due to $x', x \ll y$ [Fig. 4(d)].

Fig. 6. Current I (a,c) and Fano factor F (b,d) vs. bias voltage for the two-level system with $\tilde{\varepsilon}_1/\omega_0 = -0.25$ (a,b) and $\tilde{\varepsilon}_1/\omega_0 = -0.75$ (c,d) for various temperatures T. Other parameters: $g_1 = 2.5$, $g_2 = 0.1$, and $\Delta/\omega_0 = 0.5$.

Finally, we exhibit the temperature dependence of the NDC and super-Poissonian current noise for the two-level systems in Fig. 6. It is found that the NDC behavior of the current gradually becomes weaker with increasing temperature and nearly disappears at a relatively high temperature, $T = 0.5\omega_0$, but the noise still remains strongly enhanced, $F \gg 1$, in the low bias-voltage region even though the Fano factor F decreases with increasing temperature.

IV. CONCLUSIONS

In summary, we have analyzed equilibrated phonon-assisted tunneling and its zero-frequency current noise through a single molecular QD having two electronic orbitals with asymmetric couplings to the IVM using generic rate equations. Our results show that due to asymmetric EPC, the two-orbital molecular transistors exhibit strong and robust NDC and enhanced shot noise with a large Fano factor. We have also fully analyzed the reasons and conditions for the appearance of NDC in these systems.
