The ground state fidelity per lattice site is shown to be able to detect quantum phase transitions for the Kitaev model on the honeycomb lattice, a prototypical example of quantum lattice systems with topological order. It is found that, in the thermodynamic limit, the ground state fidelity per lattice site is non-analytic at the phase boundaries: the second-order derivative of its logarithmic function with respect to a control parameter describing the interaction between neighboring spins is logarithmically divergent. A finite size scaling analysis is performed, which allows us to extract the correlation length critical exponent from the scaling behaviors of the ground state fidelity per lattice site.

PACS numbers: 05.70.Jk, 67.40.Db, 03.67.-a

With the advent of its discovery in the fractional quantum Hall effect [1], topological order emerges as a new paradigm in the study of quantum phase transitions (QPTs) [2]. Subsequent investigations show that topological order occurs in various strongly correlated lattice systems undergoing QPTs. A characteristic feature of quantum systems with topological order is their insensitivity to any local perturbations [3]. Such an essential difference between topological and symmetry-breaking orders invalidates the usual tools used to describe a symmetry-breaking order, such as long range correlations, broken symmetries, and local order parameters [4].

Recently, much attention has been paid to an exactly solvable spin 1/2 model on a honeycomb lattice introduced by Kitaev [5] for fault-tolerant topological quantum computation [6]. The model describes a set of spins located at the vertices of a two-dimensional honeycomb lattice, subject to a spatially anisotropic interaction between neighboring spins. It has been shown that it carries excitations with both Abelian and non-Abelian braiding statistics, which do not obey ordinary bosonic and fermionic statistics, but are anyons with more intricate statistical behavior [7]. An experimentally feasible realization of the model in a system of cold atoms on an optical lattice has been addressed [8] (see also Refs. [9, 10]), with the expectation to perform quantum computation by utilizing braiding of collective excitations implanted in topologically ordered coherent quantum many-body states.

On the other hand, a viable scheme to determine the ground state phase diagram of a quantum lattice system without prior knowledge of order parameters was proposed in Refs. [11, 12, 13, 14]. This was achieved by studying the singularities in the ground state fidelity per lattice site [15]. In fact, the ground state fidelity may be interpreted as the partition function of a classical statistical vertex model with the fact, the ground state fidelity may be interpreted as the partition function of a classical statistical vertex model with the

\[ H = -J_x \sum_{x-bonds} \sigma_i^x \sigma_j^x - J_y \sum_{y-bonds} \sigma_i^y \sigma_j^y - J_z \sum_{z-bonds} \sigma_i^z \sigma_j^z, \]

where \( J_x \) are interaction (control) parameters and \( \sigma_i^\alpha \) are the Pauli matrices at the site \( j \), with \( \alpha = x, y, \) and \( z \).
tonian (1) may be fermionized by performing the Jordan-Wigner transformation [19, 21] from the Pauli spin matrices $\sigma^x$ to the spinless fermion operators $c^\dagger$ and $c$. This one-dimensional fermionization is realized by deforming the hexagonal lattice into a brick-wall lattice which is topologically equivalent to the original lattice. If we introduce the Majorana fermions: $A = (c - c^\dagger)/i$ and $A = c + c^\dagger$, then the Hamiltonian (1) becomes

$$
H = -iJ_x \sum_{x\text{-bonds}} A_x A_b + iJ_y \sum_{y\text{-bonds}} A_b A_w - iJ_z \sum_{z\text{-bonds}} \alpha_r A_b A_w,
$$

where the subscripts $w$ and $b$ denote two sublattices in the brick-wall lattice, and $\alpha_r = B_b B_w$ along the $z$-bond is conserved [20], with $r$ being the coordinate of the midpoint of the bond connecting the $b$-type and $w$-type sites. This in turn is equivalent to a model of spinless fermions on a square lattice with a site-dependent chemical potential:

$$
H = J_x \sum_r (d^\dagger_r + d_r) (d^\dagger_{r+\hat{e}_x} - d^\dagger_{r+\hat{e}_x}) + J_y \sum_r (d^\dagger_r + d_r) (d^\dagger_{r+\hat{e}_y} - d^\dagger_{r+\hat{e}_y}) + J_z \sum_r \alpha_r (2d^\dagger_r d_r - 1).
$$

Here the unit vector $\hat{e}_x$ and $\hat{e}_y$ connects two z bonds and crosses a $x$- and $y$-bond, respectively. For large enough systems, the ground state configurations are bulk vortex-free configurations [5, 21], which implies $\alpha_r = 1$ for all $r$. Therefore, the ground state may be obtained by performing a fourier transformation. Up to an unimportant additive constant, the Hamiltonian (3) in the vortex-free configuration now reads,

$$
H_g = \sum_k \left( \epsilon_k d^\dagger_k d_k + \frac{\Delta_k}{2} (d^\dagger_k d^-_k + \text{H.C.}) \right),
$$

with $\epsilon_k = 2J_x - 2J_y \cos k_x - 2J_y \cos k_y$, and $\Delta_k = 2J_z \sin q_x + 2J_z \sin k_y$. The Hamiltonian (4) is a p-wave type BCS pairing model and can be diagonalized by means of the Bogoliubov transformation. It yields that the BCS type ground state is $|g\rangle = \prod_k (u_k + v_k d^\dagger_k 10\rangle$, where $|u_k|^2 = 1/2(1 + \epsilon_k/E_k)$ and $|v_k|^2 = 1/2(1 - \epsilon_k/E_k)$, with the quasiparticle excitation energy $E_k = \sqrt{\epsilon_k^2 + \Delta_k^2}$ [19].

The ground state fidelity per lattice site. Consider two ground states $|g\rangle$ and $|g'\rangle$ corresponding to different values of the control parameters $\hat{J} \equiv (J_x, J_y, J_z)$ and $\hat{J} \equiv (J'_x, J'_y, J'_z)$, respectively. The fidelity $F(\hat{J}, \hat{J}') \equiv \langle g' | g\rangle$ asymptotically scales as $F(\hat{J}, \hat{J}') \sim d(\hat{J}, \hat{J}')$, with $N$ the total number of sites in the lattice. Here $d(\hat{J}, \hat{J}')$ is the ground state fidelity per lattice site, introduced in Refs. [11, 12]. Although $F(\hat{J}, \hat{J}')$ becomes trivially zero for continuous QPTs, the fidelity per lattice site is well defined in the thermodynamic limit:

$$
d(\hat{J}, \hat{J}') = \lim_{N \to \infty} F^N(\hat{J}, \hat{J}').
$$

It satisfies the properties inherited from the fidelity $F(\hat{J}, \hat{J}')$; (i) normalization $d(\hat{J}, \hat{J}) = 1$; (ii) symmetry $d(\hat{J}, \hat{J}') = d(\hat{J}', \hat{J})$; and (iii) range $0 \leq d(\hat{J}, \hat{J}') \leq 1$.

For the Kitaev model on the honeycomb lattice, the logarithmic function of the fidelity per site, $\ln d_{\text{sf}}(\hat{J}, \hat{J}')$, is half of the logarithmic function of the fidelity per site, $\ln d_{\text{sf}}(\hat{J}, \hat{J})$, for the model of spinless fermions on a square lattice. This results from the fact that the number of sites in the honeycomb lattice doubles that of sites in the square lattice. The BCS type ground state $|g\rangle$ yields the ground state fidelity per lattice site for the spinless fermion model on the square lattice:

$$
\ln d_{\text{sf}}(\hat{J}, \hat{J}) = \frac{1}{(2\pi)^2} \int_0^\pi dk_x \int_0^\pi dk_y \ln(u_k^2 u_k'^2 + v_k^2 v_k'^2),
$$

where $u_k$ and $v_k$ depend on $\hat{J}$, whereas $u_k'$ and $v_k'$ depend on $\hat{J}'$. Here we emphasize that although the information about the topological nature of the Kitaev model is lost in the spinless fermion representation, the unitary equivalence between the two representations preserves the fidelity. Since the extra prefactor does not affect the singularities in $\ln d_{\text{sf}}(\hat{J}, \hat{J}')$ and $\ln d_{\text{sf}}(\hat{J}, \hat{J})$, hereafter we focus on $\ln d_{\text{sf}}(\hat{J}, \hat{J}')$ to carry out the scaling analysis below, and omit the subscripts for brevity.

For a finite-size system, the Hamiltonian (4), resulted from the Jordan-Wigner, Fourier and Bogoliubov transformations, depends on boundary conditions imposed on the original spin model (1). In contrast to open boundary conditions, there is an extra boundary term if one adopts the periodic boundary conditions. However, such a boundary term does not contribute to the fidelity per site, although it carries the topological dependence of the ground state degeneracy [19]. From now on, we are only concerned with the fermion model on a square lattice with the periodic boundary conditions (i.e., a torus) to analyze the ground state fidelity per lattice site for finite-size systems [21], from which it is sufficient to extract the bulk behaviors of the model. As such, for a system on a torus with an even linear size $L$, the logarithmic function of the ground state fidelity per lattice site, $\ln d(\hat{J}, \hat{J}')$, takes the form:

$$
\ln d(\hat{J}, \hat{J}') = \frac{1}{L^2} \sum_{k_x, k_y} \ln(u_k^2 u_k'^2 + v_k^2 v_k'^2).
$$

Here $k_x$ and $k_y$ take values from the set: $\pi n/m = -(L - 1)/2, \ldots, (L - 1)/2$, and the double summation is over all positive values of both $k_x$ and $k_y$.

Ground state phase diagram and singularities in the ground state fidelity per lattice site. Now we turn to the ground state phase diagram. This follows from the singularities in $\ln d(\hat{J}, \hat{J}')$. One may show that $\ln d(\hat{J}, \hat{J}')$ in Eq. (6) and the first-order derivative with respect to a control parameter is continuous, but the second-order derivative logarithmically diverges when the phase boundaries determined by $|J_x| = |J_y|$, $|J_x| = |J_z|$, and $|J_z| = |J_x| + |J_y|$ are crossed. This is consistent with the original analysis by Kitaev [5] (see also Refs. [19, 20, 21]). In Fig. (1a), we plot the logarithm of the fidelity per site, $\ln d(\hat{J}, \hat{J}')$, as a function of
$J_z$ and $J'_z$ for $J_x = J_z = 1/2$ and $J'_x = J'_z = 1/2$. It is seen that a pinch point occurs at $(J_x, J_z) = (1, 1)$. That is, there are singularities along the lines $J_x = 1$ and $J'_z = 1$. Therefore, the drastic change of the ground state many-body wave functions at $J_{xc}$ is reflected as the singularities in $\ln d(J, \hat{J})$. Similarly, the numerical results are plotted in Fig. 1(b) for the logarithm of the fidelity per lattice site, $\ln d(J, \hat{J})$, as a function of $J_x$ and $J'_z$ for fixed $J_x = J'_x = J_z = J'_z = 1/2$, with a pinch point at $(J_{xc}, J_{xc}) = (1, 1)$.

More precisely, for any fixed $\hat{J}$, $\ln d(J, \hat{J})$ is logarithmically divergent when $\hat{J}$ is varied such that a critical point is crossed. Suppose $J_x$ and $J_z$ are fixed, and only $J_x$ is a control parameter that varies. Then we have

$$\frac{\partial^2 \ln d(J, \hat{J})}{\partial J_x^2} = k_1 \ln |J_x - J_{xc}| + \text{constant},$$

(8)

where $k_1$ is a non-universal prefactor that depends on $J_x, J_z$ and $\hat{J}$, and $J_{xc}$ is the critical value of $J_x$ for fixed $J_z$ and $\hat{J}$. The numerical results are plotted in Fig. 2(a) for $J_x = J_z = 1/2$ and $J_{xc} = 1$. The least square fit yields $k_1 \approx 0.02360$. Similarly, we have presented numerics in Fig. 2(b) for the second-order derivative of $\ln d(J, \hat{J})$ with respect to $J_x$, with $J'_x = 0.8$ and $J_x = J'_x = J_y = J'_y = 1/2$. It turns out that it diverges logarithmically in the same way as (8) with $J_x$ replaced by $J_y$, and $k_1 \approx 0.04726$.

**Finite size scaling analysis.** For a system of finite size $N \equiv L^2$ (with $L$ the linear size), there is no divergence in the second-order derivative of $\ln d(J, \hat{J})$ with respect to $J_x$, since QPTs only occur in the thermodynamic limit. Instead, as seen in Fig. 2(a), some pronounced dips occur at the so-called quasi-critical points $J_{sm}$, with the dips values logarithmically diverging with increasing linear size $L$,

$$\frac{\partial^2 \ln d(J, \hat{J})}{\partial J_x^2} |_{J_x=J_{sm}} = k_2 \ln L + \text{constant},$$

(9)

where $k_2$ is a non-universal prefactor $k_2$, which takes the value $k_2 \approx -0.02312$ for $J'_x = 0.8$ and $J_y = J'_y = J_z = J'_z = 1/2$. We set $N = L^2$ for $L \geq L_{sm}$ and $J_{sm}$.

**Scaling ansatz.** The scaling ansatz in the system exhibiting logarithmic divergences requires that the absolute value of the ratio $k_1/k_2$ is the correlation length critical exponent $\nu$. In this case, $|k_1/k_2| \sim 1.02076$, very close to the exact value $\nu = 1$. This is consistent with the fact that the gap $\Delta$ for the Bogoliubov quasiparticle scales as $\Delta \sim J_x - J_{xc}$ near the critical point $J_{xc}$. Similarly, a finite size scaling analysis is performed for $\ln d(J, \hat{J})$ with $J'_x = 0.8$ and $J_x = J'_x = J_y = J'_y = 1$. In Fig. 2(c), the least square fit yields $k_2 \approx -0.04640$. The numerics for $\partial^2 \ln d(J, \hat{J})/\partial J_x^2 |_{J_x=J_{sm}}$ and $J_{sm}$ are plotted in Figs. 2(d) and (f), respectively.

In order to address the scaling ansatz for a system exhibiting logarithmic divergence [28], we take into account the distance of the minimum of $\partial^2 \ln d(J, \hat{J})/\partial J_x^2$ from the critical
to investigate \(1 - \exp[\bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J}) - \bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J})|_{J_z = J_{z_{\text{top}}}}]\) as a function of \(L(J_z - J_{z_{\text{top}}})\) for different linear sizes \(L\). The numerical results for the linear size ranging from \(L = 401\) up to \(L = 1401\) are plotted in Fig. 3(b). The data collapsing is confirmed for \(1 - \exp[\bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J}) - \bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J})|_{J_z = J_{z_{\text{top}}}}]\). All the data from \(L = 401\) up to \(L = 1401\) collapse onto a single curve, indicating that the model is scale invariant, i.e., \(\xi / L = \xi / L'\), and that the correlation length critical exponent \(\nu = 1\). The same conclusion can be drawn from Fig. 3(b), where the data collapsing is confirmed for \(1 - \exp[\bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J}) - \bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J})|_{J_z = J_{z_{\text{top}}}}]\). All the data from \(L = 401\) up to \(L = 1401\) collapse onto a single curve. This shows that the system at a critical point is scale invariant and that the correlation length critical exponent \(\nu = 1\).

FIG. 3: (color online) (a) A finite size scaling analysis is performed for a quantity defined as \(D(\vec{J}, \vec{J}') = 1 - \exp[\bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J}) - \bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J})|_{J_z = J_{z_{\text{top}}}}]\), with \(J_y, J_z\) and \(\vec{J}'\) fixed. The scaling ansatz for logarithmic divergences implies that \(D(\vec{J}, \vec{J}')\) is a function of \(L(J_z - J_{z_{\text{top}}})\) for fixed \(J_y, J_z\) and \(\vec{J}'\). (b) A finite size scaling analysis is performed for a quantity defined as \(D(\vec{J}, \vec{J}') = 1 - \exp[\bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J}) - \bar{\delta}_{J_z}^2 \ln d(\vec{J}, \vec{J})|_{J_z = J_{z_{\text{top}}}}]\), with \(J_y, J_z\) and \(\vec{J}'\) fixed. The scaling ansatz implies that \(D(\vec{J}, \vec{J}')\) is a function of \(L(J_z - J_{z_{\text{top}}})\) for fixed \(J_y, J_z\) and \(\vec{J}'\). All the data from \(L = 401\) up to \(L = 1401\) collapse onto a single curve. This shows that the system at a critical point is scale invariant and that the correlation length critical exponent \(\nu = 1\).

Summary. We have demonstrated that the ground state fidelity per lattice site is able to detect QPTs in the Kitaev model on the honeycomb lattice. It is found that, in the thermodynamic limit, the ground state fidelity per lattice site is nonanalytic at a critical point. More precisely, the second-order derivative of its logarithmic function with respect to a given control parameter is logarithmically divergent as the phase boundaries are crossed. A finite size scaling analysis has also been performed to extract the correlation length critical exponent from the scaling behaviors of the fidelity per site. Our exact results offer a benchmark to numerically investigate QPTs for two-dimensional quantum lattice systems with topological order in the context of tensor network representations, which is currently under investigation.

We thank Yupeng Wang for insightful discussions about the Kitaev model and comments on the manuscript. Support from the Natural Science Foundation of China is acknowledged.

[4] However, the existence of a mapping from a system with topological order to a system with symmetry-breaking order is possible, as shown in Ref. [20] for the Kitaev model.
[15] It is a difficult task to evaluate the ground state fidelity per site, if a quantum lattice system is not exactly soluble. However, thanks to the latest advances in classical simulations of quantum lattice systems [23, 24, 25, 26], a practical way to compute it is now available using the tensor network algorithms for translationally invariant infinite-size quantum lattice systems [12].
[22] H.-D. Chen and J.P. Hu, cond-mat/0702366.
[27] This amounts to the statement that the fidelity per lattice site does not depend on which state has been chosen among degenerate states in the ground state subspace for a system with topological order. This has been shown for different states of the toric code [29]. That is, the tensor network representation for different states shares the same tensors except for their top tensor, where the relevant topological information is stored. Such a difference does not contribute to the fidelity per lattice site.
