# T w isted speckle entities inside w avefront reversal m irrors. 

A. Yu.O kulot<br>G eneral P hysics Institute of R ussian A cadem y of Sciences V avilova str. 38, 119991, M oscow, Russia (D ated: June 09, 2009)

#### Abstract

The previously unknown property of the optical speckle pattem reported. The interference of a speckle w ith the counter-propagating phase-conjugated speckle wave produces a random ly distributed ensemble of a tw isted entities (ropes) surrounding optical vortex lines. These entities appear in a w ide range of a random ly chosen speckle param eters inside the phase-con jugating m irrors regardless to an intemal physical mechanism of the wavefront reversal. These num erically generated interference pattems are relevant to the B rillou in PC m irrors and to a four-w ave $m$ ixing PC -m irrors based upon laser trapped ultracold atom ic cloud.

PACS num bers: $42.30 \mathrm{M} \mathrm{s} 42.50 . \mathrm{T} \times 42.65 \mathrm{Hw} 42.65 \mathrm{Es}$

Phase singularities of the optical beam $s$ attracted a substantial interest in a recent decades from the point of view of optical inform ation processing [1]. Helical wavefronts had been shown to a ect a processes of the second harm onic generation [1], im age processing $w$ ith a photorefractive $m$ irrors [2], phase-conjugated re ection via nondegenerate fourw ave $m$ ixing in a cold atom $s$ cloud [3]. The photons with helical wavefunction had been shown to possess quantized angular mom entum ~ per photon [4]. The optical nonlinearities are capable to transfer the angular $m$ om entum from photons to an ensemble of ultracold atom s [3]. This e ect is considered as a possible tool for the light storage in addition to the slow light technique based on electrom agnetically induced transparency (E IT ) [5, 6]. Recently the angular $m$ om entum transfer to BEC cloud of sodium atom $s$ via stim ulated $R$ am an schem e had been observed [7]. Of special interest is the nondegenerate four-w ave $m$ ixing a cold atom ic cloud and phase conjugated (PC) re ection of the optical vortices ( O V), i.e. Laguerre-G aussian beam s (LG) w ith helical wavefronts [B]. The re ection of the phase-conjugated LG photons from $10^{7}$ œesium atom s cooled down to $\mathrm{T} \quad 10^{3} \mathrm{~K}$ and reversal of the orbitalangularm om entum (OAM) had been interpreted as a consequence of intemalm acroscopic rotations inside atom ic cloud [8]. A fterw ards these experim ental results were analyzed from a point of view of the angular mo$m$ entum conservation for the incident and re ected photons from a B rillouin P C - m irror [9]. The goal of the current com $m$ unication is to study the spiral interference pattems w th the period of $=2$ around the nodes of optical speckle pattem. T hese coarse interference pattems tum in rotation the $B$ rillouin $m$ edium (10] producing the acoustical vortioes carrying O AM [11].

The traditional experim ental and num erical technique for the visualization of the optical phase singularities is based on $m$ ixing of a $w$ ide quasi-plane $w$ ave reference opticalbeam w th a speckle signal [12]. T he dark spots (ze-

[^0]okulov@ kapella .gpi.nu;
ros of am plitudes) appearing in intensity distribution are collocated w th the helical ram ps in phase distribution. $T$ he current com $m$ unication reports a theoreticaldescription of the altemative visualization techn ique which uses the interference of the speckle wave w th the counterpropagating phase-con jugated one. In fact this technique is autom atically im plem ented in a wavefront reversing m irrors where a phase-conjugated wave produces near the bright spot the B ragg grating of dielectric perm ittivity of the form $\cos \left(\left(k_{p}+k_{s}\right) z\right)$. In the vicinity of the dark line the $m$ odulation of the light intensity is $m$ ore com plex: the B ragg grating is transform ed into spirals of the form $\cos \left(k_{p}+k_{s}\right) z \quad 2$ '), where is the local azym uthalangle, ' is topological charge of the phase singularity, $k_{p} ; k_{s}$ are wavenum bers of incident (pum p) and re ected (Stockes) waves respectively [9, 10]. In the real PC m irrors the contrast of such gratings may be reduced due to the interference w ith a non-phase-con jugated com ponent of the radiation.

The novel feature com pared to the previous ndings $[12,13]$ is that the ideal (or close to an ideal) PC m irror visualizes in the speckle pattems a peculiar opticalentities, which $m$ ight be called the ropes. T ypically each such a rope is com posed of a 2-3 opticalvortex lines (g.1]). In contrast to the well studied straight optical vortex lines e.g. LG [1, 4], the OV in a speckle eld are self-tw isted as it seen from $g 2$. $H$ aving in $m$ ind the well know $n$ fact [12], that $O V$ appear and annihilate as a pairs of whirls with opposite circulations [0, 10] it is easy to conchide that at least tw o adjacent OV w ith opposite topological charges are needed to produce a rope ( $g \sqrt[3]{3}$ ). The $m$ ean length of each $O V$ in $Z$ direction is the $R$ ayleigh range of a speckle pattem $L_{R} \quad D^{2}=$, where $D$ is an average transverse size (in the plane $X$; $Y$ ) of the OV core, the wavelength $=2=\mathrm{k}_{\mathrm{p}}$. The $g$ 回 show s the num erically generated fragm ent of a speckle pattem which contains three ropes each com posed of a set of a vortex lines. Let us describe the num erical procedure for generating the interference pattem of the two counter-propagating speckle elds.

The standard $m$ odelof the phase con jugation via stim ulated B rillouin scattering (SBS) is the B ragg re ection from the sound grating w th period $=2 \mathrm{~m}$ oving w th

FIG. 1: G ray scale intensity plot for a sm all volum e of a speckle pattem inside $P C$ m irror in ( $\mathrm{X} ; \mathrm{Z}$ ) $-\mathrm{plane}(\mathrm{Y}=$ $23 \mathrm{~m})$. The m ean transverse size of a speckle is D 8 m . Them ean longitudinallength of a speckle entity is of the order of the $R$ ayleigh range $L_{R} \quad D^{2}=$ for 1 m . The size of the volum $e$ is 32 m in transverse ( $\mathrm{X} ; \mathrm{Y}$ ) directions and 128
$m$ in longitudinal (Z ) direction. The step of longitudinal modulation $\cos \left(\left(k_{p}+k_{s}\right) z \quad 2\right.$ ) induced by the interference of counter-propagating pum $p$ and Stockes waves is en larged here 8 tim es for visualization purposes. The characteristic -phase-jum $p$ is clearly visible in betw een adjacent B ragg's cos m odulated roll pattems.
the speed of sound $V_{a c}$ [13]. D ue to the conservation of $m$ om entum $p=\sim \tilde{k_{p}}=\sim \tilde{k_{s}}+\sim \tilde{k_{\mathrm{a}}}$ the length of the wavevector of sound $k_{a c}$ is equal to doubled length of wavevector of pum $p$ light $k_{p} w$ ith an accuracy about $10{ }^{5}$ [14]. The D oppler e ect de nes the sm all (of the order of $10^{5}$ ) frequency shift of the re ected (Stockes) wave $!{ }_{a c}=2!{ }_{p} n v_{a c}=c$, where $n$ is refractive index of $m$ edium, $c$ is the speed of light in vacuum, $!p ;!s$ is the frequency
of the pum $p$ and Stockes light respectively.
$T$ he evolution in space of the tw o counter-propagating paraxial laser beam $s$ inside Brillouin active $m$ edium obeys to $M$ axw ellequations $w$ ith the cubic nonlinear polarization induced by electrostrictive e ect [13]. The linearly polarized pum $p$ eld $E_{p} m$ oves in a positive direction of $Z$ axis, the re ected Stockes eld $E_{s} w$ ith the sam e polarization propagates in opposite direction ( g.1). $T$ he acoustic eld $Q$ is excited via electrostriction [13, 15]. $T$ he three-w ave equations for the interaction of $E_{p}, E_{s}$ $w$ th adiabatic elim ination of the $Q \quad \mathrm{E}_{\mathrm{p}} \mathrm{E}$ s are:

$$
\begin{align*}
& \frac{@ E_{p}(z ; x ; y ; t)}{@ z}+\frac{i}{2 k_{p}} \quad E_{p}=\frac{{ }^{2}!_{p} k_{a}{ }^{2}}{32{ }_{0 n c}!_{a c}} \Psi_{s}{ }^{2} E_{p} ; \\
& \frac{@ E_{s}(z ; x ; Y ; t)}{@ z} \quad \frac{i}{2 k_{s}} \quad{ }_{?} E_{s}=\frac{{ }^{2}!_{s} k_{a}{ }^{2}}{32{ }_{0} n c!a c} E_{p}{ }^{3} E_{s} ; \tag{2}
\end{align*}
$$

where $=$ (@ =@ $\ddagger$ is the electrostrictive coupling constant, 0 is the unpertubed density of $m$ edium [15]. Consider the phase conjugation $w$ ith a random phase plate which produces the chaotic transverse $m$ odulation of the phase of the incident $E_{p} w$ ith a characteristic size of the transverse inhom ogeneity of the order of $5 \quad 50 \mathrm{~m}$ [13]. In such a case the com plex envelope am plitude of the inhom ogeneous speckle eld $\mathrm{E}_{\mathrm{p}}$ at the entrance to PC m irror is given as a multim ode random eld [16]:

$$
\begin{align*}
& E_{p}(x ; z=0) \quad E_{p}{ }^{\circ} \stackrel{X}{0<j_{x} ; j_{y}<N_{g}} A_{j_{x} ; j_{y}} \\
& \exp \left[i 2 \mathrm{f} \frac{\mathrm{x} \dot{\mathrm{x}}}{\mathrm{p}_{\mathrm{x}}} j_{\mathrm{j}}+\frac{\mathrm{Y} \dot{\mathrm{y}}}{\mathrm{p}_{\mathrm{y}}} j_{\mathrm{y}}+\mathrm{i}_{j_{x} ; j_{y}} \mathrm{~g}\right] ; \tag{3}
\end{align*}
$$

where random phases $j_{x} ; j_{y}$ are the random numbers from interval $[0 ; \quad], A_{j_{x}} ; j_{y}$ are the realam plitudes of the spatialharm onics, $p_{x} ; p_{y}$ are $m$ axim altransverse sizes (in $X ; Y-p l a n e), x=(x ; y)=(r ;), j_{x} ; j_{y}$ are integers corresponding to $\mathrm{N}_{\mathrm{g}}=(16 ; 32 ; 64)$ plane waves w th random phases $j_{x ; j y}$. The random numbers $j_{x}=p_{x}=\sum_{j x}^{0}$ and $j_{y}=p_{y}=p_{j y}^{0}$ having the uniform distribution in the sm allvicinity of a 1 are responsible for a random tilt of a plane w aves constituting the spatialFourier spectrum of the light transm itted through a random phase plate. For the paraxialbeam propagation the am plitude and phase structure of the com plex eld $\mathrm{E}_{\mathrm{p}}$ have the follow ing form [17] in an arbitrary Z-plane:

$$
\begin{aligned}
& E_{p}(x ; z>0) \quad E_{p}{ }^{\circ} \exp \left(i k_{p} z\right) \quad \exp \left[i \quad j_{x} ; j_{y}\right] \\
& 0<j_{x} ; j_{y}<N_{g} \\
& A_{j_{x}} ; j_{y} \exp \left[i 2 \mathrm{f}_{\frac{x}{S_{j x}^{0}}}^{\mathrm{P}_{j x}}+\frac{Y \text { y }}{\mathrm{P}_{j y}^{0}}+\frac{z}{2 k_{p}}\left(\frac{j_{x}{ }^{2}}{\sum_{j x}^{0}{ }^{2}}+\frac{\dot{j}_{y}{ }^{2}}{\sum_{j y}^{0}}\right) g\right] ;(4)
\end{aligned}
$$

The interference pattem $I(x ; z)$ is responsible for the sound grating in a B rillouin PC-m irror. For the grating produced by a linear supenposition of the random plane waves we have:

FIG. 2: The plot of the light intensity $m$ axim a at a given $m$ om ent $t$ in a sm all volum e inside the PC-m irror. T he four pairs of spiral interference pattems w ith opposite handedness are located random ly in space. Their diam eters and directions are changed sm oothly due to di raction. The step of longitudinalm odulation $\cos \left(\left(\mathrm{k}_{\mathrm{p}}+\mathrm{k}_{\mathrm{s}}\right) \mathrm{z} 2\right.$ ) is en larged here 16 tim es.

$$
\begin{equation*}
\left.I(x ; z>0) \quad E_{p}(x ; z)+E_{s}(x ; z)\right\} ; \tag{5}
\end{equation*}
$$

w here the phase-con jugated Stockes w ave $\mathrm{E}_{\mathrm{s}}$ is given by:

$$
\begin{aligned}
& E_{s}(x ; z>0) \quad E_{p}{ }^{\circ} \exp \left(i k_{s} z\right) \quad \exp \left[i j_{x} ; j_{y}\right] \\
& 0<j_{x} ; j_{y}<N_{g} \\
& A_{j_{x} ; j_{y}} \exp \left[i 2 f \frac{x \text { x }}{\frac{Y}{S_{j x}^{0}}}+\frac{Y \dot{y}}{\sum_{j y}^{0}}+\frac{z}{2 k_{s}}\left(\frac{j_{x}^{2}}{p_{j x}^{0}}+\frac{\dot{j}_{y}^{2}}{\sum_{j y}^{0}}\right) g\right] ;(6)
\end{aligned}
$$

provided that $E_{s} \quad E_{p}$ (noiseless PC-m irror). Such an approach presum es the ideally perfect phase-con jugation w ith ultim ate re ection $\mathrm{R}=1$ or interference of the non-
 Eq. (1,2) are equal to zero.

The intensity snapshots given by (5) were obtained num erically by sum $m$ ation of the series (4) and (6) on standard Intel platform w ith dual core 1.86 Ghz processor and 1 Gbm em ory using standard educationalsoftw are. T he num erical sim ulations show that optical vortex lines intertw ine and form ropes. T he average length of a rope is of the order of R ayleigh range $\mathrm{D}^{2}=$. This $m$ ay be interpreted as a consequence of di ractive divergence w thin the angle $=D \quad(g, 1)$. The longitudinal $m$ odulation by the B ragg factor cos $\left[\left(k_{p}+k_{s}\right) z \quad 2\right]$ is accom panied by an additional bending and tw isting at characteristic w avelength K . T he latter is of the order ofa severaltenth ofoptical, resem bling $K$ elvin $m$ odes of the vortex lines [18, 19]. T he handedness of helical ropes changes random ly from one entity to another: the clockw ise and counterclockw ise ropes appear w th the equal

FIG. 3: G ray scale intensity plot for the variational anzatz (7) substituted in (5). The 1282048 points arrays are used for the intensity distributions (5) in $X \quad Z$ planes at xed $Y=64$. The single sinusoidally m odulated $L G{ }_{0}{ }^{1}$ vortex line (see eq. (7)) is show $n$ for $M=0: 1 \quad D \quad$ (a) and $M=D$ (b). TwoLG $0^{1}$ distant vortex lines $\mathrm{LGG}_{0}{ }^{1}$ (c) w ith parallel (d) opposite (e) topological charges ' constitute the rope when the distance betw een them is reduced to zero ( $\mathrm{d}, \mathrm{e}$ ). T he step of longitudinalm odulation is en larged here 32 tim es.
probability. D espite the statistical nature of a speckle pattem ( $g(1)$ the ropes are structurally stable: they appear at a di erent locations and have a variable sizes but their m orphology is reproduced from a given statistical realization to another one.

T he physical intenpretation of these num erically observed pattems is given in the g(3) using the (5) w ith the electrical elds $E_{p}=E_{s}$ in the form of a two overlapping elem entary $\mathrm{LG}_{0}{ }^{1}$ optical vortices:

$$
\begin{aligned}
& E_{p} \quad \exp \left(i k_{p} z \quad\left(x_{1}^{2}+y_{1}^{2}\right)+i_{1}\right) p \overline{\left(x_{1}^{2}+y_{1}^{2}\right)} \\
& \left.+\exp \left(i k_{p} z \quad\left(x_{2}^{2}+y_{2}^{2}\right) \quad i^{\prime}\right)_{2}\right)
\end{aligned}
$$

where the location of the vortex cores $\left(x_{1} D=x+\right.$ $\mathrm{M} \quad \cos \left(2 \mathrm{z}={ }_{\mathrm{K}}\right)$; $\left(\mathrm{y}_{1} \mathrm{D}=\mathrm{y}+\mathrm{M} \quad \sin \left(2 \mathrm{z}={ }_{\mathrm{K}}\right)\right)$ and $\left(\mathrm{x}_{2} \mathrm{D}=\mathrm{x}+\mathrm{M} \quad \cos \left(2 \mathrm{z}={ }_{\mathrm{K}}+=2\right)\right) ;\left(\mathrm{y}_{2} \mathrm{D}=\mathrm{y}+\mathrm{M}\right.$ $\sin \left(2 \quad z={ }_{k}+=2\right)$ ) changes sinusoidally w ith period $k$ along $Z$-axis, 1 and 2 are the local azim uthal angles around vortex cores. Such vortex-vortex ( gSbl) and vortex-antivortex ( g|3e) pair interference pattem is used here as a variational anzatz in eq.(5). T he g(3 reproduces qualitatively a som e features of the num erically generated speckle pattems ( 9 (1) .

In summary the nontrivial topology of the mul-
tiply connected optical speckle pattems was dem onstrated num erically. U sing the interference $w$ th the counter-propagating phase-conjugated speckle eld we have show $n$ the hidden tw isted geom etry of the multim ode wave eld com posed of the random ly tilted plane waves [16]. N otew orthy the ropes exist w ithout phaseconjugated counterpart: the re ection from PC-m irror $m$ akes these tw isted entities visible due to the characteristic -phase-jum $p$ in betw een the adjacent B ragg's sinusoidally m odulated roll pattems ( g (1). T hus it seem s probable that a rope entities exist in a wide class of a superpositional physical elds like an electrom agnetic or acoustical ones [11]. T he other $m$ ost evident examples are the blackbody radiation eld in a cavity or a monochrom atic eld in a cavity with a rough mirrors. Taking into account the phenom ena of a so-called nonlinear superposition which take place for collisions of the optical solitons, vortices [20] and form ation of the
optical vortex lattices 21] onem ight expect the nding of a stable ropes in a nonlinear elds. T he relevant exam ples are photorefractive P C m irrors [2], ultracold $m$ atter, e.g. phase-conjugating PC-m irrors based on nondegenerate four-w ave $m$ ixing in a trapped gases $[3,8]$ and the situations of the slow $[5,6,22]$ and the fast light [23, 24] propagation in a resonant $m$ edium .

The reported result extends the set of the possible form s of the photon's wavefiunction. In addition to the well known photon wavefunctions in the form of the ele$m$ entary optical vortex lines, e.g. LG beam swhich possess a helical w avefronts [1, 4], the tw isted entities each com posed of the several vortex lines o er a new form of the photon's w avefiunction [25, 26].
