COSMOLOGY W ITH GAMMA {RAY BURSTS

L.AMATI INAF - IASF Bologna, via P.Gobetti 101, I-40129 Bologna, Italy

G am m a{R ay Bursts (G R B s) are the brightest sources in the universe, em it m ostly in the hard X {ray energy band and have been detected at redshifts up to 8.1. Thus, they are in principle very powerful probes for cosm ology. I shortly review the researches aim ed to use G R B s for the m easurem ent of cosm ological parameters, which are mainly based on the correlation between spectral peak photon energy and total radiated energy or lum inosity. In particular, based on an enriched sample of 95 G R B s, I will provide an update of the analysis by A m atiet al. (2008) aim ed at extracting information on M and, to a less extent, on from the E_{p;i} { E iso correlation. I also brie y discuss the perspectives of using G R B s as cosm ological beacons for high resolution absorption spectroscopy of the IG M (e.g., W H IM), and as tracers of the SFR, up to the "dark ages" (z > 6) of the universe.

1 Introduction

A fier 40 years since its discovery, the GRB phenom enon is still one of the most intriguing and hot topics in modern astrophysics. Indeed, despite the huge observational advances occurred since the late 90s, with the discovery of the afferglow emission, optical counterparts, host galaxies, the determ ination of the cosm ological distance scale and huge lum inosity and the evidences of association with peculiar SN e, our understanding of GRBs origin and physics is still a ected by several open issues¹. Am ong these, one of the most intriguing and debated is the possible use of GRBs as com ological probes, which has been proposed in the last few years by several authors, following the mounting evidence that they are the brightest and farthest sources in the universe. In particular, many e orts have been done in order to extract information on cosm ological probes (e.g., BAO, galaxy clusters, the CMB) by "standardizing" GRBs with the so called spectrum {energy correlations. A lso, the high X {ray ux and the association of long GRBs with the death of young massive stars prom pted the investigation of GRBs as background sources for high resolution spectroscopy of the IGM with next generation experiments and as tracers of the star form ation rate (SFR) up to the re{ionization epoch.

In this article, after sum m arizing the properties that m ake GRBs potentially powerful cosm obgical probes (Section 2), I will discuss and update the analysis aim ed at estim ating cosm ological parameters by using the $E_{p;i}$ { E_{iso} correlation, the sim plest and rst discovered am ong spectrum {energy correlations (Sections 3 and 4). Then, I will review (Section 5) the results on cosm obgical parameters obtained by using other spectrum {energy correlations found by adding to $E_{p;i}$ and E_{iso} a third observable. H istorically, these correlations were the rst to be used to this purpouse since 2004. M ethods based on the joint use of spectrum {energy correlations with Type Ia SN e or other GRB correlations are outlined in Section 6. Finally, in Section 7 I brie y

Figure 1: Left: redshift distribution for the 189 GRBs with known redshift as of April 2009. Right: E iso distribution for the 95 GRBs with known redshift and spectral parameters as of April 2009.

discuss the possible use of GRBs as cosm ological beacons and tracers of the star form ation history of the universe.

For reasons of space, the citations in the text cannot be exhaustive, and the given references are review s or examples. The analysis reported in Sections 2, 3 and 4 are based on data available as of A pril 2009 and have been performed speci cally for this work.

2 Gamma{Ray Bursts as cosm ological probes

In the last years, the use of Type Ia SN e as standard candles, com bined with CMB m easurem ents, has revolutioned our view of the history of the cosm ic expansion of the universe. Indeed, within the standard CDM cosm obgical model the evidence, based on CMB observations and the implications of in ation, that the universe is at (=1) and the location of high {z SN e Ia in the Hubble diagram imply that the universe is presently accelerating and that 73% of is determined by an unknown and mostly unpredicted component or eld (e.g., dark energy, quintessence, cosm ological constant) $^{2;3;4}$. However, SN Ia as standard candles are a ected by possible system atics, like, e.g., di erent explosion m echanism s and progenitor system s, evolution with z, possible dependence on z of the light curve shape correction for lum inosity norm alization, signatures of evolution in the colours, correction for dust extinction, anom alous lum inosity {color relation, contam inations of the Hubble D iagram by no{standard SN e-Ia and/or bright SN e-Ibc (e.g. HN e) ⁵. In addition, this sources are found only up to m oderate redshift (1.4{1.7}).

Thus, the quest for alternative astrophysical sources capable to provide estimates of the cosm ological parameters in an independent way and at higher z with respect to SN e Ia is a central topic in modern astrophysics. The sources under investigation for this purpouse include, e.g., galaxy clusters and BAO, but a lot of interest has been raised in the last years by the redshift and lum inosity properties of GRBs.

In Figure 1, I show the updated distributions of z (189 events with m easured redshift) and E $_{\rm iso}$ (95 events with m easured redshift and spectral param eters) of GRBs as of A pril 2009. The redshift values were taken from the GRB table by J. G reiner^a and references therein, whereas the values of E $_{\rm iso}$ were computed based on the spectral param eters and uences reported in Am ati et al. (2008) ⁶, 70 events, and Am ati et al. (2009) ⁷, 25 m ore events, and by assuming a standard CDM cosm ology with H $_0$ = 70 km s ¹ M pc ¹, M = 0.27 and = 0.73. A s can be seen, GRBs are the brightest sources in the universe, with values of the isotropic (equivalent

Figure 2: Left: $E_{p,i}$ { E_{iso} correlation with the present sample of 95 GRBs with known redshift and $E_{p,i}$. Red dots are those GRBs localized by Swift. Right: ² value of the t of the updated $E_{p,i}$ { E_{iso} correlation (95 GRBs) with a simple power{law as a function of the value of M assumed to compute the E_{iso} values. A at universe is assumed.

radiated energies, E_{iso} , that can exceed 10^{54} erg, em it most of their radiated energy in the hard X (rays, and thus are not a ected by dust extinction problem s which a ect, e.g., type Ia SN e, and show a redshift distribution extending at least up to 8.1, much above that of any other class of astrophysical sources.

Thus, in principle GRBs are the most suitable cosm obgical probes. How ever, as can be seen in F igure 1, they are not standard candles, show ing radiated energies, and lum inosities, spanning several orders of magnitude. In the past it was proposed that the collimation (corrected radiated energy, E (see Section 5) could be clustered at around $10^{51} \text{ erg}^{8;9}$, but this evidence was not con m ed by subsequent observations. The investigation of GRBs as a new and alternative tool for the measurem ent of cosm obgical param eters was then prom pted by the discovery of a strong correlation between the spectral peak photon energy, a quantity independent on the cosm ological model, and the event intensity (radiated energy, average lum inosity, peak lum inosity), which depends on the assumed cosm ological param eters. This correlation and the methods proposed to derive from it information on cosm ological param eters are the subject of the next three Sections.

3 The $E_{p;i}$ { E_{iso} correlation

GRB spectra are non them aland are well described by a sm oothed broken power{law ("Band" function) with low and high energy photon indices in the ranges $0.5\{1.5 \text{ and } 2.1\{3.5, \text{ respectively } ^{10;11}$. Thus, when expressed in terms of F, GRB spectra show a peak. The photon energy at which this peak occurs is hence called "peak energy" and indicated as E_p when referring to the observed spectrum or $E_{p;i}$ for the cosm ological rest {fram e (i.e., "intrinsic") spectrum. $E_{p;i}$ values range from a few keV up to several thousends of keV and its distribution has the shape of a G aussian centered at around 200{300 keV with a low energy tail¹². This spectral param eter is a relevant observable form odels of the physics of GRB prom pt em ission ¹³, whose understanding is one of the main still open issues in this eld of research.

Evidence for a strong correlation between $E_{p;i}$, and E_{iso} was rst reported by Am atiet al. $(2002)^{14}$, based on a limited sample of BeppoSAX GRBs with known redshift. This correlation was later con rm ed and extended to softer/weaker events (X {Ray F lashes, XRFs) by measurements by other satellites, mainly HETE {2, Konus/W IND and, more recently also Swift and Ferm i/GBM $^{12;6;15}$ The recent estimates of z for some short GRBs provided the evidence that

Figure 3: Values of log(likelihood) (left) and $_{ext}$ (right) of the t of the updated $E_{p;i}$ { E_{iso} correlation (95 GRBs) with a maximum likelihood method accounting for extrinsic variance (see text) as a function of the value of $_{M}$ assumed to compute the E_{iso} values. A at universe is assumed.

the E_{p;i} { E_{iso} correlation holds only for long GRBs^{16;17}, with the exception of the peculiar sub{energetic GRB 980425. It was also found that the correlation holds as well if E_{iso} is substituted with the average or peak lum inosity (L_{iso} and L_{p;iso}, respectively ^{18;19}), which is not surprising given that these "intensity indicators" are strongly correlated. In Figure 2, I show the E_{p;i} { E_{iso} correlation for the most updated (A pril2009) sam ple of GRBs with known z and E_{p;i}. The main features of the E_{p;i} { E_{iso} correlation are that it extends over several orders of magnitude both in E_{p;i} and E_{iso}, it can be modeled by a power{law with slope 0.5 and it is characterized by an extra{scatter, with respect to Poissonian uctuations, of 0.2 dex^{15;12;6}.

As already discussed by several authors $^{13;20;12}$, this observational evidence has relevant in plications for the geom etry and physics of GRB prom pt emission and can be used to identify and understand sub{classes of GRBs (e.g., short, sub{energetic, XRFs). In the recent years som e authors argued that the correlation m ay be an artifact of, or at least signi cantly biased by, a combination of selection e ects due to detectors sensitivity and energy thresholds $^{21;22;23}$. However, the fact that GRBs detected, localized and spectroscopically characterized by di erent instrum ents all follow the sam e $E_{p;i}$ { E_{iso} correlation, as shown by Am ati et al. (2009) ⁷ and can also be seen in Figure 2 by comparing the location of Swift GRBs with respect to those detected by other instrum ents, supports the hypothesis of a low in pact of selection and detectors threshold e ects. M oreover, tim e resolved analysis of large sam ples of GRBs provide evidence that the correlation holds also within single bursts^{24;25}, thus pointing to a physical origin of it.

4 Estimating cosm ological parameters with the $E_{p;i}$ { E_{iso} correlation

As discussed in the previous Section, the $E_{p;i}$ { E_{iso} correlation is highly signi cant, holds for all long GRBs with known redshift and $E_{p;i}$ and is likely not strongly a ected by selection and detectors threshold e ects. Thus, given that it links a cosm ology independent quantity, $E_{p;i}$, to the burst radiated energy or lum inosity, in principle it could be used to "standardize" GRBs, in a way sim ilar to what is done with SN e Ia with the "Phillips" relation. However, the dispersion of the points around the best t power{law is signi can'ty in excess to the Poissonian one, indicating the presence of an extrinsic variance of unknown origin. In addition, given the lack of a su cient number of GRBs at very low or at the same redshift (Figure 1), the correlation cannot be calibrated, as can be done, instead, for Type Ia SN e. Because of this problem s, in the last years the "cosm ological use" of this correlation, and/or the $E_{p;i}$ { $L_{p;iso}$ correlation, consisted in the estim ate of pseudo{redshifts for those GRBs without measured redshift. This can be

Figure 4: Contour (left) and surface (right) plots showing the probability associated to $_{\rm M}$ and found by tting the updated $E_{\rm p,i}$ ($E_{\rm iso}$ correlation (95 G R B s) with a maximum likelihood method accounting for extrinsic variance (see text) and releasing the hypothesis of a at universe. The cross in the left panel indicates the best t values.

done by simply studying the track of a GRB in the $E_{p;i}$ { E_{iso} plane as a function of redshift, or by using quantities involved in the correlation to build a pseudo{redshift estim ator²⁶. Som e authors applied these m ethods on large sam ple of GRBs in order to reconstruct the lum inosity function or, assuming the association of GRB with very massive stars, the star form ation rate (SFR) evolution (Section 7).

However, recently Am atiet al. (2008) 6 have shown that the $E_{p;i}$ { E_{iso} correlation can also be used to obtain information on cosmological parameters. Their work was prompted by the evidence that, in the assumption of a at universe, the trend of the 2 of the twith a simple powerlaw as a function of the value of $_{\rm M}$ adopted to compute the lum inosity distance and hence the values of E iso shows a nice parabolic shape minimizing at M = 0.3, as can be seen in Figure 2. This is a qualitative but simple, and independent on other cosm ological probes, indication that if the universe is at, as predicted by in ation and implied by CMB m easurem ents, the universe expansion is presently accelerating and an unknown component or eld (e.g., dark energy, quintessence, cosm ological constant) is dom inating over matter and/or gravity. In order to quantify the estimate of $\ _{\rm M}$, Am ati et al. (2008) adopted a likelihood method which accounts for uncertainties on both X and Y quantities and parametrizes the extrinsic variance (i.e. the variance in excess to the Poissonian one) of the data, ext. In this way, they found $M = 0.15^{+0.25}_{-0.11}$ at 68% cl and M < 1 at a signi cance level higher than 99%. This result is fully consistent with that obtained with type Ia SNe. By means of simulations, they also showed that with the substantial increase of the number of GRBs with known z and $E_{p,i}$ expected in the next years, these constraints will be significantly reduced.

In Figures 3 I show the results obtained by repeating the same analysis on the updated sample of 95 GRBs. As can be seen, both the log{likelihood and $_{ext}$ minimize for $_{M}$ 02. In particular, I nd $_{M} = 0.21^{+0.27}_{-0.13}$ at 68% c.l. and $_{M} = 0.21^{+0.53}_{-0.16}$ at 90% c.l. These constraints are slightly tighter than those obtained by Am attiet al. (2008), con m ing the expected e ect of the sam ple enlargement. M oreover, as can be seen in Figure 4, by releasing the assumption of a at universe, the best{ t values of $_{M}$ and are 0.22 and 0.74, respectively, i.e. very close to the standard cosm ology values and to the at universe hypothesis. A lso in this case, even if at 68% c.l. they still provide only an upper limit to the contour con dence levels are tighter than what found by Am atiet al. (2008).

5 Cosm ology with three-param eters spectrum {energy correlations

Soon after the st detections of GRB optical counterparts, it was found that in some cases the optical afterglow light curve shows a steepening of its power{law decay $^{27;28}$. W ithin the standard reball { external shock scenario for the afterglow em ission, this "break" can be interpreted as due to collim ated em ission 29 (even though other explanations are possible). In this view, the jet opening angle can be derived from the break time t_b by making some assumptions on the circum {burst medium average density and prole and on the eliency of conversion of the reball kinetic energy into radiated energy. The jet opening angle, in turn, can be used to derive the collimation {corrected, or "true", radiated energy, E, from E_{iso} . As mentioned in Section 2, E is sitll not standard and is tipically in the range from 5 10^{49} { 10^{52} erg.

In 2004 it was found that when substituing E_{iso} with E the E_{p;i} { E_{iso} correlation becomes tighter, i.e. its extrinsic scatter reduces by a factor of 2²⁸. Even if based on a rather low number of events, this evidence prompted the rst system atic investigations of GRBs as cosm ological nulers ^{30;28;31}. Despite the advantage of a reduced scatter with respect to the E_{p;i} { E_{iso} correlation, the problem of the lack of calibration with low z events cannot be solved anyway, and di erent m ethods were proposed in order to avoid "circularity". The most common are the so called "scatter m ethods", consisting in thing the correlation for each set of cosm ological parameters under study, deriving a ² distribution and use it to obtain best t values and con dence intervals. This can be done either directly in the E_{p;i} { E plane or in the Hubble diagram obtained by deriving E from E_{p;i} and hence the lum inosity distance from E and the m easured uence. M ore sophisticated m ethods based on Bayesian statistics were also proposed ³¹.

The constraints on M and the limits to obtained with the $E_{p;i}$ { E correlation were sim ilar to those derived a few years later from the $E_{p,i}$ { E_{iso} correlation and described in the previous Section. The main draw backs that prevented, up to now, the expected in provem ents in the accuracy and reliability of the cosm ological param eters estim ates with this method include: i) the very slow increase of GRBs with evidence of a break in the optical afterglow light curve, mainly due to the lack of system atic monitoring (the number of GRBs that can be used for the $E_{p,i}$ { E correlation are 25% with respect to the $E_{p,i}$ { E_{iso} correlation); ii) the evidence from Swift/XRT measurements of the X (ray afterglow that, contrary to what expected in the basic jet scenario, in several cases there are not X { ray breaks or the breaks are achrom atic; iii) the debate on the real dispersion and possible existence of outliers of the $E_{p;i}$ { E correlation 32;33;iv) the fact that the E_{p,i} { E correlation is model dependent, i.e. requires assumptions on the circum (burst density pro le and, more in general, a jet model. Concerning points ii) and iv), it was noted that the correlation between $E_{p;i}$, E_{iso} and t_{b} holds even without the need of a jet interpretation, i.e. at a purely empirical level³⁴. Thus, also the $E_{p,i}$ { E_{iso} { t_b correlation was investigated for the estimate of cosm ological parameters. However, under this respect it is still a ected by the low number of events that can be used, the existence of possible outliers and the uncertainty on its true dispersion.

In 2006, it was also found that the dispersion of the $E_{p;i}\{L_{p;iso}$ correlation decreases substantially when including the "high signal time scale" $T_{0:45}$, a parameter often used in GRB variability studies. Thus, also this correlation was proposed as a tool to standardize GRBs, similarly to the $E_{p;i}$ { $E_{and} E_{p;i}$ { E_{iso} { t_{b} correlations, but with the advantage of a higher number of events, being based on promptem ission properties only. However, subsequent analysis on larger samples showed that the extrinsic scatter of this correlation m ay not be signicantly lower than that of the simple $E_{p;i}$ { E_{iso} or $E_{p;i}\{L_{p;iso}$ correlations^{35;36}.

6 Calibrating GRBs with SN e Ia and multi{correlation studies

As mentioned in the previous Sections, one of the most liming features of spectrum (energy correlations as tools to standardize GRBs is the lack of low redshift GRBs, or of a su cient number of GRBs at the same redshift, allowing to calibrate them. On the other hand, if one believes that SN Ia are reliable distance indicators, then can use them to calibrate GRB spectrum (energy correlations and take advantage of the GRB redshift distribution in order to extend the Hubble diagram from z 1.7 up to 8. This approach has been followed by several authors $^{37;38}$, allowing them not only to tighten the constraints on $_{\rm M}$ and but also to obtain inform ation on the dark energy equation of state and its evolution, or to test cosm ologicalm odels alternative to the standard CDM.

The obvious draw back of this use of GRBs for cosm ology is that it introduces a "circularity" with type Ia SNe, i.e., GRBs are no more independent probes and all the systematics and uncertainties associated with SNe propagates into the results obtained with this method.

The spectrum {energy correlations discussed in previous Sections are the tightest but not the only ones linking GRB observables to their lum inosity. For instance, signi cant correlations were found between prompt em ission variability and peak lum inosity or between prompt em ission time { lag and lum inosity. Some authors developed methods for putting together several correlations in order to derive estimates of cosm ological parameters ³⁹. However, adding to spectrum {energy correlations more dispersed correlations adds more uncertainties, thus preventing a signi cant im provement with respect to using spectrum {energy correlations alone.

7 Gamma{Ray Bursts as cosm ological beacons and SFR tracers

Besides the estimate of cosm ological parameters, GRBs are also very promising tools for cosmology under other respects. The association of long GRBs with peculiar type Ib/c SNe or hypernovae, and thus the death of very m assive stars, is supported both by theories and observations⁴⁰. Thus, given their huge lum inosity and redshift distribution extending up to at least 8, GRBs may be considered powerful and unique tracers of the SFR evolution up to the Z re-ionization epoch. For instance, the recent detection of GRB 090423 at z 8.1 is a simple and direct evidence that stars were already there at about 600 m illions of year from the big{bang and with explosion mechanism not markedly dierent from that of stars born several billions of years later ⁴¹. Several authors addressed this issues, either by comparing directly the GRB redshift distribution with the SFR up to z 4 reconstructed from other observations, or by reconstructing the GRB lum inosity function and its evolution by computing the pseudo{redshift of large num bers of GRB based on spectrum {energy correlations¹⁹. The results of these analysis indicate that GRBs are a biased tracer of the SFR evolution, which may be due to the fact, supported both by theory and observations, that GRBs are produced by low m etallicity stars in low metallicity galaxies. Under this respect, GRBs provide information on the metallicity evolution 42.

Another interesting and prom ising cosm obgical use of GRBs is to use their X {ray afterglow em ission as background source for X {ray high resolution spectroscopy of the inter{galactic m edium (IGM) and of the host galaxies inter{stellar m edium (ISM). This kind of investigations is the subject of future m issions under study, like, e.g., the EDGE m ission proposed to the ESA Cosm ic V ision 43 or the XENIA m ission subm itted to the NASA D ecadal Survey. As discussed, e.g., by Branchini et al. (2009) 44 , with state of the art X {ray m icrocalorim eters, allow ing energy resolutions of the order of 2{3 eV in the 02{2 keV energy range, an e ective area of

1000 cm² energy range, spacecraft slewing capabilities of the order of 1 m in and by assuming the X (ray afterglow photon uence distribution m easured by Swift/XRT, sensitive spectroscopy of tens of W HIM system per year could be done. In addition, by exploiting, e.g., resonant

absorption lines, such instrum entation would allow the study of the galaxy ISM properties and their evolution with redshift.
