ABSTRACT

Spectral lag, the time difference between the arrival of high-energy and low-energy photons, is a common feature in Gamma-ray Bursts (GRBs). Norris et al. 2000 reported a correlation between the spectral lag and the isotropic peak luminosity of GRBs based on a limited sample. More recently, a number of authors have provided further support for this correlation using arbitrary energy bands of various instruments. In this paper we report on a systematic extraction of spectral lags based on the largest *Swift* sample to date of 31 GRBs with measured redshifts. We extracted the spectral lags for all combinations of the standard *Swift* hard x-ray energy bands: 15-25 keV, 25-50 keV, 50-100 keV and 100-200 keV and plotted the time dilation corrected lag as a function of isotropic peak luminosity. The mean value of the correlation coefficient for various channel combinations is -0.68 with a chance probability of $\sim 0.7 \times 10^{-3}$. In addition, the mean value of the power-law index is 1.4 ± 0.3 . Hence, our study lends support for the existence of a lag-luminosity correlation, albeit with large scatter.

Subject headings: GRB; gamma rays bursts; redshift, spectral lag

1. Introduction

After decades of research, a satisfactory explanation of the temporal behavior of Gamma-ray Burst (GRB) light-curves is still lacking. Despite the diversity of GRBs, some general characteristics and correlations have been identified: Spectral lag is one such characteristic. The spectral lag is the difference in time of arrival of high-energy pulses

verses low-energy pulses. In our analysis a positive spectral lag corresponds to an earlier arrival time for the higher energy photons. The observed spectral lag is a common feature in GRBs (Cheng et al. 1995; Norris et al. 1996; Band 1997). The study of spectral lag between energy bands, which combines temporal and spectral information, potentially can constrain GRB models (Lu et al. 2006; Shen et al. 2005; Qin et al. 2004; Schaefer 2004; Ioka & Nakamura 2001; Salmonson 2000).

Based on six GRBs with known redshifts, Norris et al. (2000) found an anti-correlation between the spectral lag and the isotropic peak luminosity. Further evidence for this correlation was provided by Norris (2002), Gehrels et al. (2006), Schaefer (2007), Stamatikos et al. (2008a) and Hakkila et al. (2008). Others have used this relation as a redshift indicator (Murakami et al. 2003; Band et al. 2004) and as a cosmological tool (Bloom et al. 2003; Schaefer 2007; Liang et al. 2008; Mosquera Cuesta et al. 2008).

Hakkila et al. (2008) have used a pulse-profile fitting technique (a four-parameter pulse function

introduced by Norris et al. (2005)) to show that the correlation is between lags of the pulses and the luminosity of the pulses seen in GRBs. However, the method is limited because it applies only to very bright bursts where pulses are clearly identifiable and described by the assumed pulse profile.

Many authors have tried to explain the physical cause of the lag-luminosity relation and a number of models have been proposed. Salmonson (2000) argues that the anti-correlation is due to the variations in the line-of-sight velocity of various GRBs. Ioka & Nakamura (2001) suggest that the relation is a result of variations of the off-axis angle when viewing a narrow jet. Schaefer (2004) invokes a rapid radiation cooling effect to explain the correlation. This effect tends to produce short spectral lags for highly luminous GRBs.

Regardless of its physical origin, the spectral lag is an important measurement for GRB science because of its usefulness in differentiating long and short GRBs (Kouveliotou et al. 1993): Long bursts give large lags and short bursts give relatively small lags (Norris 1995; Norris & Bonnell 2006). Even though a few exceptions to this classification scheme have been found, such as GRB 060614 (Gehrels et al. 2006), the GRB community still continues to use the spectral lag as one of the classification criteria. Note that more elaborate classification schemes based on multiple observational parameters, such as the host galaxy property, has also been proposed (Donaghy et al. 2006; Zhang et al. 2009).

Moreover, based on the analysis of GRB 080319B, Stamatikos et al. (2009) show that there is a possible correlation between the prompt optical emission and the evolution of spectral lag with time.

Most of the previous work on spectral lags has been based on observations with the Burst and Transient Source Experiment (BATSE) on the Compton Gamma Ray Observatory (Tsutsui et al. 2008; Hakkila et al. 2008, 2007; Chen et al. 2005; Band et al. 2004; Salmonson & Galama 2002; Norris 2002; Band 1997). The launch of the *Swift* satellite (Gehrels et al. 2004) ushered in a new era of GRB research. In this paper we present a detailed study of spectral lags using a subset of Swift Burst Alert Telescope (BAT) data.

The structure of the paper is the following: In

section 2 we discuss our methodology with a case study featuring GRB 060206. In section 3 we present our results for a sample of 31 *Swift* BAT long bursts and investigate the lag-luminosity relation for various channel combinations. Finally, in section 4 we discuss some implications of our results. Throughout this paper, the quoted uncertainties are at the 68% confidence level.

2. Methodology

2.1. Light Curve Extraction

Swift BAT is a highly sensitive instrument, which utilizes a coded aperture mask to localize bursts (Barthelmy et al. 2005). The basic imaging scheme is that a gamma-ray source illuminates the coded aperture mask, and casts a shadow onto a position sensitive detector. Each position in the sky will produce a unique shadow pattern in the detector plane. Hence by comparing the observed shadow with precalculated shadow patterns for all possible points in the sky it is possible to find the actual position of the source that created the given shadow pattern. However, in practice each detector can be illuminated by many points on the sky whereas each point on the sky can illuminate many detectors. To disentangle each point in the sky, special software designed by the *Swift* BAT team is used.

In order to generate light curves, a process called mask weighting is utilized. The mask weighting assigns a ray-traced shadow value for each individual event, which then enables the user to calculate light curves or spectra. We used the `batmaskwtevt` and `batbinevt` tasks in FTOOLS to generate mask weighted, background-subtracted light curves for our analysis. Resulting light curves and their uncertainties are calculated by propagation of errors from raw counts (subject to Poissonian noise).

2.2. The Cross Correlation Function and Spectral Lag

There are at least three well known ways of extracting spectral lags; (1) pulse peak-fit method (Norris et al. 2005; Hakkila et al. 2008), (2) Fourier analysis method (Li et al. 2004), and (3) cross-correlation function (CCF) analysis method (Cheng et al. 1995; Band 1997). The

pulse peak-fit method gives a simple straight forward way for extracting lags. It does however assume a certain pulse function for the pulses in the light curve and may also be limited to very bright bursts. It is not immediately clear how this method would fare in cases where the light curves are sufficiently complex i.e., not dominated by a prominent pulse. For transient events such as GRBs using the Fourier analysis technique also has its difficulties (Li et al. 2004). Since GRB light curves do not exhibit obvious periodicities, Fourier transforms typically yield a large number of coefficients to describe their temporal structure. These coefficients, in turn, produce a spectral lag value for each corresponding frequency component i.e., a spectrum of lags is generated. The generated spectra exhibit a variety of shapes depending on the complexity of the light curve (Li et al. 2004) thus making the extraction of an intrinsic lag questionable. Hence, in this work, we develop a method to calculate the time-averaged spectral lag and its uncertainty via a modification of the CCF method.

The use of the Pearson cross-correlation function is a standard method of estimating the degree to which two series are correlated. For two counting series x_i and y_i where $i = 0, 1, 2, \dots, (N-1)$, the CCF with a delay d is defined as

$$CCF_{\text{Std}}(d, x, y) = \frac{\sum_{i=1}^{N-d} (x_i - \bar{x})(y_{i+d} - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2}}. \quad (1)$$

Here $\bar{x}$ and $\bar{y}$ are average counts of the two series x and y respectively. The denominator in the expression above serves to normalize the correlation coefficient such that $-1 \leq CCF_{\text{Std}}(d, x, y) \leq 1$, the bounds indicating maximum correlation and zero indicating no correlation. A high negative correlation indicates a high correlation but of the inverse of one of the series. Note that the time delay (τ) is given by $\tau = d \times \text{time bin size}$.

However, Band (1997) proposed that for transient events such as GRBs, non-mean subtracted definition given below is more suitable for the time-averaged lag.

$$CCF_{\text{Band}}(d, x, y) = \frac{\sum_{i=\max(1, 1-d)}^{\min(N, N-d)} x_i y_{i+d}}{\sqrt{\sum_i x_i^2} \sqrt{\sum_i y_i^2}} \quad (2)$$

We have tested both definitions of the CCF using synthetic light curves with artificially intro-

duced spectral lags. Our tests showed that the CCF_{Band} consistently recovered the introduced lag while CCF_{Std} sometimes failed (possible reasons for this failure are noted in Band (1997)). Hence in our analysis we used the CCF_{Band} definition and from this point onwards in the paper we refer to it simply as the CCF.

For a given pair of real light curves, we determine the CCF using Equation 2. At this stage the resulting CCF values do not have any uncertainties associated with them. In order to determine these uncertainties, we use a Monte Carlo simulation. Here we make 1,000 Monte Carlo realizations of the real light curve-pair based on their error bars as shown below.

$$LC_{\text{bin}}^{\text{simulated}} = LC_{\text{bin}}^{\text{real}} + \xi \times LC_{\text{bin}}^{\text{real error}} \quad (3)$$

Where ξ is a random number generated from a gaussian distribution with the mean equal to zero and the standard deviation equal to one. For each simulated light curve-pair we calculate the CCF value for a series of time delays. This results in a 1,000 CCF values per time-delay bin. The standard deviation of these values per time-delay bin is then assigned as the uncertainty in the original CCF values obtained from the real light curves.

2.3. Extracting Spectral Lags

We realize there may be number of ways to define the spectral lag, but in this work, we define it as the time delay corresponding to the global maximum of the cross-correlation function. To locate this global maximum, we fit a Gaussian curve to the CCF. The uncertainties in the CCF are obtained using a Monte Carlo procedure discussed in section 2.2. In essence, our fitting procedure locates the centroid of the cross correlation function and is thus relatively insensitive to spurious spikes in the CCF. We tested and verified the robustness of this procedure by performing a number of simulations in which artificial lags were first introduced into the light curves and then successfully recovered. In addition, our tests with these artificial light curves show that the CCF can become asymmetric (around its global maximum) if the shape of one of the light curves is significantly different from the other. This energy dependent feature potentially requires a more complex fitting function than a Gaussian or a quadratic to fit the CCF over the entire range. Instead of resorting

to a more complex fitting function we were able to recover the (known) lags by fitting the CCFs (with a Gaussian) over limited but asymmetric ranges.

2.3.1. Time Bin Selection

For *Swift* GRBs the minimum time binning is 0.1 ms but one can arbitrarily increase this all the way up to the duration of the burst. It is important to understand the effect of time binning on the extracted spectral lags. Presumably, by changing the time binning of the light curve one is affecting the signal-to-noise ratio. By employing increasingly coarser binning one is averaging over the high frequency components of the light curve. Clearly, one has to be careful not to use overly large time bin sizes otherwise one risks losing the sought-after information from the light curve.

In order to understand the effect of time binning more fully, we did a number of simulations utilizing peak normalized synthetic light curves (composed of FRED¹-like pulse shapes with Gaussian distributed noise) in which artificial lags were introduced. We incrementally increased the noise level and studied its effect on the maximum correlation value in the CCF vs time delay (CCF-Max) plot. In Fig. 1 we display the synthetic light curves with several noise levels (0%, 20%, 40% and 60% respectively) as well as the calculated CCF with typical Gaussian fits. As expected, the CCF-Max value (see the right panel of Fig. 1) decreases gradually as the noise level increases. We also note that the scatter in the CCF increases considerably with the noise level. The global maximum in the CCF is clearly visible at the 40% noise level and a good fit is obtained with a Gaussian. However, this is not the case for the 60% noise-level curve, in which the scatter is quite significant, and the CCF global maximum is barely visible leading to a poor fit.

In Fig. 2 we show the behavior of the CCFMax value and the extracted spectral lag as a function of the noise level. We first note that the CCFMax value smoothly tracks the signal-to-noise level in the light curves (see the upper panel of Fig. 2). Secondly, we note that the extracted lag value agrees well with the artificially introduced lag of 10 seconds up to a noise level of about 40%. We further note that the scatter in the extracted lag

value increases as the noise contribution increases beyond 40%. Although it is not immediately obvious from this figure, CCF values above a noise level of 40% show large scatter (see bottom right panel of Fig. 1) thus making the extracted lag value uncertain. This is directly reflected by the increasing error bars in the extracted value. These simulations were repeated for number of time lags and in all cases similar results were obtained, in particular, the behavior of the CCFMax as a function of the noise level was confirmed. Based on the results of these simulations, we chose a CCFMax ~ 0.5 , corresponding to a noise level of about 40%, as our guide for picking the appropriate time binning.

Procedurally, we start with a time bin size of 1024 ms and decrease the time binning by powers of two until the CCFMax becomes ~ 0.5 and use that time bin size as the preferred time binning for the lag extraction. By using this procedure we are able to arrive at a reasonable bin size that preserves the fine structure in the light curve and at the same time keeps the contribution of the noise component at a manageable level.

2.3.2. Uncertainty in Spectral Lags

We have studied three methods to determine the uncertainty in the extracted spectral lags. The first method is to use the uncertainty that is obtained by fitting the CCF with a Gaussian curve. The second method is an adaptation of equation (4) used in Gaskell & Peterson (1987)

$$\sigma_{\text{lag}} = \frac{0.75 W_{\text{HWHM}}}{1 + h\sqrt{n-2}}. \quad (4)$$

Here W_{HWHM} is the half-width half-maximum of the fitted Gaussian, h the maximum height of the Gaussian and n is the number of bins in the CCF vs time delay plot. This method utilizes more information about the fit and the CCF such as the width, height, and number of bins to estimate the uncertainty. The third method utilizes a Monte Carlo simulation. We found that the first method gives systematically smaller uncertainty in the lag by a factor of two or more relative to the other two methods. The second and third methods give comparable values. We adopted the most conservative of the three methods (i.e. the one based on the Monte Carlo simulation) to determine the uncertainties in the lag.

¹Fast Rise Exponential Decay

2.3.3. Lag Extraction: Case Study

To illustrate the lag extraction procedure more clearly, we present a case study using GRB 060206. The light curve segment is selected by scanning both forward and backward directions from the peak location until the count rate drops to less than 5% of the peak count rate (using 15 – 200 keV light curve). This selection method is chosen to include the most intense segment of the burst and to capture any additional overlapping pulses near the main structure. Presumably, these pulses also contribute to the overall spectral lag. In the case of GRB 060206 this corresponds to a light curve segment starting 1.29 seconds prior to the trigger and 8.18 seconds after the trigger (see Fig. 3). Next we calculate the CCF and plot it as a function of time delay as shown Fig. 4. Error bars on the CCF points were obtained via a Monte Carlo simulation of 1,000 realizations of the original light curves (see section 2.2). As noted earlier, we start with time bin size of 1024 ms and decrease the time binning by powers of two until the CCFMax becomes ~ 0.5 for a given channel combination, in this case BAT standard channel 2 (25–50 keV) and 3 (50–100 keV). For GRB060206 channel 2 and 3, the time bin size correspond to 8 ms. The global maximum of the CCF vs time delay plot corresponds to the spectral lag and its value is obtained by fitting a Gaussian curve. We choose a range of the time delay (in this case from -1.5 seconds to 1.5 seconds) manually to identify the global maximum. In order to obtain the uncertainty in the spectral lag, we employ another Monte Carlo simulation, in which we create 1,000 additional realizations of the input light curves as described in section 2.2, and repeat the previously described process for the simulated light curves. A histogram of the resulting (1,000) spectral lag values is shown in Fig. 5 for GRB 060206. The standard deviation of these values is the uncertainty in the spectral lag.

2.4. Isotropic Peak Luminosity

To compare observations with different instruments we need to calculate flux over some fixed energy band. In order to do this we need to know the best-fit spectral function to the observed spectrum and its spectral parameters. Often, GRB spectra can be well fitted with the Band

function (Band et al. 1993), an empirical spectral model defined as follows:

$$N = \begin{cases} A(\frac{E}{100 \text{ keV}})^\alpha e^{-(2+\alpha)E/E_p}, & E \leq (\frac{\alpha-\beta}{2+\alpha})E_p \\ A(\frac{E}{100 \text{ keV}})^\beta [\frac{(\alpha-\beta)E_p}{(2+\alpha)100 \text{ keV}}]^{\alpha-\beta} e^{(\beta-\alpha)}, & \text{otherwise.} \end{cases}$$

There are four model parameters in the Band function; the amplitude (A), the low-energy spectral index (α), the high-energy spectral index (β) and the peak of νF_ν spectrum (E_p).

If the GRB spectrum is well described by the Band function, then the values of α , β , E_p and the observed peak flux, f_{obs} , in a given energy band (E_{min} and E_{max}) are often reported. We can calculate the normalization A with

$$A = \frac{f_{\text{obs}}}{\int_{E_{\text{min}}}^{E_{\text{max}}} N'(E) dE} \quad (5)$$

where f_{obs} is given in photons $\text{cm}^{-2} \text{s}^{-1}$ and $N' = N/A$.

The observed peak flux for the source-frame energy range $E_1 = 1.0 \text{ keV}$ to $E_2 = 10,000 \text{ keV}$ is

$$f_{\text{obs}}^{\text{new}} = \int_{E_1/(1+z)}^{E_2/(1+z)} N(E) E dE. \quad (6)$$

The isotropic peak luminosity is

$$L_{\text{iso}} = 4\pi d_L^2 f_{\text{obs}}^{\text{new}} \quad (7)$$

where d_L is the luminosity distance given by,

$$d_L = \frac{(1+z)c}{H_0} \int_0^z \frac{dz'}{\sqrt{\Omega_M(1+z')^3 + \Omega_L}} \quad (8)$$

For the current universe we have assumed, $\Omega_M = 0.27$, $\Omega_L = 0.73$ and the Hubble constant H_0 is $70 (\text{kms}^{-1})/\text{Mpc} = 2.268 \times 10^{-18} \text{s}^{-1}$ (Komatsu et al. 2009).

To determine the uncertainty in L_{iso} , we employ a Monte Carlo simulation. We simulate spectral parameters α , β , E_p and flux assuming their reported value as sample mean and reported uncertainty as sample standard deviation, then calculate L_{iso} , for 1,000 variations in these parameters. If a parameter has uneven uncertainty values then each side around the parameter is simulated with different uncertainty values as standard deviation. Then we take the 16th and the 84th ranked values (1σ uncertainty) as the lower limit and the upper limit of L_{iso} respectively.

3. Results

We selected a sample of long GRBs ($T_{90} > 2$ sec, excluding short bursts with extended emission), detected by *Swift* BAT from 2004 December 19 to 2009 July 19, for which spectroscopically confirmed redshifts were available. Out of this initial sample (102), a subset of 41 GRBs were selected with peak rate > 0.3 counts/sec/det (15 – 200 keV, 256 ms time resolution). Finally, we selected 31 GRBs for which a clear global maximum can be seen in the CCF vs time delay plots with maximum correlation of at least 0.5 (with 256 ms time binning) for all channel combinations. The spectral parameters of the final sample are given in Table 1. We note that our final sample contains bursts with redshifts ranging from 0.346 (GRB 061021) to 5.464 (GRB 060927) and the average redshift of the sample is ~ 2.0 .

Out of our sample, 18 bursts have all Band spectral parameters measured and comprise our “Gold” sample. The remaining 13 bursts are further divided into “Silver” and “Bronze” samples. In the “Silver” sample, 10 bursts have E_p determined by fitting a cutoff power-law² (CPL) to spectra and for GRB 060418, E_p is reported without uncertainty, so we assumed a value of 10%. These 10 bursts do not have the high-energy spectral index, β , measured, so we used the mean value of the BATSE β distribution, which is -2.36 ± 0.31 (Kaneko et al. 2006; Sakamoto et al. 2009). The “Bronze” sample (consisting of 3 bursts) does not have a measured E_p . We have estimated it using the power-law index (Γ) of a simple power-law (PL) fit as described in Sakamoto et al. (2009). For these 3 bursts, the low-energy spectral index, α and the high-energy spectral index, β , were not known, so we used the mean value of the BATSE α and β distribution, which is -0.87 ± 0.33 and -2.36 ± 0.31 respectively (Kaneko et al. 2006; Sakamoto et al. 2009). All estimated spectral parameters are given in square brackets in Table 1.

Using the spectral parameters and redshift information in Table 1 we have calculated the peak isotropic luminosities for all the bursts in our sample: these results are shown in Table 2. GRB 080430 has the lowest luminosity in the sample ($\sim 1.03 \times 10^{51}$ erg s⁻¹), and GRB 080607 has the

highest luminosity ($\sim 7.19 \times 10^{53}$ erg s⁻¹). The sample spans roughly three orders of magnitude in luminosity.

We extracted the spectral lags for all combinations of the canonical BAT energy bands: channel 1 (15–25 keV), 2 (25–50 keV), 3 (50–100 keV) and 4 (100–200 keV). We took the upper-boundary of channel 4 to be 200 keV because we found that after the mask weighting the contribution to the light curve from energies greater than ~ 200 keV is negligible. The nomenclature is straightforward, i.e. the spectral lag between energy channels 4 and 1 is represented by Lag 41. As such there are six channel combinations and the results for all six are shown in Table 3. The segment of the light curve used for the lag extraction ($T + X_S$ and $T + X_E$, T is the trigger time), the time binning of the light curve, and the Gaussian curve fitting range of the CCF vs time delay plot (with start time, and end time denoted as LS and LE respectively) are also given in Table 3.

We noticed, as did Wu & Fenimore (2000), that the lag extraction is sensitive to a number of parameters. Hence, in Table 3, we specify the band pass that we used to extract the lag, segment of the light curve used, temporal bin resolution, and the fitting range used in the CCF vs time delay plot. These additional parameters are reported in order to facilitate reproduction of the results and direct comparison with other extraction techniques.

Figures 6 through 11 show log-log plots of isotropic peak luminosity vs redshift corrected spectral lag for various energy channel combinations. Red circles represent bursts from the “Gold” sample, blue diamonds shows bursts from the “Silver” sample and green triangles are bursts from the “Bronze” sample. The best-fit power-law curve is also shown in these plots with a dash line. Since there is a large scatter in these plots, to compensate, the uncertainties of the fit parameters are multiplied by a factor of $\sqrt{\chi^2/\text{ndf}}$ (see Table 4)³. The dotted lines indicate the estimated 1 σ confidence level, which is obtained from the cumulative fraction of the residual distribution taken from 16% to 84%.

It is interesting to note that GRB 080603B exhibits five negative lags out of six possible combi-

² $dN/dE \sim E^\alpha \exp(-(2 + \alpha)E/E_p)$

³ndf - number of degrees of freedom

nations. While these negative lags are not shown in the plots, it is worth noting that negative lags are not necessarily unphysical (Ryde 2005). Moreover, in the few cases where the uncertainty is large, i.e. the extracted lags are consistent with zero, these points are not plotted either but are listed in Table 3. We recognize that the omission of these negative and zero lags is a potential source of bias.

As seen in Fig. 6 through 11, our results support the existence of the lag-luminosity correlation originally proposed by Norris et al. (2000). Table 4 lists the correlation coefficients for all six channel combinations. The lag for channel combination 31 has the lowest correlation with L_{iso} , where the correlation coefficient is -0.60 (with chance probability of $\sim 1.5 \times 10^{-3}$) and the lag for channel 43 has the highest correlation with coefficient of -0.77 (with chance probability of $\sim 3.0 \times 10^{-4}$). However, we note that there is considerable scatter in the plots. The results of our best fit curves for each energy band combinations are also given in Table 4. The mean value of the power-law indices that we get for various channel combinations is 1.4 ± 0.3 . Our value is consistent with the 1.14 power-law index Norris et al. (2000) reported using lags between BATSE energy bands $100 - 300$ keV and $25 - 50$ keV. Our results are also consistent with Stamatikos et al. (2008a) and Schaefer (2007) who reported values of 1.16 ± 0.21 and 1.01 ± 0.10 (assuming an uncertainty of 10%), respectively.

4. Discussion

Band (1997) showed that gamma-ray burst spectra typically undergo hard-to-soft peak evolution, i.e. the burst peak moves to later times for lower energy bands. In our sample we have six lag extractions for each burst. The perfect hard-to-soft peak evolution scenario is indicated by positive lag values for all channel combinations plus $\text{lag41} > \text{lag42} > \text{lag43}$ and $\text{lag31} > \text{lag32}$. However, all bursts in our sample do not show this perfect behavior. Band (1997) used a scoring method to quantify the degree of hard-to-soft peak evolution. We used a more elaborate scoring method to assign a score to each GRB as follows: First, we increase the burst score by one if one of the six lag values is positive or decrease

it by one if it is negative. Thus, a GRB can get a score ranging from -6 to $+6$ at this first step. Then, we compare the lag values of channel 4 as the base (lag43 , lag42 , and lag41). The score is increased by one if the burst meets one of the following conditions: $\text{lag41} > \text{lag42}$, $\text{lag41} > \text{lag43}$ or $\text{lag42} > \text{lag43}$. We continue this procedure for channel 3 as the base also ($\text{lag31} > \text{lag32}$). We decrease the score by one if it is otherwise. According to this scoring scheme a score of $+10$ corresponds to the perfect case that we mentioned earlier. A positive score indicates overall hard-to-soft peak evolution in the burst to some degree. A negative value indicates soft-to-hard peak evolution. Out of 31 bursts in our sample 19 bursts show perfect hard-to-soft peak evolution with a score of $+10$. About 97% of bursts in our sample have a score of greater than zero, which is consistent with the 90% value reported by Band (1997).

If one wants to use the lag-luminosity relation as a probe into the physics of GRBs (in the source rest frame), then a few corrections to the spectral lag are required; 1) correct for the time dilation effect (z-correction), 2) take into account the fact that for GRBs with various redshifts, observed energy bands correspond to different energy bands at the GRB rest frame (k-correction). Gehrels et al. (2006) approximately corrected observed spectral lag for the above mentioned effects. We also examined these corrections. The z-correction is done by multiplying the lag value by $(1+z)^{-1}$. The k-correction is approximately done by multiplying the lag value by $(1+z)^{0.33}$ (Gehrels et al. 2006; Zhang et al. 2009). In table 5 we list the correlation coefficients with no correction, only z-correction, only k-correction and both corrections applied. For example correlation coefficient of Lag31 and L_{iso} is -0.38 without any corrections. After the k-correction the correlation coefficient is -0.29 . Therefore, we do not gain a significant improvement in the correlation by applying the k-correction. However, the correlation improves significantly after the z-correction (-0.60). The approximate k-correction of (Gehrels et al. 2006) is based on the assumption that the spectral lag is proportional to the pulse width and pulse width is proportional to the energy (Zhang et al. 2009; Fenimore et al. 1995). These approximations depend on clearly identifying a pulse in the light curve and may be of limited validity for multi-

pulse structures. A better method would be to define two energy bands in the GRB rest frame and project those two bands into the observer frame and extract lags between them (Ukwatta, et al., 2010 in preparation).

5. Conclusion

In this work we have used the CCF technique to extract spectral lags for a sample of *Swift* BAT GRBs with known redshifts. By using Monte Carlo simulations, we have extended this technique to reliably determine the uncertainties in the extracted spectral lags. Normally these uncertainties would be very difficult to calculate analytically.

This study provides further support for the existence of the lag-luminosity correlation, originally proposed by Norris et al. (2000). We note however, that there is a significant scatter in the correlation.

The authors are indebted to the late Dr. David L. Band for fruitful and insightful discussions on the CCF methodology. In addition, we take this opportunity to acknowledge useful input from David A. Kahn regarding the luminosity calculations. We also thank the anonymous referee for comments and suggestions that significantly improved the paper. The NASA grant NNX08AR44A provided partial support for this work and is gratefully acknowledged.

^a1-second peak photon flux measured in photon cm⁻² s⁻¹ in the energy range 15 – 150 keV.

^bPeak energy is given in keV. Values in brackets indicates estimated values using the method described in Sakamoto et al. (2009).

^cValues in brackets indicates estimated high-energy photon index, α , which is the mean value of the BATSE α distribution (Kaneke et al. 2006; Sakamoto et al. 2009).

^dValues in brackets indicates estimated high-energy photon index, β , which is the mean value of the BATSE β distribution (Kaneke et al. 2006; Sakamoto et al. 2009).

NOTE.—Note that uncertainties of parameters that are reported with 90% confidence level have been reduced to 1 σ level for consistency.

TABLE 2
GRB REDSHIFT AND CALCULATED ISOTROPIC PEAK LUMINOSITY

^aIsotropic equivalent peak photon luminosity in erg s^{-1} between GRB rest frame energy range 1 and 10,000 keV as described in Section 2.

Fig. 1.— The effect of noise on the CCF. Panels on the left show two synthetic light curves, in which a 10-second artificial lag is added. From top to bottom the noise level is increased as 0%, 20%, 40% and 60% respectively. The corresponding CCF vs time delay plots are shown in the right panels along with Gaussian fits.

Fig. 2.— The effect of noise on the maximum correlation of the CCF (CCFMax) and the extracted spectral lag. The horizontal line (blue) in the bottom panel indicates the 10-second artificial lag.

Fig. 3.— Swift-BAT prompt gamma-ray (8 ms time bin) light curves for GRB 060206 with canonical energy channels 2 (25-50 keV) and 3 (50-100 keV).

Fig. 4.— CCF as a function of time delay for the two light curves in Fig.3. The time delay corresponding to the peak of the Gaussian fit is the spectral lag of the burst, which is 278 ± 13 ms. The uncertainty quoted here is from the fit, which tends to be factor of two or more less than the value obtained by the Monte Carlo simulation shown in Fig. 5.

Fig. 5.— Histogram of 1,000 simulated spectral lag values. We take the standard deviation of the distribution of simulated spectral lag values as the uncertainty of the fitted spectral lag value which was found in Fig. 4. The final spectral lag value is 278 ± 74 ms.

Fig. 6.— Isotropic luminosity as a function of spectral lag between BAT channel 2 (25–50 keV) and 1 (15–25 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.

Fig. 7.— Isotropic luminosity as a function of spectral lag between BAT channel 3 (50–100 keV) and 2 (25–50 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.

Fig. 9.— Isotropic luminosity as a function of spectral lag between BAT channel 4 (100–200 keV) and 3 (50–100 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.

Fig. 8.— Isotropic luminosity as a function of spectral lag between BAT channel 3 (50–100 keV) and 1 (15–25 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.

Fig. 10.— Isotropic luminosity as a function of spectral lag between BAT channel 4 (100–200 keV) and 2 (25–50 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.

Fig. 11.— Isotropic luminosity as a function of spectral lag between BAT channel 4 (100–200 keV) and 1 (15–25 keV). The “Gold”, “Silver”, and “Bronze” samples are represented with red circles, blue diamonds, and green triangles respectively.
