In this paper we consider in detail the properties of dynam ical heterogeneity in lattice glass models (LGM s). LGM s are lattice models whose dynam ical nules are based on them odynam ic, as opposed to purely kinetic, considerations. We devise a LGM that is not prone to crystallization and displays properties of a fragile glass-form ing liquid. Particle motion in this model tends to be locally anisotropic on intermediate time scales even though the nules governing the model are isotropic. The model demonstrates violations of the Stokes-E instein relation and the growth of various length scales associated with dynam ical heterogeneity. We discuss future avenues of research com paring the predictions of lattice glass models and kinetically constrained models to atom istic system s.

I. IN TRODUCTION

The cause of the dram atic slowing of dynamics close to the empirically de ned glass transition is a subject of great continued interest and debate [1, 2]. Di erent theoretical proposals have been put forw ard aim ed at describing some or all of the phenom ena commonly observed in experiments and computer simulations [3, 4, 5, 6, 7, 8, 9]10, 11, 12, 13]. W hile these proposals are often based on com pletely divergent view points, many of them are able to rationalize the same observed behaviors. This fact stems from the som ew hat limited am ount of information available from experiments and simulations. Since the growth of relaxation times in glassy systems is precipitous, it is very di cult, and in som e cases in possible, to distinguish models solely on the basis of di erent predictions of gross tem perature dependent relaxation behavior. In addition, computer simulations, which are often m ore detailed than experim ents, are lim ited by the range of tim es scales and sizes of system s that can be studied. These di culties have hindered the search for a consensus on the m icroscopic underpinnings of vitri cation.

D espite the continued debate that revolves around the theoretical description of supercooled liquids and glasses, little argum ent exists regarding the importance of dynam ical heterogeneity as a key feature of glassy behavior [14, 15, 16, 17, 18, 19]. D ynam ical heterogeneity refers to the fact that as a liquid is supercooled, dynam ics becom e starkly spatially heterogeneous, requiring the cooperative m otion of groups of particles for relaxation to occur. Dynam icalheterogeneous motion manifests in several ways, and leads to violations of the Stokes-Einstein relation [20, 21, 22, 23, 24], cooperative hopping motion relected in nearly exponential tails in particle displacem ent functions [5, 25, 26, 27, 28], and growing length scales such as those associated with the recovery of Fickian di usion [29, 30, 31, 32], growing multi-point correlation functions [3, 33, 34, 35, 36, 37, 38, 39, 40, 41]. Indeed, the relatively recent explication of the phenom ena of dynam ical heterogeneity has dram atically shifted the focus of the eld and has placed new constraints on the necessary ingredients for a successful theory of glass form ation.

G iven the sim ilarity of som e aspects of dynam ical heterogeneity to critical uctuations in standard critical phenom ena, it is natural to investigate two and three dim ensional simplied coarse-grained models that encode the crucial features of this heterogeneity. Currently, the most investigated class of coarse-grained models are the \kinetically constrained models" (KCMs) [5, 6, 42, 43, 44]. KCMs are spin or lattice models that generate slow, glassy relaxation via constraints on the dynam icalm oves that are allowed. The slowing down of the dynamics is caused by rarefactions of facilitating regions, also called defects. Importantly, although the dynamics is com plex the therm odynam ics is trivial since the dynam ical rules are such that all con gurations are equally likely. The philosophy of this view point is that therm odynam ic quantities, such as the con gurational entropy, are not the fundam ental underlying cause of the growing time scales in supercooled liquids. It has been argued that the quantitative disagreem ent [45] between therm odynam ic features of KCM s and real experiments is of little dynam ical consequence [46]. In support of this perspective is the fact that KCM s have been rem arkably successful in generating features of dynam ical heterogeneity such as Stokes E instein decoupling, growing dynam ical length scales, and excess tails in the real-space particle displacement function [22, 31, 47, 48].

On the other hand, one may wonder if a deeper viewpoint would allow for an understanding of the kinetic rules that govern particle motion in the supercooled liquids. It is natural to speculate that such aspects might have roots in the therm odynamics of con gurations. Indeed, sim ple local M onte C arlo \dynamics" can reproduce all features of dynam ical heterogeneity seen in N ewtonian molecular dynamics simulations, and are based sim ply on making local moves that are con gurationally allowed [49]. Lattice models based on this concept are called \lattice glass models" (LGM s), and were rst considered by B iroli and M ezard [50]. The rules for such models seem at rst sight like that of KCM s. For example in the simplest versions of such models a particle

Figure 1: Comparison and distinction of a caricature of a kinetically constrained model with a lattice glass model. In the KCM any con guration is allowed, but move may only be made if a particle has at least one missing neighbor before and after the move. In the LGM, the global con guration is de ned such that all particles must have at least one missing neighbor, and all dynamical moves must respect this rule. Note that the local environment around the moving particle is identical in this example, while the global con gurations are distinct. Periodic boundary conditions are assumed for both panels.

may move if it is surrounded by no more than a xed num ber of nearest neighbors before and after the move [51, 52, 53, 54]. Locally this is identical to the type of dynam ical constraint that appears in the KCM s introduced by K ob and Andersen [43]. How ever, this constraint must be m et globally: all particles m ust have no m ore than a xed num ber of nearest neighbors. A s the density of the system increases, fewer and fewer con gurations exist for which these constraints may be satis ed. It is thus the entropy of con gurations that governs the slow ing of dynam ics, intim ately connecting the non-trivial therm odynam ic weight of states accessible to the local dynam ics. Indeed, LGM s can be solved exactly within the Bethe approximation, or on Bethe lattices [50, 53], and have been shown to have a glass transition due to the vanishing of the con gurational entropy. The distinction between the KCM and LGM viewpoint is illustrated in Fig. 1.

LGM s have been studied by a number of groups, but the focus has not generally been on real-space aspects of dynam ical heterogeneity. For example, Coniglio and cow orkers have developed a sim ple LGM that avoids crystallization and displays many features of typical glassform ing materials, including a growing multi-point susceptibility ( $_4$  (t)) [53, 54]. On the other hand, this system appears to behave as a strong glass-form er, with a stretching parameter close to one, and exhibits essentially no Stokes Einstein violation. Our goal in this work is to survey in detail the dynam ical behavior of a new LGM which bears sim ilarity to the original Biroli-M ezard m odel but is not prone to crystallization. The main conclusion that we draw is that LGM s are at least as realistic as KCM s in their description of all com m only studied features of dynam ical heterogeneity. In this regard, sim ple coarse-grained lattice m odels based on the therm odynam ic weight of states are no less viable as fundam ental caricatures of glassy liquids than are KCMs based on weights of trajectories. We conclude our work by highlighting several key ways that LGMs and KCMsmay be distinguished. We reserve the investigation of these com parisons for a future study. Our paper is organized as follows: Sec. II outlines the model. Sec. III discusses both simple averaged dynamics as well as aspects of dynamical heterogeneity. In Sec. IV we conclude with a discussion of the meaning of our notings and the future directions to be pursued.

### II. M O D E L

Here we de ne the LGM that forms the basis of our simulations. The originalm odel of B iroli-M ezard is quite prone to crystallization [50]. This fact makes its use problem atic for the study of glassy behavior since crystallization always intervenes before supercooling becomes signi cant. The crystallization problem persists on a square lattice for all binary mixtures we have studied. However, we have found that certain generalizations of the B iroli-M ezard model with three species of particles are stable against crystallization for the densities that are su ciently high that glassy dynam ics may be clearly observed.

O ur model follows the original rules of the Biroli-M ezard model. Particles exist on a cubic periodic lattice of side L = 15 and each lattice site can contain only zero or one particle. A ll particles, at all times, must satisfy the condition a particle of type  $\mbox{m}$  must have m or fewer neighbors of any type. A neighbor is considered any particle in one of the 2d (d= dimensionality) closest lattice sites along the cubic coordinate axes <sup>1</sup>.

The particular three species model we employ is dened by 10% type 1 particles, 50% type 2 particles, and 40% type 3 particles. We denote this model the \t154" model to indicate its basis in them odynamics and to specify the types and percentages of each particle. The composition of t154 model was determined via trial and error by picking particle types with clashing crystallization motifs thereby fustrating crystallization. C rystallization was monitored by inspection of the angle resolved static structure factor, direct inspection of

<sup>&</sup>lt;sup>1</sup> It should be noted that LGM s of the type described here involve extrem e constraints that must be globally satis ed and are thus not realistic translations of o -lattice particle-based models. Such constraints m ight indeed induce arti cial behavior, especially at higher densities. It would be most interesting to investigate \soft" versions of such models where constraints m ay be locally violated at the cost of an energy penalty. In this regard, such models would be the con gurational analog of K CM s where dynam ical constraints m ay be broken at the cost of an energy penalty. Such models would be the con gurational analog of K CM s where dynam ical constraints m ay be broken at the cost of an energy penalty, see Chandler, D. and J.P.G arrahan, \D y-nam ics on the W ay to Form ing G lass: Bubbles in Space-tim e" arX iv 0908.0418v1; Subm itted to Annual R eviews of Physical Chem istry (2010).

con gurations, and by monitoring bulk therm odynamic quantities.

As discussed in the introduction, there appear to be strong sim ilarities between the rules that govern KCM s such as the Kob-Andersen model and the t154 model [43]. For example both models employ constraints with a maximum number of neighbors, but in the Kob-Andersen model this restriction only applies to the mobile particles, while in the t154 m odel applies to all particles. Our m odel does not require any special dynam ics m ethods. W e em ploy local canonical M onte C arlo \dynam ics" via prim itive translationalm oves [49]. Note that for the t154 m odel the energy can only be zero (no packing violations) or in nite (packing violation or overlap), thus the acceptance criteria reduces to rejection if there is a packing violation and acceptance otherwise. This allows us to implement an event-driven algorithm which accelerates the simulation of lattice dynamics [55].

For therm odynam ic studies we employ grand-canonical M onte Carlo with both translational m oves as well as particle insertion/deletion. Fig. 2 contains a plot of the density of the system as a function of the chemical potential of type 1 particles. M odels which crystallize (such as original binary m odel of B iroli-M ezard) have a sharp jump in this curve at the crystallization point. C learly, this feature is absent in the t154 m odel. For com parison, both curves are displayed  $^2$ .

# III. DYNAM ICAL BEHAVIOR

### A. Simple Bulk Dynamics

In this subsection we describe the behavior of a sim ple 2-point observable, namely the self-interm ediate scattering function [58], de ned as

$$F_{s}(k;t) = \frac{1}{N} \frac{X}{i} e^{ik [r_{i}(t) r_{i}(0)]} :$$
(1)

Figure 2: Crystallization them odynam ics in LGM. Top: The t154 m odel.  $_1$  refers to the chem ical potential of the type 1 particles. The maximum density observed for the  $15^3$  lattice is 5479 (exactly 1849 out of 3375 lattice sites occupied). The three plotted quenching rates vary between a .01 and .05 increase of  $_1$  per 10000 cycles. B ottom : A close up of the equivalent plot for the BM m odel. Note the clear discontinuity upon crystallization. Slower -increase rates produce a sharper discontinuity.

W e m easure  $F_{\rm s}$  (k;t) only for the type-2 particles which are present in the greatest fraction for the three distinct species. Throughout this paper, we report k-vectors using k<sup>0</sup>, where  $k=\frac{2}{L}k^0$ . We have checked that  $F_{\rm s}$  (k;t) is qualitatively sim ilar for the other species of particles. The relaxation of  $F_{\rm s}$  (k;t) of the system at the wavevector  $k^0=5$  (k =  $\frac{2}{3}$ ) for various densities is shown in Fig. 3. The bulk of the decay m ay be t to a stretched exponential function,  $F_{\rm s}$  (k;t) = exp( (t= (k))  $^{(k)}$ ). As is custom ary, the alpha-relaxation time is found by the value  $F_{\rm s}$ () = 1=e and the (k) exponent is determined by a direct t to the term inaldecay. We nd that for densities below approximately = 0:48 the value of saturates at the expected value = 1 characteristic of sim ple non-glassy dynam ics, while for the highest density sim ulated,

= 0:7. This behavior, over a similar range of supercooling, is rem iniscent of the behavior found in atom istic models of glass-forming liquids [59, 60]. In order to better reveal the relaxation behavior,  $F_s$  (t) is also displayed on a log-log vs. log-time scale. In this plot, the slope of the long time grow this related to the exponent :We have found that the values of extracted from the slopes of the long time portion of the log-log vs. log plot indeed

 $<sup>^2</sup>$  A subtle issue arises in the nature of glassy behavior observed in the t154 m odel outlined in this work. LGMs could have a dynam ical percolation-like transition, as in the spiralm odel [56]. This has been indeed found in some LGM s on the Bethe lattice [57] and would slow down the dynam ics for reasons com pletely di erent from the dim inishing of the con gurational entropy. If there is a low-lying crystal phase then one can show that this dynam ical percolation-like transition cannot take place in nite dim ension. A lthough we have not found a crystal phase for the m odel, the existence of such a transition seem s unlikely and irrelevant for our present work. First, it can be shown that blocked structures, if they exist, have to verify much more constraints than in the spiralm odel [56]. Second, we have found that the relaxation time grow th of the persistence functions with increasing density in local canonical M onte C arlo simulations are similar to those under grand-canonical dynam ics, which cannot contain any blocked structure. The union of these two facts render the dynam ical blocking scenario highly unlikely.

coincide with that found by a direct t to a stretched exponential form. At the highest densities a shoulder appears in the short time relaxation. This feature is indicative of a secondary relaxation feature perhaps akin to beta-relaxation in realistic glass-forming liquids. It should be noted, how ever, that the amplitude of this feature is very close to unity. This is quantitatively distinct from the plateau values expected in atom istic o -lattice m odels [59, 60] and even LGM s with m ore complicated lattice degrees of freedom [53, 54], but is sim ilar to that encountered in simple spin m odels such as variants of the R andom O rthogonalM odel [61].

As is typical of fragile glass-form ing system s, the t154 m odel exhibits relaxation times that do not follow the (generalized) Arrhenius form [62]. This behavior is illustrated in Fig. 4. At low densities, plots of log() versus indeed follow a straight line, how ever in the vicinity of

0:5 the plot of versus deviates from this straight line and the functional density dependence of the relaxation time becomes much more precipitous. While we have not attempted to quantitatively characterize this density dependence, it should be noted that the onset of increased sensitivity to changes in density occurs is the same narrow window that marks the noticeable decrease in the values of the stretching exponent .

### B. M otion on the A tom ic Scale

W e begin our discussion of the nature of heterogeneous dynam ical behavior in the t154 LGM by observing the qualitative details of particle m otion under supercooled conditions. This will set the stage for analysis of quantitative m easures of dynam ical heterogeneity in the m odel. For the sake of com parison, we also investigate the analogous behavior in the K ob-A ndersen m odel. This com parison is useful because it suggests how m odels with sim ilar local rules but di erent global rules (rooted in either the purely kinetic or therm odynam ic basis of the particular m odel) m ay give rise to distinct dynam ics at the particle scale.

We start by simply observing the patterns of mobility in real space starting from a set initial condition of the t154 m odel found at a given density after equilibration. A similar analysis has been performed recently by Chaudhuriet al. for the K ob-Andersen m odel, where no equilibration is required since all initial con gurations with a set density of defects are allowed [63]. For a theoretical description of the dynam ics of the K ob-A ndersen model, see [64]. We note that, as expected, the t154 m odel exhibits regions of spatially localized particle activity against a backdrop of transiently im m obilized particles. A rather remarkable feature of the patterns of mobility in this model is that we nd evidence of stringlike m otion, w here a group of particles m oves over a short distance, each taking the place of the previous particle in the string [65, 66]. This motif can be seen mostly on tim escales less than the -relaxation time, but occasion-

Figure 3: Decay of the self-interm ediate scattering function  $F_s(k;t)$  for  $k^0 = 5$  ( $k = \frac{2}{L}k^0$ ). Densities are 3, 4, 45, 48, 50, 51, 52, 53, 535, 5375, 5400, 5425 from fastest relaxation to slow est relaxation. These densities are used in all plots in this paper unless otherwise indicated. Top: P lotted on a linearlog scale. B ottom : Same data as upper panel plotted on a log ( $\log_{10}(F_s(k;t))$ ) vs log(t) scale. Low est density curves are at the top left.

ally string-like motion may be seen to persist on longer timescales. This behavior is demonstrated in Fig. 5.

The behavior of particle motion observed in the Kob-Andersen model is somewhat dierent than that seen in the t154 m odel as described above. As in the t154 model, and as observed by Chaudhuri et al., motion in the Kob-Andersen model shows similar activity regions in the vicinity of defect sites giving rise to heterogeneous motion. However, the boundaries between active and inactive regions at comparable tim escales appear to be m ore distinct in the K ob-Andersen m odel. Furtherm ore, the particle scale motion in the Kob-Andersen is much m ore isotropic, exhibiting much few er cases of directional m obility com pared with the t154 m odel. It would be interesting to compare the two models by quantifying this di erence via the type of directional multi-point correlators devised by Doliwa and Heuer [67]. It is not clear if the di erence between the models is related to the fundamental distinction between LGM s and KCM s or just the speci cs of the particular models considered. In particular, the t154 is a multi-component model, unlike the K ob-Andersen model. The string-like motion on short time scales seem s to occur predom inantly on the rather rough boundaries of slow clusters [68]. This behavior, rem inis-

cent of the picture of dynam ic heterogeneity that put forward by Stillinger [69], m ight be strongly in uenced by compositional heterogeneity. A useful way to address general issues related to how the initial con guration constrains subsequent dynam ics would be a system atic isocon gurational ensemble analysis comparing LGM s and KCM s [70]. This will be the topic of a future publication [71].

In the next few sections, we discuss how some of the most important indicators of dynam ical heterogeneity in supercooled liquids manifest in the t154 model. The quantities that we discuss are the magnitude of violations of the Stokes-E instein relation, exponential tails (indica-

Figure 5: Exam ples of string-like m otion apparent in the t154 m odel. (a) An exam ple of a string with all neighboring particles rem oved. (b) A sim ilar string in the context of other particles. N ote that here the string is truly isolated in space, away from other mobile particles. In these gures, type 1 particles are white, type 2 particles are blue, and type 3 are green. Sites occupied at the initial time but vacated at the nal time are shown in red. These pictures show only the di erences in position of particles between the origin of time and the nal time, not the path the particles took to achieve that displacement. All gures are at a density of 5400, with t times in (a) 251, (b) 199526. The -relaxation time for  $k^0 = 5$  at this density is about 7:8  $10^6$ 

Figure 6: Exam ples cluster shapes in the (a) the t154, m odel, density = :5400 and (b) the K ob-A ndersen m odel, density = :8500. A rrows indicate m otion between initial and nal times. Time separation is 1/10th of the -relaxation time. In the t154 m odel, we see m ore fractal and disconnected clusters, while in the K A m odel, m obile dom ainstend to be sm oother clusters.

tive of hopping transport) in the van H ove function, the existence of a F ickian length scale and the developm ent of a dynam ical length scale quanti ed by the multi-point function  $S_4$  (q;t). Unless otherwise stated, speci c correlation functions and transport coe cients are calculated with respect to type-2 particles.

# C. Stokes-Einstein Violation

In typical uids a mean-eld linear-response relationship asserts that the product of the tracer particle diffusion constant and the uid viscosity divided by the

temperature is a constant [58]. This connection between di usion and dissipation is known as the Stokes-E instein relationship, and empirically is known to hold even at the atom ic scale in liquids over a wide range of densities and tem peratures. In supercooled liquids, the Stokes-Einstein relation generally does not hold [20, 21, 22, 23, 24, 25, 72, 73]. In fact, the product of the diusion constant and the viscosity of a liquid may exceed that expected from the Stokes-Einstein relation by several orders of m agnitude close to the glass transition. There are many theoretical explanations for Stokes-Einstein violations in supercooled liquids, which essentially all invoke dynam ical heterogeneity as the fundam ental factor leading to the breakdown of the simple relationship between di usion and viscosity. It should be noted that sim ilar relationships hold between the di usion constant and the self and collective time constants associated with the decay of density uctuations. In this work we focus on the relaxation time of the selfintermediate scattering function de ned above as our proxy for the uid viscosity.

It is well known that the product D , where is the -relaxation time of the self-interm ediate scattering function shows a strong tem perature/density dependence in both realistic atom ic simulations as well as in the class of KCM s that describe fragile glass-form ing liquids. No direct studies of this quantity have been m ade in LGM s. The LGM of Coniglio and coworkers would appear to show essentially no Stokes-Einstein violations because the di usion constant and the relaxation timem ay both be t to power laws with exponents that have, within num erical accuracy, the sam e m agnitude [53, 54]. This, however is not surprising since many of the features of the model resemble those of a strong glass-forming system, where violations of the Stokes-E instein relation are, at most, weak. The features of the t154 m odel with regard to non-exponential relaxation and the density dependence of the relaxation time indicate that this m odel behaves m ore like a fragile glass form er. Thus, we expect clear violations of the Stokes-E instein relation. Indeed, as shown in Fig. 7, D increases markedly as density is increased. Over the range densities that we can access, the magnitude of the violation is very similar to that seen in the canonical K ob-Andersen Lennard Jones mixture over a comparable range of changes in relaxation time [27]. Interestingly, violations begin to become pronounced at densities sim ilar to where the relaxation tim es and stretching exponents becom e strongly sensitive to increased density. Thus, a consistent onset density is observed as in m ore realistic atom istic system s.

# D. van Hove Function

It is now rather well established that an additional \quasi-universal" feature of dynamical heterogeneity near the glass transition is contained in the shape of the real-space van H ove function [26, 27, 28, 29]. In particu-

Figure 7: V iolation of the Stokes-Einstein relation, D constant, using at  $k^0=5$ . Data has been normalized to D = 1 at the lowest density.

lar it has been argued the tails of the self van H ove function should be approxim ately exponential in form . T hese \fat tails" in ply that the rare particles that do undergo large displacements exist in populations in excess of what would be expected in a purely G aussian displacement distribution. W hile non-G aussian tails should be expected of any distribution for the wings that falloutside of lim its of bounds set by the C entralL in it T heorem, the palpable exponential tails in supercooled liquids in ply large non-G aussian e ects indicative of transport that is strongly e ected by heterogeneous hopping motion.

Here, we demonstrate that such e ects occur in the t154 m odel in a manner sim ilar to that seen both in experiments in colloidal and granular systems as well as in computer simulations of atom ic systems. Fig. 8 shows the self part of the real-space van Hove function,

$$G_{s}(x;t) = h(x j (1/t) r_{i}(0)) j;$$
 (2)

for the type two particles in the t154 m odel. Because we are on a lattice, we restrict our distances along the three coordinate axes & individually in our calculation. We see that for times of the order of the —relaxation time, these tails are clearly visible. For very long or short time scales, the shape of the tail deviates somewhat from the more exponential form exhibited at intermediate times. This behavior is quite similar to that seen in simulations of atom istic systems [27, 28], and is fully consistent with the behavior found in KCM s [25].

### E. Fickian Length

R elated to the existence of excess tails in the van H ove function is the existence of a length scale that characterizes the anom alous transport. M ore speci cally, the exponential tails in the van H ove function are distinguished from the G aussian form of the displacem ent distribution obtained at relatively short distances for xed times. The crossover from F ickian to non-F ickian behavior should be characterized by time scales as well as length scales over which this crossover occurs. A non-F ickian length scale

Figure 8: van H ove function for = 5375 and various times. D istances are measured independently along each coordinate axis. The times plotted, from left to right, are  $10^5$ , 316227 (approx. the -relaxation time), and  $10^6$ . An exponential t to the tail of the t = 316227 case is shown by a dotted line.

Figure 9: k-dependent di usion constant =  $1 = k^{\ell\ell}$  (k). D ensities of 3000 (upper) and 5425 (low er). The higher density curve is multiplied by a scale factor of 2:992  $10^5$  for ease of comparison. A dotted at line is included for reference of behavior expected in the purely Fickian case.

m ay be de ned by exam ining the k-dependent di usion constant D  $(k) = \frac{1}{k^2}$  [30, 31, 32]. The wavevector that characterizes the crossover from the expected di usive behavior to an anom alous regime is inversely related to such a length scale. In Fig. 9 we plot D  $(k^0)$ . C learly, as the density is increased, the length scale separating the Fickian and non-Fickian regimes increases. This behavior is consistent with that found in KCM s and sim – ulations of atom istic glass-form ing liquids. It should be noted that Stokes-Einstein violations, the development of exponential tails in the self van H ove function, and a well-developed Fickian length scale are allmanifestations of related aspects of dynam ically heterogeneous motion in supercooled liquids [27].

### F. 4 and S4 Fluctuation M easures

The Fickian length scale is merely one length scale that arises naturally in systems where dynamics become increasingly heterogeneous. Perhaps more fundamental is the growth of dynamical length scales associated with multi-point correlations of the dynamics. Supercooled liquids do not show simple static correlations that would indicate a growing correlation length. It should be noted that this does not exclude growing static correlations of a m ore complex kind, for example point-to-set correlations [3, 38, 74]. Regardless, cooperativity in dynamics may be measured via rst de ning a local overlap function [5, 17, 34, 35, 36]

$$f_{k}(q;t) = \frac{1}{N} \sum_{i}^{K} e^{iq r_{i}(0)} [\cos(k (r_{i}(t))) F_{s}(k;t)]$$
(3)

where  $r_i(t) = r_i(0)$   $r_i(t)$ .  $f_k(q;t)$  is defined for one conguration, and the average is over all k and q with the magnitudes k and q. Then,  $S_4(q)$  is defined as

where this average is over the most general ensemble of con gurations [36]. The  $_4$  value is de ned as the lim it  $S_4$  (q ! 0).  $_4$  (t) may be calculated strictly at q = 0 from

where the average is over the entire ensemble and all k consistent with the magnitude of k. Note that, as discussed in [36], the value of  $_4$  (t) computed in thism anner is a lower bound for the extrapolation of  $S_4$  (q ! 0;t).

The quantity  $S_4$  (q;t) is a multi-point dynam ical analog of S (q). Just as the low q behavior of S (q) indicates a growing (static) length scale in systems approaching a second order phase transition, scattering from dynam ically heterogeneous regions undergoing cooperative motion will manifest growth in the amplitude of the low q region of  $S_4^{ol}$  (q;t), indicative of the size scale of the dynam ical correlations for systems approaching the glass transition.

The behavior of the quantity  $S_4^{ol}(q;t)$  is shown in Fig. 10. Only type-2 particles have been used in the calculation. As can clearly be seen, for densities above 0.5 which constitutes the onset density of this system, the low q behavior shows a marked upturn as q! 0. The growth of  $S_4^{ol}(q;t)$  as q! 0 as density is increased suggests a growing length scale as supercooling progresses. This non-trivial behavior is what is found in atom istic simulated system s. Future work will be devoted to a precise characterization of the length scale that m ay be extracted from  $S_4^{ol}(q;t)$  in the t154 m odel so that a com parison m ay bem adew ith recent work detailing the behavior of this length in realistic o -lattice system s [39, 75].

# IV. CONCLUSION

In this paper we have presented a new LGM based on the original B iroli-M ezard m odel [50]. V ia the introduction of an additional species of particle, we have dem onstrated that our m odel is stable against crystallization.

Figure 10: Top: Top: Plot of  $S_4$  (q;t) at for densities 0.51, 0.52, 0.53 and 0.54. Bottom : Plot of  $_4$  (t) for the same densities. Peak values correspond to lower bounds for of the value of  $S_4$  (q;t) in the upper panel at q = 0.

This fact allows us to study su ciently high density congurations that manifest features of dynam ical heterogeneity. Unlike som e previous LGMs, ourm odel exhibits the canonical features of a fragile glass-form er. In term s of the gross features of relaxation behavior, our LGM shows behavior sim ilar to the standard K ob-A ndersen Lennard-Jones (KALJ) mixture. In particular, we nd that the degree of violation of the Stokes-Einstein relation and the magnitude of stretching in the decay of the self-interm ediate scattering function track the relaxation times at densities above the onset of supercooling in a manner consistent with that seen in the KALJ system . Features of dynam ical heterogeneity such as exponential tails in the van H ove function, the grow th of a dynam ical length scale as quanti ed by the function  $S_4$  (g;t), Stokes-E instein violations and the emergence of a Fickian length scale all occur in a manner expected from experiments and simulations of fragile glass-form ing liquids.

The sim ilarity between the description of dynam ic heterogeneity found in KCM s and LGM s stands in stark contrast to the underlying foundations of the m odels them selves. As emphasized in the introduction, KCM s are based on a constrained dynam ics for which the num ber of available dynam ical paths leading to relaxation becom es increasingly rare as the density increases and the num ber of defects decrease. In KCM s all real-space con gurations at a xed number of defects (excluding rare blocked con gurations) are equally likely. On the other hand LGM s are based on transitions between realspace con gurations that become increasingly scarce as the density is increased. This is not to say that there is not a facilitated-like dynam ics in LGM s. On the contrary, as we have demonstrated in sec. III, local and som etim es anisotropic dynam ics m ay be generated naturally in LGM s without the explicit introduction of facilitating defects. An important message that emerges from this study is that the phenom enology of dynam ic heterogeneity is not su cient to distinguish pictures or validate models based on transitions between sets of states in con guration space from those based on sets of paths in space-tim e.

How then might these pictures be di erentiated? W hile contrasting competing models that generate seem ingly similar dynamical behavior is a di cult endeavor, severalpossible studies might be useful for this task. Here we outline four avenues that could provide key inform ation that distinguish the purely dynamical picture from one based on transitions therm odynamic states.

a) The mosaic length scale: The Random First Order Theory (RFOT) of Wolynes and cow orkers posits the existence of a static length scale which is de ned by the region over which particles are pinned by the surrounding self-generated amorphous con guration [3, 12, 38]. This length scale also exists in KCM s, but it is decoupled from the relaxation dynamics of the system [76]. Recent atom istic com puter simulations have successfully located the mosaic length scale [38]. It would be quite useful to perform an analysis similar to that devised by Jack and Garrahan for LGM s [76]. Since LGM sare based on the entropy of real-space con gurations, it is expected that here the mosaic length does couple to the glassy dynam ics. Since LGMs are much simpler than atom istic o -lattice models, the direct study of the mosaic length (and point-to-set correlations in general) in LGM sm ight provide key avenues for the testing of the putative coupling between relaxation and such length scales in simulated atom istic system s.

b) Correlations between con gurational entropy and dynam ics: Empirical correlations between the con gurational entropy and the -relaxation time have been noted for many years, and this correlation lies at the heart of several prominent theories. Such correlations are still widely debated, but seem to hold at least crudely in many glass-forming systems [77, 78]. LGMs should be expected to exhibit such correlations, while it is known that KCMs do not exhibit such correlations. Recently Karmakaretal. purported to show that nite-size e ects relaxation time follow precisely the A dam -G ibbs ofthe relation between the con gurational entropy and the relaxation time in the KALJ system [39]. If true, such correlations would be a challenge to KCM s, since it is difcult to envision how the con gurational entropy would

track the -relaxation time for di erent system sizes if it were not a crucial component of relaxation phenom ena. Such correlations, however, are subtle to measure since the A dam -G ibbs relationship is an exponential one and the apparent correlation could depend on the som ew hat indirect com putational method used in [39] to de ne the con gurational entropy. It would be most useful to investigate such e ects in the sim pler LGM s, which might provide a cleaner means of isolating the con gurational entropy. It should be noted that nite size e ects do appear to follow an approxim ate A dam -G ibbs relationship in at least one other lattice model [79]. Such studies might spurm ore detailed investigations in simulated atom istic system s thus allowing for a clear com parison between LGM s, KCM s and more realistic system s.

c) Single-particle and collective predictability ratios: In an important piece of work, Jack and Berthier devised metrics that access the degree to which single particle and collective dynam ics are determ inistically predicted by a set initial con guration over a given time scale [80]. KCM sand LGM sdier in how allowed con gurations are constructed. KCM s have explicit defects, while con gurations in LGM s are determined by global constraints, and thus do not contain explicit defects. Since the very composition of initial conditions di erm arkedly in these m odels, one expects that the metrics de ned by Jack and Berthier would behave di erently in KCM s and LGM s. Thus, it would be very pro table to exam ine the density and tem perature dependence of the single particle and collective predictability ratios in KCMs and LGMs as a possible means of distinguishing between state-based, and dynam ical constraint-based pictures [71].

d) Evolution of the facilitation mechanism approaching the glass transition: Although in both KCM and LGM pictures facilitation plays an important role in the relax-

ation of the system, a peculiar and di erent tem perature and density evolution is expected. In particular, in the KCM picture, facilitation is due to them otion of mobility regions or defects. Dynam ics slows down, and concom itantly dynam ic heterogeneity increases, because these regions become rarer approaching the glass transition. A crucial assumption is that these defects are conserved or at least that non-conservation is a rare event that becom es rarer at lower tem perature/high density. These assumptions in pose in portant constraints on the evolution of the facilitation mechanism. Thus, it would be very interesting to exam ine this issue for exam ple using the cluster analysis developed in [81] to study the relaxation dynam ics of granular system s.

Investigation of these and other studies aimed at distinguishing the underlying pictures that LGM s and KCM s are based on will be the subject of future work.
