In modeling nonequilibrium systems one usually starts with a de nition of the microscopic dynamics, e.g., in terms of transition rates, and then derives the resulting macroscopic behavior. We address the inverse question for a class of steady state systems, namely complex uids under continuous shear ow: how does an externally imposed shear current a ect the microscopic dynamics of the uid? The answer can be form ulated in the form of invariant quantities, exact relations for the transition rates in the nonequilibrium steady state, as discussed in a recent letter [A.Baule and R.M.L.Evans, Phys. Rev. Lett. 101, 240601 (2008)]. Here, we present a more pedagogical account of the invariant quantities and the theory underlying them, known as the nonequilibrium counterpart to detailed balance (NCDB).Furtherm ore, we investigate the relationship between the transition rates and the shear current in the steady state. We show that a uctuation relation of the Gallavotti-C ohen type holds for system s satisfying NCDB.

I. IN TRODUCTION

O ne of the greatest trium phs of nineteenth century physics was the developm ent of equilibrium statistical mechanics a theory that exactly determ ines the probability of encountering any given arrangement of (the positions and momenta of) a large collection of interacting bodies (atom s, molecules, etc.), even though their equations of motion are intractable. From that probabilistic description, macroscopic properties en masse can be found, such as a uid's pressure, density, anisotropy, etc. The theory assumes the existence of thermodynamic equilibrium, an asymptotic long-time limit solution to the entire dynamics in which the statistical properties are unchanging and independent of initial conditions. Conversely, since the birth of statistical mechanics an exact prediction of the statistics of the particles' motion has been unobtainable in the presence of ow, instead requiring various approximations or simplic cations, which are the bread and butter of much present-day research into nonequilibrium phenomena.

There is a certain class of highly nonequilibrium states of matter that possesses time-invariant statistics, and therefore might be approachable by exact statistical analysis without simplified modeling or near-equilibrium approximations. Such states arise when continuous shear ow is applied to complex uids | materials composed of classical particles much larger than atoms. Under ow the structure of complex uids can be radically re-ordered, even to the point of undergoing shear-induced phase transitions.

For instance, a solution of amphiphiles in the worm-like micelle phase can exhibit a negative gradient in the characteristic ow curve if driven at high shear rates. This means that for a range of shear rates the viscosity decreases under shear. If the uid is continuously sheared in this regime, it becomes mechanically unstable and separates into bands' of high and low shear rate [1]. Also, at higher concentration the solution of amphiphiles can undergo a phase transition from a lamellar phase into complex densely packed onion-like structures [2]. Both phenomena are structural phase transitions that are controlled by shear rate in addition to the usual parameters (temperature, pressure, concentration) and are examples in which the uid undergoes drastic microscopic re-con guration in response to the imposed (macroscopic) driving at the boundaries.

A uid in a sheared steady state is described by the same H am iltonian as at equilibrium, since no external eld is applied to drive the system; only the boundary conditions are di erent. N evertheless, since they contain non-zero uxes, such states fall outside the jurisdiction of equilibrium statistical mechanics, despite exhibiting all the vast variety of reproducible behaviors, structures, and transitions seen in equilibrium therm odynamic system s.

A statistical description of complex uids under continuous shear ow, starting from rst principles, is provided by a theory of nonequilibrium transition rates, known as the nonequilibrium counterpart to detailed balance (NCDB) [3, 4, 5]. This theory addresses the following question: given an externally imposed m acroscopic shear current at the boundaries of the uid, what is the e ect on the microscopic dynamics (the transition rates) in the bulk of the uid? In the absence of any driving, that is, at therm all equilibrium, the microscopic transition rates are constrained to satisfy the principle of detailed balance, namely that the ratio of forward to reverse transition rates between any

pair of m icrostates m ust equal the Boltzm ann factor of their energy di erence:

$$\frac{!_{ij}}{!_{ji}} = e^{(E_j E_i)};$$
(1)

where !_{ij} denotes the transition rate from microstate i to j and the inverse temperature. Detailed balance is a consequence of the in uence of the uid's therm al surroundings: it is immersed in a larger volume of uid at a certain temperature which acts as an equilibrium heat reservoir. The stochastic in uence of this heat reservoir puts constraints on the allowed microscopic transitions in the form of Eq. (1).

If shear is in posed at the boundaries of the heat reservoir detailed balance no longer holds. How ever, a uid region within the bulk continues to receive stochastic forces from the reservoir, which is now itself under ow. In the steady state this nonequilibrium heat reservoir in poses constraints on the transition rates according to NCDB, which can be expressed in the form of a one-to-one mapping between the transition rates at equilibrium and those in the sheared steady state [4]

$$(j) = !_{jj} e^{-x_{ji} + -q_{ji}(j)}$$
 (2)

Here, $_{ij}$ () denotes a transition rate in the sheared steady state, param etrized by , a Lagrange multiplier characterizing the driving strength of the reservoir. Under the in uence of shear forces applied at the boundaries of the whole ensemble, the rates are thus enhanced or attenuated with respect to equilibrium. The factor e $^{x_{ji}}$ exceeds unity if the transition i ! j involves a conform ational change that increments the shear strain by a positive amount x_{ij} . This factor simply boosts every transition in the forward direction irrespective of the state space structure. By itself, it would represent a simple mean - eld expression for the driven transition rates. Important non-mean - eld information about the global properties of the state space is contained in the quantities q_{ji} (), whose precise de nition is given further below, in Sec. III.

Recently, it has been demonstrated that the constraints of NCDB can be cast into the form of invariant quantities that remain unchanged by the driving [6] and apply to any pair of microstates in the following way: (i) The product of forward and reverse transition rates remains invariant under the driving, i.e., is the same in the equilibrium and in the sheared steady state: $|_{ij}|_{ji} = |_{ij}|_{ji} p$ where $|_{ij}$ denotes the transition rate in the sheared state). (ii) The di erence of total exit rates remains invariant: $|_{k}(|_{ik} |_{jk}) = |_{k}(|_{ik} |_{jk})$. These invariant quantities represent exact relations for the transition rates in the sheared steady state and represent a prediction of NCDB that can be tested in an experiment. Furthermore, using a graph representation of NCDB we have devised a system atic method to calculate the driven transition rates from a set of algebraic equations for arbitrary con gurations of the system state space, thus greatly enhancing the applicability of the theory.

In this article we present a more pedagogical account of these recent results and the theory of NCDB underlying them. In particular, we provide a detailed derivation of the various representations of NCDB from a nonequilbrium sheared ensemble. Furthermore, we investigate the properties of the shear current in systems satisfying NCDB and show that the shear current exhibited by an individual system trajectory satis es a uctuation relation of the G allavotti-C ohen type.

The remainder of this article is organized as follows. The nonequilibrium ensemble on which the derivation of NCDB relies is introduced in Sec. II. In Sec. III we present a detailed review of the di erent representations of NCDB as previously discussed in Refs. [3, 4, 5]. A graph representation is presented in Sec. IV providing an intuitive way to discuss M aster equation system s in discrete state spaces. The invariant quantities are derived in Sec. V, where we also form ulate the system atic calculation m ethod for the transition rates in the sheared steady state. The relationship between the shear current and the transition rates is discussed in Sec. VI. Our rather form al results are elucidated in two sim ple hopping m odels which allow for an explicit calculation of the driven transition rates and other relevant quantities of the NCDB form alism (Secs.VII and VIII). Even in these sim ple m odels it is evident that the predictive power of NCDB goes well beyond sim ple m ean- eld theories.

II. NONEQUILIBRIUM ENSEMBLE AND PATH ENTROPY

In order to describe nonequilibrium states of complex systems subject to noise, one usually relies on a probabilistic description in terms of transition rates. In such an approach the main quantity of interest is the set of probability distributions $fp_i(t)g$ over states i = 1; ...; n, which express the probability to nd the system in state i at time t. The nature of these states depends on the level of description; for reasons that will become clear below they are considered to be classical microstates in the following. The dynamical evolution of the system is then governed by the M aster equation, a balance equation for the probability:

$$\frac{d}{dt}p_{i}(t) = \begin{cases} X \\ [!_{ji}p_{j}(t) & !_{ij}p_{i}(t)]: \\ f_{jg} \end{cases}$$
(3)

The sum is here taken over the set of states f jg connected with i, where $!_{ij}$ denotes the rate of transition from state i to state j. The di erence $!_{ji}p_j(t) = !_{ij}p_i(t)$ is interpreted as the m icroscopic probability current between states i and j, and therefore Eq. (3) states the conservation of probability. For a probabilistic interpretation of the $p_i(t)$ we require the conditions 0 $p_i(t) = 1$ and $\prod_{i=1}^{n} p_i(t) = 1$.

A steady state is characterized by stationarity of the statistics, in plying that all single-time distributions are time independent. If we set $dp_i(t)=dt = 0$ in Eq. (3) we not that the condition for a steady state is given by the balance of total in- and outgoing ow for every state i

X
[!
$$_{ji}p_{j}$$
 ! $_{ij}p_{i}$] = 0: (4)
fjg

Nonequilibrium steady states are characterized by a non-zero net ow of particles, heat, etc., running through the system. By contrast, in equilibrium this ow vanishes, a fact which is manifest as the strong condition of detailed balance: the net probability current between any two con gurations of the system is zero at equilibrium. This is expressed as

$$!_{ji}p_{j} = !_{ij}p_{i};$$
 (5)

for all i, j so that Eq. (4) is trivially satis ed.

The condition of detailed balance is a physical property of transition rates in equilibrium system s and can be derived from Liouville's equation for closed, isolated, physical system s [7]. Physical' refers to the existence of an underlying H am iltonian such that the dynam ics is determ inistic and m icroscopically reversible. Isolation' in plies that energy is a conserved quantity, i.e., a constant of motion. The trajectory in phase-space is then restricted to a shell of constant energy and no transitions between shells of di erent energy are possible. For a canonical system, these considerations apply in the same way to the combination system plus reservoir. The probability distribution of the system is then known to satisfy Boltzm ann's law $p_i^{eq} / e^{-E_{-1}}$. In this context detailed balance can be interpreted as a statem ent of four fundam ental properties characterizing system and heat reservoir: (i) ergodicity, (ii) m icroscopic reversibility, (iii) tim e-translation invariance of statistical properties, and (iv) conservation of energy. As a result of these properties there are m =2 constraints acting on m transition rates of the system, expressed by Eq. (1).

Having specied an equilibrium state in this way, we may consider a particular class of driven steady state systems, namely uids under continuous shear. Let us consider a uid region far from the boundaries as our system'. The heat reservoir consists of the uid volum e surrounding this region. If we assume that any correlation lengths are negligibly small compared with the uid volum e (a condition that may be unenforcable for turbulent ow s), then this reservoir is only characterized by its macroscopic observables, which are in this case mean energy and mean shear rate. The stochastic in uence on the system is here not that of an equilibrium reservoir, but of a reservoir which is itself in a nonequilibrium condition, under shear. In this case the properties (i) (iii) remain valid. Ergodicity is generally di cult to prove rigorously even for the simplest system s at equilibrium, but it is assumed on empirical grounds, since experimental observations are repeatable, irrespective of precise initial conditions. Since the shear acts only at the boundaries of the reservoir, the dynamics of individual molecules is still governed by the same equations ofm otion as in equilibrium and thus microscopic reversibility holds. Property (iii) remains true by de nition while (iv) continues to govern all interactions between the system and reservoir, or between di erent systems in an ensemble (Fig. 1). We therefore nd that the four conditions for detailed balance apply to a sheared uid, amended by an additional conserved quantity, the total shear. These amended conditions give rise to a nonequilibrium counterpart to detailed balance, that can be derived from familiar statistical considerations in a straightforw ard way.

We continue, below, to derive the exact consequences of the above conditions, in terms of the resulting m icroscopic transition rates. That derivation is performed without approximation, and therefore applies arbitrarily far from equilibrium. However, as with any investigation, the degree to which a real experimental system is approximated by the idealized assumptions depends on the uid in question. For instance, the applicability of any exact equilibrium calculation depends on how well a real system has been equilibrated and how well its symmetries are represented by the theory. For the driven cases considered here, the question of how close the experiment comes to a true steady state is even less straightforward. In an experiment on an isolated system by the driving force, tending to heat the uid. Nevertheless, the above assumptions can be experimentally realized to arbitrarily high accuracy. Let us elucidate the types of uid to which the above assumptions apply. In many complex uids a solvent acts as a therm ostat for the system of interest, as it possesses many more degrees of freedom than the mesoscopic particles of interest, so the temperature remains relatively constant. In the lim it of large ratio of solvent to com plex degrees of freedom, the steady state condition becomes exactly realized. Since the relaxation time of the solvent is usually much smaller than that of the com plex uid, the solvent remains close to equilibrium even when the complex uid is driven to a highly nonequilibrium state. In practice, experiments on complex uids are able to obtain reproducible bulk

FIG. 1: A sketch of a large volum e of sheared uid: the uid is hypothetically divided into a large num ber of subvolum es, the System s'. The height of each subvolum e is much larger than the correlation length L_{corr} such that interactions with the surroundings, i.e., the heat reservoir', only take place at the boundaries. The time evolution of a single system accumulates a certain am ount of shear which is di erent for each system (indicated by the varying slopes).

steady-state behavior, indicating that the system is insensitive to spatial or tem poral tem perature gradients. These form the class of systems for which NCDB is expected to hold, and that reproducible behavior is the subject of our exact theory.

W ith these prerequisites in place, we can begin the derivation of NCDB from a nonequilibrium ensemble. In agine a very large volume of uid divided into a large number N of sub-volumes or 'systems'. These sub-volumes are still large enough that correlated regions within them are negligibly small (see Fig. 1). The crucial idea in our derivation is to in agine this volume to be so large that it constitutes an ensemble in which the sub-volumes can be considered as representations of all possible realizations of our system under consideration. A certain constant shear rate J is applied to the volume by moving top and bottom boundaries (while perpendicular dimensions are in nite or periodic). Each system i then follows a particular trajectory in phase-space over a time period accumulating a certain am ount of shear. In order to ensure steady state properties we will eventually take ! 1, so that any initial transient behavior has decayed.

W ith the nonequilibrium ensemble constructed in this way, the probability distribution of trajectories can be found by G ibbs's familiar method for deriving the probability distribution of a large collection of countable objects, which is exact when no correlations exist between those objects, as is the case here. The probability that a system follows phase-space trajectory is p() = n = N, where n is the number of times is realized in the ensemble. Here, we take phase space and time to be discretized to make trajectories countable. Eventually the discrete intervals will vanish in the continuum limit and probabilities p() will be replaced by distributions p[]D.

The statistical weight of the ensemble W $_{\rm N}$ is the number of distinct ways we can arrange the systems in the ensemble, which is given by the usual combinatorial form ula

$$W_{N} = \frac{N!}{n!};$$
(6)

since system s follow ing the same trajectory are indistinguishable. The most likely distribution of trajectories (the one adopted by the overwhelm ing majority of such ensembles) is the one with maximal statistical weight and can be found by maximizing the corresponding ensemble entropy $S_E = \ln W_N$. Applying Stirling's formula $\ln N$! N $\ln N$ N for large N yields

$$S_{E} = N p() \ln p():$$
 (7)

Thus, the ensemble entropy per system is the path entropy

$$S = p() \ln p():$$
 (8)

This path entropy is familiar from approaches to nonequilibrium statistical mechanics in the spirit of Jaynes's method of maximum entropy inference (M axEnt). In fact, the rst derivation of NCDB was based on this information theoretic approach [3]. In the present fram ework of the nonequilibrium ensemble (cf. [5]) we are able to avoid certain controversial aspects of M axEnt. Instead of a subjective interpretation of probabilities as representations of our state of know ledge, we have de ned probabilities in term s of countable physical realizations. Furtherm ore, we have a clear idea of the prior set of trajectories that we reweight in the maxim ization procedure; it is the set of all physical trajectories with the same weights that they have at equilibrium. All unphysical ones are given zero weight a priori.

The distribution p() is found by maximizing S subject to the constraint

$$X$$
 p() () = J (9)

due to conservation of shear. Here, () is the total shear acquired by an individual system following path . With J = 0, the maximization just returns p^{eq} (), the equilibrium distribution of trajectories de ned as the prior for the calculation. In the driven steady state we obtain instead the result

$$p^{dr}() / p^{eq}() e^{()};$$
 (10)

where is the Lagrange multiplier associated with the shear constraint Eq. (9).

This form of the nonequilibrium distribution is a direct consequence of the way in which the system is driven, namely by uid at the boundaries such that the equations of motion of the driven system are the same as in equilibrium. In fact, the measure de ned on trajectory space for the driven ensemble is the same as in equilibrium, the trajectories are only reweighted under the additional shear constraint giving rise to the factor $e^{(-)}$.

Now that we are in possession of the statistical weight of nonequilibrium trajectories, we can consider the implications of Eq. (10) on the individual transition rates, which give rise to all the complexity of the system 's evolution. It is with this change of perspective that a useful and testable result can be obtained.

III. RULES FOR TRANSITION RATES

From now on we denote a transition rate between states i and j in the driven steady state with $_{ij}$ in order to distinguish it from the corresponding equilibrium transition rate $!_{ij}$ that satis es equilibrium detailed balance. The transition rate is de ned as the probability of making the transition i! j per unit time t, where it is understood that t is so small that only one transition can occur. This means that transitions from i to j via a third state are neglected. In probability theory the de nition of the transition probability P (jji) is usually in terms of a joint probability P (j;i), i.e. P (jji) = P (i). If the distribution of trajectories p() is known, these probabilities of individual microstates are determined by counting those trajectories containing state i at time t and state j at time t + t. A transition rate is then de ned as $_{ij} = P(jji) = t$ in the limit of vanishing t, where

$$P(jji) = \frac{P_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}{\frac{p_{j(i;j)2} p()}}}$$
(11)

The sum $\int_{j(i;j)}$ denotes a sum m ation over all trajectories containing the transition i ! j. U sing Eq. (10) a transition rate in the driven steady state can be written as

$$_{ij} = \frac{P(jji)}{t} = \frac{p_{j(ij)2}}{t} \frac{p^{eq}()e^{-()}}{p^{eq}()e^{-()}};$$
(12)

Inserting unity as the delta-function (())d yields

$$_{ij} = \frac{{}^{R_1} e^{p}}{t_1 e^{p}} \frac{p^{j(ij)2}}{ji2} (()) p^{eq} () d}{t_1 e^{ji2}}$$
(13)

We notice that the average over the delta-function (()) is related to the conditional probability distribution $p^{eq}(j_i;j)$:

$$p^{eq}(j;j) = \frac{p^{peq}(j)p^{eq}(j)}{p^{j(2)}p^{eq}(j)};$$
(14)

The distribution $p^{eq}(ji;j)$ contains the probability that the system at equilibrium accumulates a total amount of shear over a time period due to equilibrium uctuations, given that it made a transition from ito j. Similarly, the denominator in Eq. (12) leads to an expression containing $p^{eq}(ji)$. The subscript denotes the implicit dependence of these distributions on the duration of the trajectory . The driven rate now reads

$$_{ij} = \lim_{l \to 1} \frac{\frac{p^{eq}(j)}{p^{eq}(j)} \frac{p^{eq}(j)}{p^{eq}(j)} \frac{p^{eq}(j)}{p^{eq}(j)} \frac{p^{eq}(j)}{p^{eq}(j)} e^{-d}}{t^{eq}(j)}$$
(15)

Here, the ! 1 limit guarantees that the system has attained its stationary state. A fler factoring out the equilibrium rate

$$!_{ij} = \frac{p^{j(i;j)2} p^{eq}()}{t_{ji2} p^{eq}()};$$
(16)

we can write the driven transition rate as

$$_{ij} = !_{ij} \lim_{! = 1} \frac{R_1^{i} p^{eq}(j;j) e d}{R_1^{i} p^{eq}(j;j) e d};$$
(17)

We refer to this result as the canonical- ux representation of NCDB for a transition rate i! j in the driven ensemble [4]. Note that the driven rate is a function of the Lagrange multiplier, the ux conjugate parameter. This parameter is the analogue of the inverse temperature which characterizes the heat transfer in canonical equilibrium systems. O ne notices that the driven transition rate is proportional to the equilibrium rate, enhanced or attenuated by a factor which is determined by the equilibrium statistics. If an equilibrium transition from i to j is likely to lead on to a certain amount of shear in the future, then this transition rates, therefore Eq. (17) can be considered as a nonequilibrium counterpart to detailed balance. The important conclusion is that for the class of driven steady states obeying the principles (i) | (iv) we obtain the microscopic dynamics of the nonequilibrium steady state from the corresponding equilibrium ensemble.

Depending on the physical system, many set of equilibrium (prior) rates !_{ij} are possible, from exact and deterministic ones obtained from a Ham iltonian formulation to stochastic ones. Transitions which have zero probability in equilibrium (i.e., unphysical ones) are forbidden in the driven system as well.

A. A lternative representations

In the above derivation of NCDB the nonequilibrium ensemble was constrained by a xed mean shear J (Eq. (9)). In analogy to equilibrium ensembles we can therefore consider Eq. (17) as a canonical representation of the driven ensemble: shear is a quantity which can be exchanged between the system and the nonequilibrium reservoir with a xed average. Indeed both numerator and denominator in the enhancement factor take the form of an average where the conditional probability $p^{eq}(j;j)$ (respectively $p^{eq}(j)$) is weighted with the shear distribution e over all possible shear . A microcanonical- ux ensemble allows only for a xed total shear $_0$. One can intuitively argue that in this ensemble the ux distribution has to be substituted by a Dirac delta function: e ! ($_0$) (for an alternative derivation see [4]). W ith this substitution Eq. (17) reads

$$_{ij} = !_{ij} \lim_{! \ 1} \frac{p^{eq} (_{0} ji; j)}{p^{eq} (_{0} ji)}:$$
(18)

This representation proves favorable when the conditional probability distributions of $_0$ are explicitly known. Similar to the ensembles in equilibrium statistical mechanics, microcanonical and canonical ux ensemble yield the same result in the therm odynamic limit, which is here the limit of large N and .

From Eq. (17) it is also possible to derive a -independent representation of the driven transition rates [4]. We reproduce the derivation here in full as it is used in the following investigation of NCDB in the context of discrete state spaces. Let us de ne the quantity x_{ji} which denotes the shear contribution of the transition i! j in time t. U sing x_{ji} we can write the conditional probability distribution $p^{eq}(ji;j)$ as

$$p^{eq}(ji;j) = p^{eq}_{t}(x_{ji};j);$$
 (19)

i.e., p^{eq} (j; j) is given by the probability distribution of accumulating the remaining shear x_{ji} in the remaining time t, starting from state j. Dening the function m_i (;) as

$$m_{i}(;)$$
 ln $p^{eq}(ji) e d;$ (20)

allows us to rewrite Eq. (17) in the form

$$\ln \frac{ij}{!_{ij}} = \lim_{! = 1}^{2} \ln \frac{p^{eq}}{t} (x_{ji}ji) e d m_i(;) :$$
(21)

A change of the integration variable then leads to

$$\ln \frac{ij}{!_{ij}} = x_{ji} + \lim_{! = 1} [m_j(; t) m_i(;)]$$
(22)

$$= x_{ji} + \lim_{i=1} [m_{j}(;) m_{i}(;)] \quad (; t);$$
(23)

where

 $(; t) \lim_{j \to 1} [m_j(;) m_j(; t)]:$ (24)

An important property of the function is its state-independence, which follows from Eq. (23) upon changing ! + t. To rst order in two then have

$$(; t) = \lim_{j = 1}^{\infty} \frac{0}{0} m_j(;) t;$$
 (25)

We now introduce two important -independent quantities [4]. Firstly, we identify

$$q_{ji} = q_j()$$
 $q() = \lim_{i \to 1} [m_j(;) m_i(;)];$ (26)

and secondly, the state-independent rate of change of m_i (;) in the long-time limit is denoted as

$$Q() = \lim_{i \to 1} \frac{\partial}{\partial e} m_{i}(;):$$
 (27)

W e therefore see that Eq. (23) gives rise to

$$ij() = !_{ij} e^{x_{ji} + q_{ji}() Q() t};$$
(28)

which is a -independent representation of NCDB. Equation (28) reduces to Eq. (2) in the continuous time limit, t! 0.

If we compare Eq. (28) with Eq. (17) we realize that the ratio of equilibrium G reen's functions is here translated into three distinct factors. The factor x_{ji} measures the direct ux contribution of a transition and is large if either the ux carried by the transition i! j is large (x_{ji} 1) or the system is strongly driven (1). By itself this factor would simply boost every transition in the ux direction irrespective of the state space structure. The important extension to such mean-eld ideas is expressed in the factor $q_{ji}()$, where q_{ji} is form ally de ned as (cf. Eqs. (20) and (26))

$$q_{ji}() \lim_{l \to 1} \ln \frac{R_1}{R_1} p^{eq}(jj) e d \\ \frac{R_1}{p^{eq}(jj)} e d \\ \frac{R_1}{p^{eq}(jj)} e d$$
(29)

This quantity measures the increase (or decrease) in probability that the system will go on to exhibit the imposed shear if it performs the transition i! j. Thus the rate of a transition not only depends on the immediate ux contribution, but also on the prospect for future ux.

Form ally, the function Q () can be de ned as the scaled cum ulant generating function of the shear current J = =

Q()
$$\lim_{j \to 1} \frac{1}{2} \ln p^{eq} (J j j) e^{-J} dJ;$$
 (30)

FIG. 2: Example diagram of a basic graph for a ve-state system. The dotted line denotes an exterior edge connecting the same type of states in di erent periods. Here states 0 and 5, as well as states 1 and 6 are of the same type.

which agrees with Eqs. (20) and (27) upon transforming from the (extensive) shear to the (intensive) shear current J. The distribution p^{eq} (J ji) contains the probability to observe a shear current J over time in the equilibrium system, given it was initially in state i. Eq. (30) expresses the fact that and J are conjugate quantities in the sense of large deviation theory and implies that Q () is the Legendre transform of the rate function of J [4, 8]. Consequently, Q () and J are related via

$$\frac{\mathrm{d}}{\mathrm{d}}Q() = \mathrm{J}; \tag{31}$$

In the following we refer to the function Q () as 'ux potential' due to the analogy with the usual them odynamic potentials.

In order to fully determ ine the transition rates of a system in the driven steady state according to Eq. (28) one therefore has to know the set of equilibrium transition rates, their individual shear contribution x_{ji} as well as the ux potential Q and the functions q_{ji} . At equilibrium the $!_{ij}$ are usually strongly constrained by detailed balance and symmetry considerations. The x_{ji} are local and constant properties of the states. The crucial and non-trivial task is to not the potential Q and the set of q_{ji} 's, which depend on the global structure of the state space.

IV. GRAPH REPRESENTATION FOR NCDB

M aster equation system s can be discussed intuitively with the help of a graph representation, in which vertices are assigned to the di erent states i of the system and edges to the possible transitions [9]. If a transition is physically allowed to take place, i.e., $!_{ij} > 0$, then equilibrium detailed balance dem ands that the reverse transition $!_{ji}$ is also non-zero. Only connected graphs are considered in order to satisfy the requirement of ergodicity. For the following discussion of driven steady states further assumptions are necessary. In order to guarantee that the system can exhibit a constant m acroscopic steady state shear current J, it is assumed that the state space has a periodic structure along a direction x, which is associated with the am ount of shear accumulated. This assumption is made without loss of generality since one period may be arbitrarily large. A transition i ! j contributes the shear increment x $_{ji}$ x_j x_i. The periodic structure in plies that, for a given period n, the j + nth vertex is of the same type as the jth with x-position shifted by a xed am ount. Likewise, if vertices i and j with 1 i; j n are connected by an edge so are vertices n + i and n + j.

We de ne the basic graph as the graph corresponding to the non-periodic connected set of n vertices. Its set of edges will be denoted interior edges in order to distinguish them from exterior edges connecting vertices of the basic graph with vertices of the next or preceding period. M ore precisely, an edge is exterior if it connects a vertex i of the basic graph with a vertex l where l n + 1 or l 0.0 by by exterior edges always occur in pairs connecting the same states in di erent periods. U sing this convention one has to bear in m ind that two states of the same type can be connected by m ore than one edge, namely by one interior edge and multiple exterior edges (connecting, e.g., to the previous or next period, pr both). See Fig. (2) for a depiction of such a basic graph. The total number of transition rates in the system is $\prod_{i=1}^{n} d_i$, where d_i is the degree (or connectivity) of the ith vertex of the sim ple graph including exterior edges. The m inim al number of transition rates in an n-state driven system is 2n which corresponds to a graph in the form of a simple connected path. For this class of state spaces the problem of nding the driven transition rates has a particularly straightforw and solution (see Sec.V B below).

FIG. 3: Example diagram of a three state system mapping onto a periodic graph structure.

This notion of a periodic graph structure is basically a convenient way to visualize the current in the state space. System s with a limited number of states would usually be depicted as a basic graph alone without any exterior edges. Yet, if the system exhibits a nonequilibrium steady state with some kind of current, the periodicity automatically arises as a consequence of the ux carrying transitions. Consider for example the three state system in Fig. 3. The only way the system can be in a driven steady state is by featuring a rotational current which is measured by the windings performed in time . This then naturally maps onto a periodic network with a simple connected path as basic graph. The loop 1! 2! 3! 1 in the original depiction then becomes an external loop 1! 2! 3! 4, where state 4 is of the same type as 1 yet distinct due to the accumulated integrated current of one period.

At this point it is appropriate to brie y discuss the distinction between external and internal bops, which is connected to Kolm ogorov's criterion, an equivalent statement of equilibrium detailed balance [10, 11]. In order to elucidate this we focus on transition rates in continuous time with t ! 0 such that Eq. (28) assumes the simpler form of Eq. (2).

If we consider a closed internal loop in the basic graph, i.e., a closed path leading back to the identical state such as, e.g., the loop 2 ! 3 ! 4 ! 2 in Fig. (2), we see that the product of transition rates following this loop in a given direction of rotation is the same as in equilibrium

$$_{23} \ _{34} \ _{42} = \ ! \ _{23} \ ! \ _{34} \ ! \ _{42} : \tag{32}$$

This is a simple consequence of the fact that both x_{ji} and q_{ji} are given as di erences of state properties, in plying that along a closed internal loop the product of exponential factors vanishes. Therefore, for any internal closed loop in the basic graph we have

$$_{12} \quad n \quad 1; n \quad n1 = !_{12} \quad n \quad 1; n! :$$
(33)

Since the equilibrium rates satisfy detailed balance, the ratio of forw and and backward transitions is given as $!_{12} = !_{21} = e^{-(E_2 - E_1)}$. It is then easy to see that the following equality holds

$$\frac{!_{12}}{!_{21}} \frac{n_{1}!_{n}!_{n1}!_{n1}}{n_{1}!_{1}!_{1n}} = 1:$$
(34)

D ue to Eq. (33) the same relation is true for the product of driven transition rates

$$12 n 1;n n1 = 21 n;n 1 1n;$$
(35)

K olm ogorov's criterion now states that equilibrium detailed balance holds if and only if Eq. (35) is satis ed for every closed path in state space. NCDB according to Eq. (2) satis es this criterion for every internal loop. However, this does not lead to a contradiction, since K olm ogorovs criterion is violated for external loops in state space. For an external loop we have instead of Eq. (35)

$$\frac{12 \qquad n \ 1m \ n^{10}}{21 \qquad nm \ 1 \ 1^{0}n} = e^{2 \qquad x_{1} o_{1}};$$
(36)

where 1^0 denotes the state of type 1 in the next period and x $_{1^01}$ is the accumulated shear or Yength' of a period. The conclusion of this discussion is that the graph representation for NCDB in terms of a periodic graph structure is consistent if the system does exhibit a steady state current. In this case NCDB leads to a violation of K olm ogorov's criterion as expected.

$$S_{kl} = \frac{!_{kl}!_{l2} - 1_{kl}!_{nl}!_{nl}}{!_{lk}!_{2l} - 1_{kl}!_{ln}!_{lk}}$$
(37)

is independent of the path between k and l. Out of equilibrium this path-independence is not generally expected. Instead one can consider $\ln S_{kl}$ as an action functional associated with a particular path and derive a uctuation relation for the entropy production [13].

V. TOTAL EXIT RATE RELATION

In the rem ainder of this chapter we focus on NCDB in the context of continuous time M arkov chains, where NCDB is expressed in the form of Eq. (2). In this case it is possible to derive a fundam ental relationship between the ux potentialQ () and the driven transition rates which is a central result of this article and leads to a variety of important conclusions for NCDB.

Consider an individual state i connected to d_i other states. The system in state i spends a random time until it makes a transition to one of the connected states. For a continuous time M arkov chain this waiting time has the exponential distribution [11]:

$$h_{i}(t) = i e^{-it};$$
(38)

where the total exit rate is defined as $_{i}$ $_{fjg}$! $_{ij}$. The probability that the particle jumps to site j is then $P_{ij} = !_{ij} = i$. Our quantities of interest are the conditional probabilities or G reen's functions p^{eq} (ji) which, if known, would fully specify the driven transition rates via Eqs. (29) and (2). The G reen's function for state i can be determined by the following considerations. From state i the system can only perform a transition of that state j within the network, from where its further displacement is determined by the G reen's function of that state j. Taking into account the waiting time in state i and the probability P_{ij} to perform the jump to state j, p^{eq} (ji) is therefore related to the d_i G reen's functions of the neighbouring sites according to

$$p^{eq}(ji) = dth_{i}(t) P_{ij}p_{t}^{eq}(x_{ji}jj) + i(j(j));$$
(39)

where $_{i}()d$ denotes the probability that no jump has occurred¹ out of state i up to time : $_{i}() = 1$ $_{0}^{i}h_{i}(t)dt = e^{-i}$. In the next step we introduce the quantities $m_{i}(;)$, Eq. (20), which are ultimately related to the functions $q_{i}()$ in the long time limit via Eq. (26). Multiplying Eq. (39) by e and summing over all possible shear from state i yields, after a shift in the summation variable ,

$$e^{m_{i}(i)} = \int_{0}^{\Delta} dth_{i}(t) P_{ij}e^{m_{j}(i)+t} x_{ji} + e^{i}:$$
(40)

In the next step we can substitute P_{ij} , and $h_i(t)$ (Eq. (38)). Rearranging terms then yields

$$e^{m_{i}(;)+i} = \int_{0}^{Z} dt e^{it} |_{ij} e^{m_{j}(;t)+i} |_{x_{ji}} + 1:$$
(41)

The integral can be removed by taking a derivative with respect to on both sides. This leads to

$$\frac{\varrho}{\varrho} m_{i}(;) + i e^{m_{i}(;) + i} = e^{i} !_{ij} e^{m_{j}(;) + x_{ji}}:$$
(42)

Or, after further rearrangem ent,

$$\frac{\varrho}{\varrho} m_{i}(;) + i = \begin{cases} X \\ ij e^{m_{j}(;) m_{i}(;) + x_{ji}} \end{cases}$$
(43)

¹ The contribution of _i() () to the G reen's function p^{eq} (ji) was erroneously neglected in the derivation presented in Ref. [6]. Nevertheless, the nalresult Eq. (45) remains unchanged.

In the long time limit Eqs. (26) and (27) hold. The result of taking the ! 1 limit in Eq. (43) is thus

$$Q() + _{i} = \bigvee_{j}^{X} !_{ij} e^{-q_{ji}() + x_{ji}}$$
(44)

On the right-hand side we can identify the transition rates in the driven steady state according to Eq. (2). We therefore obtain a fundam ental relationship between the equilibrium transition rates, the corresponding rates in the driven steady state, and the ux potential Q ():

$$Q() = i() \quad i; \tag{45}$$

where i() f_{jg} ij(). Eq. (45) states that, for every state i, the totalexit rate in the driven steady state di ers from its equilibrium counterpart only by a ux dependent (but state independent) constant. On the basis of this central result a number of important implications of NCDB can be derived. It turns out that it is not necessary to know the G reen's functions of the equilibrium system in order to determ ine the q's and the driven transition rates. R ather, as we will see m ore explicitly below, the quantities of the NCDB form alism are intrinsically related to the graph structure via Eq. (45).

A. Invariant quantities

It is now straightforward to form ulate two sets of invariant quantities for the sheared steady state. The rst was found in Ref. [4] and is a consequence of the asymmetric property of q_{ji} and x_{ji} . From Eq. (2), the product constraint' follows directly,

$$_{ij} _{ji} = !_{ij}!_{ji}$$
 (46)

Secondly, Eq. (45) directly in plies the 'total exit rate constraint',

$$i \quad j = i \quad j: \tag{47}$$

We therefore nd that in the driven steady state both the product of forward and reverse transition rates and the di erence of total exit rates for every pair of m icrostates are the same as in equilibrium and therefore invariant with respect to the driving. No near-equilibrium assumptions have been made in the derivation, so the above relations are both exact and valid arbitrarily far from equilibrium.

W ith the form alism devised here, the task of nding the microscopic nonequilibrium dynam ics given an imposed macroscopic current is greatly simplied and follows straightforward rules. The above relations are furthermore accessible to veri cation in an experiment or simulation [12].

B. Network rules

W ith these results we are able to devise a system atic m ethod to determ ine the driven transition rates for arbitrary graph con gurations. Considering the whole basic graph with n states, there are n equations in the form of Eq. (45). This set of equations is su cient to determ ine all the unknown quantities, i.e., the ux potential Q and the q's, as we now show. Due to the relationship $q_{ij} = q_{ji}$, every edge of the basic graph is associated to two transition rates (forward and backward transitions) depending on one q. The number of independent q's is further constrained by closed paths (loops) in the graph, i.e., paths that begin and end at the same type of vertex, because the sum of q's always n along such a path is obviously zero (loop constraint). One can then easily see that the total number of independent q's in the basic graph is always n 1, as follows. Consider rst the most simple basic graph con guration, namely all n states connected as a simple path without any bops. In this case the number of edges is trivially n. Since one loop constraint is generated by the periodicity, there are n 1 independent q's. From this simple connected graph all graphs of higher degrees can be generated by adding new edges. But adding an edge generates a new q and at the same time a new loop constraint, so that the number of independent q's always remains n 1.

We form ulate the following network rules for the calculation of the driven transition rates in networks of arbitrary connectivity:

Edge rule. Every interior edge and every pair of exterior edges in the basic graph corresponds to two rates containing the dependence on one q. The driven transition rates are given by Eq. (2).

Vertex rule. For every vertex in the basic graph the di erence between the driven and equilibrium total exit rates equals the ux potential Q (Eq. (45)).

Loop rule. For every closed path of edges the sum of the q's along this path is zero.

In this form ulation there are in total n equations and n unknowns, namely one Q and n 1 q's. The number of independent equations can always be further reduced by eliminating Q, such that one is essentially left with n 1 equations for n 1 unknown q's. The solution of this system of equations fully speci es all the driven rates in the system as well as the ux J which is related to the ux potential via dQ ()=d = J, Eq. (31). In the given fram ework the driven transition rates and the ux are determ ined as functions of the ux conjugated parameter .

An alternative, -independent representation is based on Eqs. (46) and (47). However, the num ber of constraints is here not su cient to determ ine all the driven rates for general network structures. On the one hand there are $\int_{i=1}^{n} d_i=2$ product constraints and n 1 exit rate constraints. On the other hand, for an arbitrary graph con guration, there are $\int_{i=1}^{n} d_i$ transition rates. Therefore only for graphs with the topology of a simple connected path (where $d_i = 2$), we can determ ine the rates completely from the invariant quantities without using the network rules. In this case we have 2n transition rates and 2n 1 constraints stem ming from the exact relations. The transition rates are fully determ ined if additionally the relationship between the transition rates and the current is provided. In this form ulation the driven rates depend on J directly instead of being param etrized in terms of the param eter . The relationship between current and rates is further elucidated in the next section.

VI. CURRENT RELATIONS

In M aster equation systems the stationary current J is generally defined as the average of the functions of every state i over the steady state distributions p_i

$$J = p_{i} \qquad x_{ji \ ij}; \qquad (48)$$

At equilibrium J is identically zero due to detailed balance, Eq. (5), and the property $x_{ji} = x_{ij}$. In general, at steady state, the distribution pp_i is the solution of the M aster equation (3) under the condition of stationarity $dp_i(t)=dt=0$ and norm alization $_ip_i=1$. The solution can be form ally obtained by m atrix inversion as follows [10]. In m atrix notation Eq. (3) is given as (w riting the transition rates now capitalized):

i.e., as ${}_{j}^{P}M_{ij}p_{j} = 0$, where M is a n n m atrix with entries

$$M_{ij} = j_{i} \quad i_{j} \quad i$$
 (50)

It has been noted earlier that, due to the periodic graph structure, in addition to the internal edge, there can be multiple exterior edges connecting the same types of states in di erent periods. These additional rates are contained in $_{ij}$ which denotes the sum of all transition rates from a state of type i into a state of type j. In the M aster equation this is considered in the sum mation fjg over the set of adjacent sites which includes the exterior edges. D enoting the transition rate matrix including the norm alization (e.g., in the rst row) by M, that is

$$M = \begin{bmatrix} 0 & 1 & 1 & 1 & 1 \\ B & 12 & 2 & 32 & n2 \\ B & 13 & 23 & 3 & n3 \\ C & \vdots & \vdots & \vdots & \ddots & \vdots \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & n \end{bmatrix}$$
(51)

the Master equation including normalization reads

We therefore nd the occupancies p_i by matrix inversion as M¹ e_1 , i.e. in the rst column of the inverse matrix M¹.

A new relationship between the current J and the transition rates is obtained when we take the derivative (denoted by a prime) of Eq. (45) with respect to :

$$Q^{0} = \sum_{\text{fig}}^{X} (q_{ji}^{0} + x_{ji})_{ij};$$
(53)

for every state i. Here and in the following the -dependence is dropped. Using $q_{ji}^0 = q_j^0 \quad q_j^0$ we can rewrite these equations as

$$Q^{0} + q_{i}^{0} \quad i \qquad \begin{array}{c} X \\ f_{j} \\ f_{$$

Since all relevant physical information is contained in the di erences rather than the individual q_i 's, we have the freedom to x one boundary value. If we choose $q_1 = const$, obviously $q_1^0 = p_0$ and thus $q_{i}^0 = q_{1i}^0$. Defining the two column vectors q^0 (Q^0 ; q_{12}^0 ; ...; q_{1n}^0)^T and $a = (a_1; ...; a_n)^T$ with $a_i = f_{jg} = x_{ji}$, we can cast the system of equations (54) into the following matrix form

W e realize that the left hand side reveals the transpose m atrix of M . Eq. (55) is therefore equally expressed as

$$\mathbf{M}^{\mathrm{T}} \mathbf{q}^{0} = \mathbf{a}; \tag{56}$$

W ith this result we can rederive the fundam ental relationship Eq. (31) between the ux potential Q and the ux J. Eq. (56) is form ally solved via m atrix inversion

$$q^{0} = M^{T} \quad a:$$
 (57)

For any matrix the transpose of the inverse matrix is the inverse of the transpose matrix: $(M^T)^1 = (M^1)^T$. Since $M^{-1}e_1$ is the form al solution of the M aster equation, we can deduce that the rst row of $(M^T)^{-1}$ contains the steady state occupancies p_i . Solving Eq. (57) for Q^0 with the given expressions a_i therefore leads to

$$Q^{0} = \begin{array}{c} X & X \\ p_{i} & x_{ji \ ij}; \\ i & fjg \end{array}$$
(58)

so that by comparison with Eq. (48), we can conclude that $Q^0 = J$, i.e., Eq. (31) holds. We have therefore shown that

$$J = \begin{cases} X \\ (q_{ji}^{0} + x_{ji}) \\ ij; \end{cases}$$
(59)

for every state i, which is a new representation of the steady state current J in term s of q_{ji}^0 instead of the m icrostate distributions p_i .

At this point it is instructive to associate a physical interpretation with the derivative of the q_{ji} . Taking the derivative of Eq. (29) with respect to leads to the following expression:

$$q_{ji}^{0} = \lim_{l \to 1} \frac{R_{1}}{1} p^{eq}(jj) e d \frac{R_{1}}{1} p^{eq}(jj) e d}{1} \frac{R_{1}}{1} p^{eq}(jj) e d} = \frac{R_{1}}{1} p^{eq}(jj) e d}$$
(60)

In the discussion of the path-entropy maxim ization in Sec. III we obtained the fundamental result (Eq. (10)) that in the driven ensemble the trajectories are reweighted with the exponential factor e. This implies that in the present context p^{eq} (jj) e can be related to the unnormalized conditional probability that the system exhibits shear from state i under the driven dynamics, i.e.,

in the lim it of large . Introducing

$$h_{i}(;)i = \frac{R_{1}^{1}}{P_{1}^{eq}(ji)e d};$$
(62)

which denotes the mean shear that the system accumulates over time in the steady state from state i, one can then express Eq. (60) as

$$q_{ji}^{0} = \lim_{i=1}^{m} [h_{j}(;)i \quad h_{i}(;)i];$$
(63)

ie, as the di erence in mean shear between states i and j over in nite time. Furthermore, from Eq. (57) we nd that the quantities q_{ij}^0 can be determined using C ram er's rule [10]:

$$q_{1i}^{0} = \frac{\det (M^{T})^{(i)}}{\underbrace{h \quad i}}; \qquad (64)$$

where $(M^T)^{(i)}$ m eans that the ith column of M^T has to be replaced by a. From the set of q_{1i}^0 all other quantities q_{ji}^0 follow by subtraction: $q_{ji}^0 = q_{1i}^0 = q_{1j}^0$.

Relationship (59) is remarkable because the stationary shear current is determ ined from the properties of a single state and its neighbors only, instead of the average Eq. (48) over the whole basic graph. It does not involve energetics, since the know ledge of two constant 'shear values' in addition to the transition rates is su cient to determ ine the current. One constant, x_{ji} , measures the immediate di erence in shear between states i and j and the other, q_{ji}^0 , the di erence in mean shear that the system accumulates in the steady state over in nite time from states i and j. The set of q_{ji}^0 is directly related to the transition rate matrix M' via Eq. (64).

From a computational point of view, no advantage is gained by determ ining the ux via Eq. (59) if the quantities q_{ji}^{0} are determ ined by the same form alm atrix inversion method as the probability distributions. How ever, Eq. (59) provides us with a new interpretation of the steady state current and of the elements of the inverse transition rate matrix M⁻¹. The quantities q_{ji}^{0} have a precise physical meaning independent of the NCDB form alism. It might be possible to identify related current expressions for other steady state system s that are not contained in the class of system s for which NCDB is valid.

A. Fluctuation relation for the shear current of a trajectory

F luctuation theorem s are m athem atical relations for the uctuations of therm odynam ic quantities like heat (entropy production) or work in nonequilibrium systems (see [14] and references therein). In a nonequilibrium steady state the so called asymptotic or steady state uctuation theorem (SSFT) states that the probability distribution p () of nding a particular value of the therm odynam ic quantity over time satisfies a certain symmetry relation of the form (cf. [13, 15, 16, 17])

$$\frac{p()}{p()} = e^{c}$$
; (65)

where = indicates the asymptotic behavior for large and c is a constant. The SSFT Eq. (65) (also referred to as Gallavotti-Cohen uctuation theorem) represents a renement of the second law of therm odynamics in that it quantiles the probability of observing tem porary second law violations (negative) in the nonequilibrium steady state. Relations similar to Eq. (65) have been derived for a variety of system s with diment therm ostatting mechanisms. For determ inistic system s in a compact phase space the SSFT for the entropy production is expected to hold universally under the chaotic hypothesis [16]. However, stochastic system s do not exhibit the same generality in their uctuation behavior. Here, the validity of Eq. (65) relies, e.g., on the characteristics of the noise, or on the therm odynamic

quantity considered. In a particular paradigm atic nonequilibrium particle model the SSFT has been shown to hold for the heat uctuations, when the system is therm ostatted by an equilibrium heat bath with Gaussian white noise characteristics [18]. However, when one considers the heat uctuations, or the work uctuations under the in uence of non-Gaussian noise, the SSFT is violated [19, 20, 21, 22, 23].

In a shear ow, a uid region in the bulk of the volume receives noise from the sheared uid surrounding it, which represents a nonequilibrium heat bath. NCDB quanti es the stochastic in uence of such a nonequilibrium heat bath on the dynam ics of the uid. In system s satisfying NCDB a relation in the form of the SSFT holds for the uctuations of the shear current of an individual trajectory and can be derived in a straightforward way. Our starting point is the nonequilibrium path distribution p^{dr} () of Eq. (10). Using this path distribution, the distribution of the shear current j of trajectories of duration can be form ally expressed as

$$p(j) = \frac{p'(j) - (j) - p^{dr}(j)}{p^{dr}(j)};$$
(66)

where the total shear of a phase space trajectory is denoted by (). Substituting Eq. (10) yields P

$$p(j) = e^{j} \frac{p(j(j)) = p^{eq}(j)}{e^{-p^{eq}(j)}}:$$
(67)

Here, the numerator is just the unnormalized probability distribution of observing the shear current j at equilibrium. Clearly, this distribution has to be symmetric under a change of sign of j, i.e., at equilibrium the probability of observing a shear current j over time is the same as observing j over the same time period. Taking the ratio p(j)=p(j) then immediately implies

$$\frac{p(j)}{p(j)} = e^{2j};$$
(68)

for large . The distribution p (j) depends in plicitly on the parameter .

The current uctuation relation Eq. (68) characterizes the uctuations of j in the steady state and implies that the system's trajectory is overwhelmingly likely to follow the direction prescribed by the imposed driving, which is specified by the sign of the ux conjugated parameter . Similar uctuation relations for the current have previously been derived in the context of lattice gasm odels [24] (see also [14] and references therein). In the present case we have shown the validity of such a current uctuation relation for a very large class of nonequilibrium steady state system s, namely uid ow's under continuous shear, as described by NCDB.Eq. (68) follows then very naturally due to the G ibbs property of the path distribution p^{dr} (). The general relationship between the SSFT and G ibbs distributions has been discussed in [25].

In the remainder of this article we apply the form al results of the previous sections to two simple M arkovian jump m odels.

VII. ANALYTIC SOLUTION OF THE TWO STATE GRAPH

A sour rst example we discuss a basic graph with two di erent types of states 1 and 2. For generality, an asymmetric separation between the states is assumed. Two distinct arrangements are then possible: (i) a simple connected path leading to a zig-zag shaped graph, and (ii) a graph in the form of connected triangles. (O ther connectivities are also possible, one of which was considered in [4].) For both types of graphs the driven transition rates can be calculated exactly using the results of the previous sections. O bviously, (i) is a special case of (ii) where the horizontal transition rates are set to zero. For clarity we rst discuss the simpler zig-zag graph in some detail in Secs. V IIA and V IIB and then present results for case (ii) in Sec.V IIC.

Let us rst consider a zig-zag arrangement of the two states leading to a ratchet shaped state space. A lihough the solution of this two state model follows quite intuitively, we apply the network rules of Sec. V B in a system atic way.

A. Network rules

Edge rule. The basic graph in Fig. 6 reveals one interior edge and one pair of exterior edges. In the following we use an intuitive notation for (u)pwards and (d)ow nwards rates in positive (+) and negative direction (-). D riven rates are capitalized while their equilibrium counterparts are lower case. To the interior edge the transition rates U^+_{12} and D_{21} are associated, which depend on q_{21} and carrying the shear x_{21} . To the pair of exterior edges

FIG. 4: Basic graph of the two state zig-zag m odel. The dotted lines denote exterior edges.

we associate the rates U $_{10}$ and D⁺ $_{23}$, which depend on q_{32} and x_{32} (note that $q_{32} = q_{10}$ and $x_{32} = x_{10}$). At equilibrium the number of di erent transition rates remains four due to the asymmetry of the state space, but equilibrium detailed balance requires that $u = d^+ = u^+ = d = e^- E$, with E being the energy di erence between states of type 1 and 2. Throughout the following calculations the inverse temperature is set to unity. A coording to Eq. (2) the driven transition rates are then given by:

$$U^{+} = u^{+} e^{-x_{21} + -q_{21}}; \quad D = d e^{-x_{21} - q_{21}};$$

$$U = u e^{-x_{32} - q_{32}}; \quad D^{+} = d^{+} e^{-x_{32} + -q_{32}}; \quad (69)$$

Vertex rule. There are two distinct vertices in the basic graph. To each corresponds an equation in the form of Eq. (45)

$$Q = U^{+} + U \qquad (u^{+} + u);$$

$$Q = D^{+} + D \qquad (d^{+} + d):$$
(70)

Loop rule. There is one external closed loop 1 ! 2 ! 3 corresponding to subsequent transitions U⁺ and D⁺. The loop constraint for the q's then reads

$$q_{21} + q_{32} = 0: (71)$$

In total we have the system of equations

d e

 $u^{+}e^{x_{21}+q_{21}}+ue^{x_{32}}q_{32}$ $(u^{+}+u) = Q;$ (72)

$$x_{21} q_{21} + d^{+} e^{x_{32} + q_{32}} (d^{+} + d^{-}) = Q;$$
 (73)

 $q_{21} + q_{32} = 0;$ (74)

for the three unknowns Q, q_{21} , and q_{32} . The solution can be found in a straightforward way. We simplify notation by setting $q q_{21} = q_{32}$, as well as $x_1 x_{21}$ and $x_2 x_{32}$. Furthermore, we use the notation for the total exit rates $_1 = u^+ + u$ and $_2 = d^+ + d$. Substitution of the loop constraint yields

$$(u^{+}e^{x_{1}}+ue^{x_{2}})e^{q} = Q;$$
 (75)

(d e $x_1 + d^+ e x_2$) e $q_2 = Q$: (76)

E lim ination of e $\,^{
m q}\,$ in this set of equations leads to a quadratic equation for Q , namely

$$Q^{2} + (_{1} + _{2})Q + (_{1 2} (u^{+}e^{x_{1}} + u e^{x_{2}})(d e^{x_{1}} + d^{+}e^{x_{2}})) = 0:$$

(77)

Due to equilibrium detailed balance we furtherm ore have

$$1_{1,2} (u^{\dagger} e^{x_1} + u e^{x_2}) (d e^{x_1} + d^{\dagger} e^{x_2}) = 2u^{\dagger} d^{\dagger} (1 \cosh((x_1 + x_2))):$$
(78)

The positive root then reads

$$Q() = \frac{1p}{2} (1+2)^2 + 8u^+ d^+ (\cosh((x_1 + x_2))) + \frac{1}{2}(1+2);$$
(79)

In turn, q is determined from Eq. (75) as

$$q = \ln \frac{Q + 1}{u^+ e^{-x_1} + u \cdot e^{-x_2}}$$
: (80)

For a given set of equilibrium rates, the driven transition rates are now completely determ ined as functions of the ux conjugated parameter . With Q and q we can furtherm ore calculate the shear current J() = dQ()=d and the mean shear di erence $q^0 = d q()=d$ (see also below). Equilibrium is characterized by = 0. As expected the ux then vanishes: J(=0) = 0. One can also easily see that for = 0 both Q (0) = 0 and q(0) = 0, and the driven rates Eqs. (69) reduce to the equilibrium rates.

B. Invariant quantities

Since the asymmetric two state zig-zag graph is obviously a simple connected path, we can alternatively determine the driven transition rates using the -independent representation. To this end we have to set up the invariant quantities and nd the relation between the rates and the particle ux. The invariant quantities follow immediately from Eqs. (46) and (47):

$$U^{+}D = u^{+}d; \qquad (81)$$

$$D^+ U = d^+ u ; (82)$$

$$D^{+} + D \quad (U^{+} + U^{-}) = d^{+} + d \quad (u^{+} + u^{-}):$$
 (83)

F inally, to nd the ux, we calculate the probability distributions of states 1 and 2. The M aster equation for the two state graph has the following matrix form

$$(U^+ + U^-)$$
 $D^+ + D^ p_1^- = 0$: (84)
 $U^+ + U^ (D^+ + D^-)$ p_2^-

Including the norm alization in the transition m atrix leads to

$$M \quad \begin{array}{c} p_1 \\ p_2 \end{array} = \begin{array}{c} 1 \\ 0 \end{array} ; \tag{85}$$

where

$$M' = \frac{1}{U^{+} + U} \frac{1}{(D^{+} + D)} ;$$
(86)

M atrix inversion then yields the probability distributions (or occupancies) p_1 , p_1 , which, in turn allow for the calculation of the current J via Eq. (48). The results for the probability distributions as functions of the driven transition rates are

$$p_1 = \frac{D^+ + D}{U^+ + U^- + D^+ + D};$$
(87)

$$p_2 = \frac{U^+ + U}{U^+ + U^- + D^+ + D};$$
(88)

A coording to the results of Sec.VI we can alternatively determ ine the current and the mean shear di erences q^0 from Eq. (57). This equation is given by

FIG. 5: Basic graph of the two state loop model. The dotted lines denote exterior edges.

The matrix algebra is straightforward and yields

$$J = (x_1 + x_2) \frac{U^+ D^+ U D}{U^+ + U + D^+ + D};$$
(90)

$$q^{0} = \frac{(D^{+} + U^{-}) \times 2}{U^{+} + U^{-} + D^{+} + D}; \qquad (91)$$

The last two expressions agree with the ones obtained in the -representation, if the driven rates are substituted according to Eq. (69) with the known expressions for Q and q, Eqs. (79) and (80).

For a given set of equilibrium rates and a prescribed particle ux, the transition rates in the driven steady state are determ ined as solutions of the set of equations (81) | (83) and (90). In this case the driven rates are parametrized by J.

C . $\mathsf{T} \, \mathsf{w} \, \mathsf{o}$ state graph w ith a loop

If we add two additional external edges 2! 0 and 2! 4 to the two state zig-zag graph of F ig. 6, we obtain a state space with the structure of F ig. 8. The system in state 2 can now choose to reach state 4 directly or by going rst downhill' to a state of type 1 and then 'uphill'. The choice will depend on which path is more favourable to achieve the imposed ux J for given parameter values. As before, NCDB precisely quantiles the change in the transition rates under driving.

We denote the transition rates associated to the additional exterior edges with H $^+$ ₂₄ and H $_{20}$. Both rates are independent of q since they connect states of the same type and symmetry requires that the corresponding equilibrium rates are equal. The rates are therefore fully specied as

$$H^{+} = he^{(x_{1}+x_{2})}; \quad H^{+} = he^{(x_{1}+x_{2})}:$$
(92)

The e ect of the additional edges on the other rates can be calculated analogously to the zig-zag graph. The total exit rate relation for state 2 (used in the vertex nule) has to be extended by the new rates, whereas the relation for state 1 rem ains unchanged. This leads to

$$Q = U^{+} + U \quad (u^{+} + u);$$
 (93)

$$Q = D^{+} + D + H^{+} + H$$
 (d⁺ + d + 2h): (94)

Introducing the total exit rate $_2 = d^+ + d^- + 2h$ and substituting the expressions for the driven rates, we can write the system of equations as

$$(d e^{x_1} + d^+ e^{x_2})e^{q} + 2h\cosh((x_1 + x_2)) = Q;$$
(95)

$$(u^+ e^{x_1} + u e^{x_2})e^q_1 = Q$$
: (96)

The quadratic equation for the ux potential then reads

$$0 = Q^{2} + (_{1} + _{2} - 2h\cosh((x_{1} + x_{2}))Q + _{1}_{2} - _{1}2h\cosh((x_{1} + x_{2}))Q + _{1}$$

FIG. 6: (a) The four transition rates of the two-state zig-zag model (h=0.0) plotted as functions of the current J. (b) The function q() of Eq. (80) (with Q () given by Eq. (98)) for two values of the equilibrium rate h. Parameter values: E = 2.0, $d^+ = 1.0$, d = 0.8, $x_1 = 1.0$, $x_2 = 0.5$.

with the positive root

$$Q() = \frac{1P}{2} \overline{(_1 + _2)^2 + 2h\cosh((x_1 + x_2))^2 + 8(_1h + u^+ d^+)(\cosh((x_1 + x_2)))^2)} = \frac{1}{2} (_1 + _2)^2 2h\cosh((x_1 + x_2)))$$
(98)

As above, q is determined from Eq. (80).

H aving thus speci ed all the driven rates, we can determ ine the remaining quantities in the matrix form alism. Since the rates H⁺ and H connect two states of the same type, their e ect on the occupancies balances to zero. The transition rate matrix M is therefore identical to Eq. (86) and the probability distributions are given by Eqs. (87) and (88) as in the zig-zag case. The shear current J and the mean shear di erence q^0 are determined by Eq. (57), which reads here

W e thus obtain

$$J = (x_{1} + x_{2}) \frac{U^{+}D^{+} UD + (U^{+} + U)(H^{+} H)}{D^{+} + D + U^{+} + U};$$
 (100)

$$q^{0} = \frac{(D^{+} + U^{-}) \times 2}{D^{+} + D^{-} + U^{+} + U^{-}} (X_{1} + X_{2})$$
(101)

In the lim it h ! 0 the two-state loop m odel obviously reduces to the zig-zag m odel discussed in the previous section. The four transition rates U^+ , U^- , D^+ , D^- in this case are plotted in Fig. 6 (a) parametrically as functions of the current J for given values of the parameters E, d^+, d^- , x_1 , and x_2 . C learly, the transition rates in the direction of J are enhanced for larger J, while the transition rates in the opposite direction are attenuated. For large J the transition rates in the direction of the driving become proportional to J, as im plied by the current relation Eq. (100). The occupancies p_1, p_2 , which at equilibrium (J = 0) are determined by Boltzm ann's law, converge to the value 1=2 in the lim it of J ! 1, indicating that the energy difference between states 1 and 2 becomes irrelevant for strong driving (see Fig. 7(a)).

When $h \notin 0$ the system is able to gain a shear increment $x_1 + x_2$ by going directly from state 2 to state 4, i.e., another state of type 2, without rst going to state 3, a state of type 1. This in plies that, under (strong) forward driving, it is advantageous for the system in state 2 to make the transition 2 ! 4 instead of the transition 2 ! 3, because it is then able to gain an increment $x_1 + x_2$ in one step instead of two. This intuitively expected behavior of the two-state loop m odel is evident in Fig.8, where we plot the three forward transition rates under forward driving. While in the zig-zag case the rate D⁺ is enhanced under increased forward driving, it is attenuated in the loop case due to the presence of the additional edge. The system of that being in state 1 is less favorable in order to achieve shear, than being in state 2.

The quantity $q = q_{21}$, Eq. (80) (with Q of Eq. (98)), is plotted in Fig. 6(b) for the two cases h = 0 and $h \neq 0$. In the zig-zag case (h = 0) one notices that, for the given choice of the parameters $x_1 > x_2$, q becomes negative

FIG.7: The occupancies p_1 and p_2 of Eqs. (87) and (88) plotted as functions of the current J for parameter values E = 2.0, $d^+ = 1.0$, d = 0.8, $x_1 = 1.0$, $x_2 = 0.5$. (a) In the two-state zig-zag model both distributions converge to 1=2 for large J. (b) In the two-state loop model, with h = 0.5. The occupancy of type 2 states, p_2 converges to 1 for large J, while p_1 decays to zero.

FIG.8: The three forward transition rates in the two-state loop model. Parameter values: $E = 2.0, d^+ = 1.0, d^- = 0.8, x_1 = 1.0, x_2 = 0.5, h = 0.5.$

for large forward driving (large), indicating that state 1 has a larger propensity for future shear than state 2. This is because from state 1 the system can gain a larger (forward) shear increment (x_1) than from state 2 (x_2). For weak driving (sm all) a crossover behavior is observed, where q exhibits local maxim a and m inim a. In the loop case ($h \notin 0$) state 2 is favored due to the additional edge and thus q increases for both larger forward and backward driving. In fact, from the analytical expression Eq. (80) one nds that q() / jj for large in the case $h \notin 0$, while $q() / (x_2 x_1)$ in the case h = 0.

VIII. THREE STATE GRAPH

A basic graph with three distinct states allows for a variety of periodic graph structures with di erent connectivities. In the following we consider a basic graph that contains an internal closed loop (see Fig. 9). For this arrangement the driven transition rates can only be found using the network rules, since the number of independent rates exceeds the number of invariant quantities plus current relation.

Edge rule. There are three internal edges and one pair of external edges in the basic graph. The three internal edges correspond to six distinct rates: $_{12}$, $_{13}$, $_{23}$, and the associated reverse rates. The pair of external edges is associated with $_{10}$ and $_{34}$, where state 0 is of the same type as 3 and 4 of the same type as 1. The set of driven

FIG.9: Basic graph of a three state model with an interior loop. The dotted lines denote exterior edges.

transition rates is speci ed as in Eq. (2)

$$_{ii} = !_{ii} e^{x_{ji} + q_{ji}}$$

Vertex rule (Eq. (45)) gives one relation for each vertex. These three equations read

$$Q = {}_{12} + {}_{13} + {}_{10} (!_{12} + !_{13} + !_{10});$$
(102)

$$Q = {}_{23} + {}_{21} (!_{23} + !_{21});$$
(103)

$$Q = {}_{31} + {}_{32} + {}_{34} \quad (!_{31} + !_{32} + !_{34}):$$
(104)

Loop rule. There is one external loop 0 ! 1 ! 3 and one internal loop 1 ! 2 ! 3 ! 1 so constraints on the four q's read

$$q_{10} + q_{31} = 0;$$
 (105)

$$q_{21} + q_{32} + q_{13} = 0$$
: (106)

Furtherm one the internal loop requires that $x_{31} = x_{21} + x_{32}$. We use the following simplifying notation:

$$\ln z q_{21};$$
 (107)

$$\ln y = q_{32};$$
 (108)

$$W_{ij} = l_{ij} e^{X_{ji}}$$
 (109)

The loop constraints then in ply that $q_{01} = q_{31} = \ln(yz)$. In this notation the vertex rules read

(W

$$W_{12} z + (W_{10} + W_{13}) y z_1 = Q;$$
 (110)

$$W_{23} V + W_{21} Z^{1} = 0;$$
 (111)

$$_{31} + W_{34})(yz)^{-1} + W_{32}y^{-1} \qquad _{3} = Q:$$
 (112)

where the total exit rates are as before $i = \begin{bmatrix} i \\ j \end{bmatrix}$ in the initial of Q then leads to two quadratic equations

$$(W_{10} + W_{13})z^2y + W_{12}z^2 \quad W_{23}yz + (_2 \quad _1)z \quad W_{21} = 0;$$
 (113)

$$W_{23}y^2z + (3)yz + W_{21}y + W_{32}z + (0)yz + W_{21}y + W_{32}z = 0;$$
 (114)

O ne realizes that already for the three state m odel an analytical solution is exceedingly di cult to obtain. Solving for example Eq. (113) for y and substituting into Eq. (114) yields an equation for z which is of fth order and therefore not exactly solvable. A lternatively one can determ ine the driven transition rates in a straightforward way by solving Eqs. (113) and (114) num erically for y and z.

The current and probability distributions are easiest obtained from the matrix methods outlined in Sec.VI. For the three state graph of Fig. 9 the master equation reads in matrix form

FIG.10: The four forward transition rates of the three-state loop model of Fig. 9. Parameter values: $E_{12} = 3.0$, $E_{32} = 2.0$, $!_{10} = 1.0$, $!_{13} = 1.0$, $!_{32} = 1.5$, $x_{21} = 1.8$, $x_{32} = 1.0$, $x_{43} = 0.5$.

The probability distributions are then obtained as

 \sim

where

$$M = \begin{pmatrix} 0 & & & 1 \\ 1 & 1 & 1 \\ 12 & (23 + 21) & 32 \\ 13 + 10 & 23 & (31 + 32 + 34) \end{pmatrix}$$
(117)

U sing Eq. (57) we can then determ ine the shear current and the m ean shear di erences:

By solving Eqs. (113) and (114) num erically for q_{21} and q_{32} given a set of equilibrium rates !_{ij} and distances x_{ji} , one can determ ine the driven transition rates as well as the ux potential for the three state graph of Fig. 9. Eqs. (116) and (118) can then be used to obtain the probability distributions, the current and the mean shear di erences.

The results for the driven transition rates in the forward direction are shown in Fig. 10. For forward shear three of the transition rates are strongly enhanced. However, we observe that the transition 1 ! 2 is attenuated at high shear rate, even though it contributes a positive shear increment x_{21} . This indicates that the system disfavors the path via state 2 that requires two transitions to acquire the shear increment x_{32} . For large shear rates the system will thus predom inantly choose the high-m obility \channel" 1 ! 3. A similar observation is made for the transition 2 ! 3, which, for backward driving, remains signil cant because it connects to the favorable direct channel.

A coordingly, the steady state occupancies p_1 and p_3 converge to the value 1=2 for strong driving in both forward and backward direction (cf. Fig. 11). On the other hand, the occupancy of state 2, energetically favored over states 1 and 3 at equilibrium, decays to zero for larger shear.

IX. SUMMARY

The search for fundamental principles governing the behavior of systems in out of equilibrium situations has long been an area of intensive research. We have discussed a statistical theory (NCDB) that starts from st principles

FIG.11: The steady state distributions p_1 , p_2 , p_3 of Eq. (116) plotted param etrically as functions of the current J. Param eter values: E $_{12} = 3.0$, E $_{32} = 2.0$, $!_{10} = 1.0$, $!_{13} = 1.0$, $!_{32} = 1.5$, $x_{21} = 1.8$, $x_{32} = 1.0$, $x_{43} = 0.5$.

and governs the steady-state motion of any owing system on which work is done by a weakly-coupled nonequilibrium reservoir that is ergodic and microscopically reversible, such as a complex uid under continuous shear. NCDB provides a description of the microscopic dynamics of these systems in the form of exact constraints on the transition rates in the driven steady state, arbitrarily far away from equilibrium, akin to the principle of detailed balance for equilibrium systems. In this article we have investigated this theory for systems evolving in discrete state spaces. We derived a simple relationship between the ux potential and the total exit rates, which leads to a num ber of important further results.

Two simple sets of invariant quantities have been formulated: (i) the product of forward and reverse transition rates and (ii) the di erences in total exit rates, for every pair of microstates, equal the corresponding equilibrium values and are thus unchanged by the driving. These invariant quantities are non-trivial and experimentally accessible predictions of NCDB.We have devised a system atic method to determ ine the driven transition rates by setting up a system of equations from simple network rules. Furthermore, we have investigated properties of the shear current in system s satisfying NCDB.We show that the stationary shear current can be determined independently of the steady state distribution of microstates. Considering the shear current exhibited by an individual system trajectory, we show that the uctuations of this shear current satisfy a uctuation relation of the G allavotti-C ohen type. The validity of such a uctuation relation is related to the G ibbs form of the path distribution p^{dr} () (cf. [25])

In a system with two types of states all quantities of the NCDB form alism can be expressed analytically. How ever, even for just three states results are only obtainable numerically. Both types of system show consistent behavior. In state-spaces containing a loop, the particular path favoured at highest driving is the one most accommodating for carrying ux. Even in these simple models the non-local nature of NCDB becomes evident. Whereas mean-eld theories without the quantity qwould simply boost any transition in the forward ux direction, NCDB takes into account the future propensity for achieving ux. That propensity depends on the global structure of the state space, and is communicated in the noise from the reservoir of other system s exploring the possibilities of the steady-state dynam ics. A particular transition will thus be attenuated if it connects to a state which is blocked or from where subsequent transitions carry low ux. This striking property indicates that NCDB might ultim ately be able to describe the counter-intuitive phase behavior exhibited for example by real complex uids under shear.

Future work in this context will predom inantly focus on further applications of NCDB to more realistic models as well as independent experimental tests. In particular the invariant quantities provide a straightforward criterion to check the validity of the theory (cf. [12]). Even though these new exact relations are based on a rigorous statistical mechanical derivation, only comparison with experimental data can shed light on their signi cance for our understanding of nonequilibrium phenomena.
