Abstract

We have generalized the approach of Brodsky *et al.* for the intrinsic charm quark distribution in the nucleons to the light-quark sector involving intrinsic \bar{u} , \bar{d} , s and \bar{s} sea quarks. We compare the calculations with the existing $\bar{d} - \bar{u}$, $s + \bar{s}$, and $\bar{u} + \bar{d} - s - \bar{s}$ data. The good agreement between the theory and the data allows the extraction of the probabilities for the $|uudu\bar{u}\rangle$, $|uudd\bar{d}\rangle$, and $|uuds\bar{s}\rangle$ five-quark Fock states in the proton. We also calculate the x -dependence of the intrinsic charm after taking into consideration the QCD evolution of the intrinsic quark distribution.

Key words: nucleon structure, five-quark states, intrinsic sea quark

PACS: 12.38.Lg, 14.20.Dh, 14.65.Bt, 14.65.Dw, 13.60.Hb

The origin of sea quarks of the nucleons remains a subject of intense interest in hadron physics. Brodsky, Hoyer, Peterson, and Sakai (BHPS) [1] suggested some time ago that there are two distinct components of the nucleon sea. The first is called the “extrinsic” sea originating from the splitting of gluons into $Q\bar{Q}$ pairs. This extrinsic sea can be well described by quantum chromodynamics (QCD). Another component of the nucleon sea is the “intrinsic” sea which has a nonperturbative origin. In particular, the $|uudQ\bar{Q}\rangle$ five-quark Fock states can lead to the “valence-like” intrinsic sea for the Q and \bar{Q} in the proton. This intrinsic component is expected to carry a relatively large momentum fraction x , in contrast to the extrinsic one peaking at the small- x region. Brodsky *et al.* [1] proposed that the $|uudc\bar{c}\rangle$ five-quark state can lead to enhanced production of charmed hadrons at the forward rapidity region. The CTEQ collaboration [2] has examined all relevant hard-scattering data and concluded that the data are consistent with a wide range of the intrinsic charm magnitude, ranging from null to 2-3 times larger than the estimate by the BHPS model. This suggests that more precise experimental measurements are needed for determining the magnitude of the intrinsic charm component.

In a recent work [3], we generalized the BHPS model of the five-quark Fock states to the light-quark sector. This work was motivated by the expectation that the probability for the $|uudQ\bar{Q}\rangle$ Fock state is approximately proportional to $1/m_Q^2$, where m_Q is the mass of the quark Q [1]. Although this $1/m_Q^2$ dependence is applicable only when the quark mass is heavy [4], the light five-quark states $|uudu\bar{u}\rangle$, $|uudd\bar{d}\rangle$ and $|uuds\bar{s}\rangle$ are likely to have significantly larger probabilities than the $|uudc\bar{c}\rangle$ state, and could be more readily observed experimentally.

By solving the Bjorken- x distribution of the \bar{Q} sea

quark for the $|uudQ\bar{Q}\rangle$ five-quark state in the BHPS model numerically, it was found [3] that the existing $\bar{d}(x) - \bar{u}(x)$ and $\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x)$ data can be well described by the calculation, provided that the QCD evolution [5] of these distributions is taken into account. Moreover, the probabilities for the $|uudu\bar{u}\rangle$ and the $|uudd\bar{d}\rangle$ five-quark states could also be extracted from these data. However, the extracted values of these two probabilities depend on the assumption adopted for the probability of the $|uuds\bar{s}\rangle$ state [3].

In this paper, the previous work is extended further to determine the probability of the $|uuds\bar{s}\rangle$ five-quark state using the recent $s(x) + \bar{s}(x)$ data from the HERMES collaboration [6]. We found that the $s(x) + \bar{s}(x)$ data in the $x > 0.1$ region are quite well described by the BHPS model, allowing the extraction of the probability of the $|uuds\bar{s}\rangle$ state. Using this probability for the $|uuds\bar{s}\rangle$ five-quark component, more precise values for the $|uudu\bar{u}\rangle$ and the $|uudd\bar{d}\rangle$ states could then be obtained from the comparison of the BHPS calculations with the $\bar{d}(x) - \bar{u}(x)$ and $\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x)$ data. We have also examined the effect of the QCD evolution on the x distribution of the intrinsic charm. In particular, we note that the region most sensitive to intrinsic charm is shifted to lower x as a result of QCD evolution. This has implication on future searches for intrinsic charm.

For a $|uudQ\bar{Q}\rangle$ five-quark Fock state of the proton, the probability for quark i to carry a momentum fraction x_i is given in the BHPS model [1] as

$$P(x_1, \dots, x_5) = N_5 \delta(1 - \sum_{i=1}^5 x_i) [m_p^2 - \sum_{i=1}^5 \frac{m_i^2}{x_i}]^{-2}, \quad (1)$$

where the delta function ensures that the proton momentum is shared among the individual constituents. N_5 is the normalization factor for the five-quark Fock state, and

m_i is the mass of quark i . Eq. 1 was solved analytically in Ref. [1] for the limiting case of $m_{4,5} \gg m_p, m_{1,2,3}$, where m_p is the proton mass. For the more general case, Eq. 1 can be solved numerically as discussed in Ref. [3]. In particular, the x distribution of \bar{Q} in the $|uudQ\bar{Q}\rangle$ state, called $P^{Q\bar{Q}}(x_{\bar{Q}})$, can be calculated numerically. The moment of $P^{Q\bar{Q}}(x_{\bar{Q}})$ is defined as $\mathcal{P}_5^{Q\bar{Q}}$, namely,

$$\mathcal{P}_5^{Q\bar{Q}} = \int_0^1 P^{Q\bar{Q}}(x_{\bar{Q}}) dx_{\bar{Q}}. \quad (2)$$

$\mathcal{P}_5^{Q\bar{Q}}$ represents the probability of the $|uudQ\bar{Q}\rangle$ five-quark Fock state in the proton. In the limit of $m_{4,5} \gg m_p, m_{1,2,3}$, one can obtain [1] $\mathcal{P}_5^{Q\bar{Q}} = N_5/(3600m_{4,5}^4)$. For the more general case, the relation between $\mathcal{P}_5^{Q\bar{Q}}$ and N_5 can be calculated numerically [3].

To compare the experimental data with the prediction based on the intrinsic five-quark Fock state, it is necessary to separate the contributions of the intrinsic sea quark and the extrinsic one. The $\bar{d}(x) - \bar{u}(x)$ is an example of quantities which are free from the contributions of the extrinsic sea quarks, since the perturbative $g \rightarrow Q\bar{Q}$ processes will generate $u\bar{u}$ and $d\bar{d}$ pairs with equal probabilities and have no contribution to this quantity. The $\bar{d}(x) - \bar{u}(x)$ data from the Fermilab E866 Drell-Yan experiment at the Q^2 scale of 54 GeV² [7] are shown in Fig. 1. Also shown in Fig. 1 are the data obtained at a lower scale of $Q^2 = 2.5$ GeV² by the HERMES collaboration in a semi-inclusive deep-inelastic scattering (SIDIS) experiment [8].

The BHPS model has a specific prediction on the shapes of the x distributions for \bar{d} and \bar{u} , since these anti-quarks originate from the $|uudd\bar{d}\rangle$ and $|uudu\bar{u}\rangle$ configurations and can be readily calculated. In the BHPS model, the \bar{u} and \bar{d} are predicted to have the same x -dependence if $m_u = m_d$. However, the probabilities of the $|uudd\bar{d}\rangle$ and $|uudu\bar{u}\rangle$ configurations, $\mathcal{P}_5^{d\bar{d}}$ and $\mathcal{P}_5^{u\bar{u}}$, are not known from the BHPS model, and remain to be determined by the experiments. Non-perturbative effects such as Pauli-blocking [9] could lead to different probabilities for the $|uudd\bar{d}\rangle$ and $|uudu\bar{u}\rangle$ configurations. Nevertheless the shape of the $\bar{d}(x) - \bar{u}(x)$ distribution shall be identical to those of $\bar{d}(x)$ and $\bar{u}(x)$ in the BHPS model. Moreover, the normalization of $\bar{d}(x) - \bar{u}(x)$ is known from the measurement of Fermilab E866 Drell-Yan experiment [7] as

$$\int_0^1 (\bar{d}(x) - \bar{u}(x)) dx = \mathcal{P}_5^{d\bar{d}} - \mathcal{P}_5^{u\bar{u}} = 0.118 \pm 0.012. \quad (3)$$

Equation 3 allows us to compare the calculations from the BHPS model with the $\bar{d}(x) - \bar{u}(x)$ data.

The $\bar{d}(x) - \bar{u}(x)$ distribution from the BHPS model is first calculated using Eq. 1 with $m_u = m_d = 0.3$ GeV/ c^2 , and $m_p = 0.938$ GeV/ c^2 , and Eq. 3 for the normalization. Since the E866 and the HERMES data were obtained at Q^2 of 54 GeV² and 2.5 GeV², respectively, it is important to evolve the $\bar{d}(x) - \bar{u}(x)$ distribution from the initial scale μ , expected to be around the confinement scale, to the Q^2

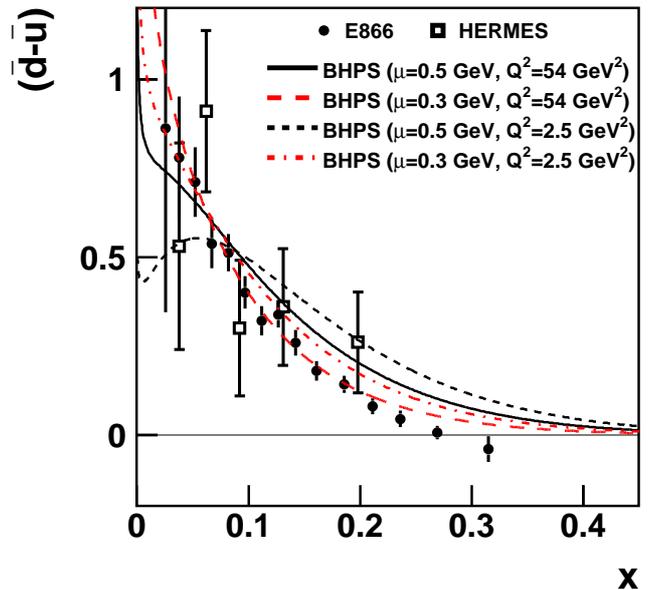

Figure 1: Comparison of the $\bar{d}(x) - \bar{u}(x)$ data from Fermilab E866 and HERMES with the calculations based on the BHPS model. Eq. 1 and Eq. 3 were used to calculate the $\bar{d}(x) - \bar{u}(x)$ distribution at the initial scale. The distribution was then evolved to the Q^2 of the experiments and shown as various curves. Two different initial scales, $\mu = 0.5$ and 0.3 GeV, were used for the E866 calculations in order to illustrate the dependence on the choice of the initial scale.

corresponding to the data. As $\bar{d}(x) - \bar{u}(x)$ is a flavor non-singlet parton distribution, its evolution from μ to Q only depends on the values of $\bar{d}(x) - \bar{u}(x)$ at the initial scale μ , and can be readily calculated using the non-singlet evolution equation [5]. For the initial scale, we adopt the value of $\mu = 0.5$ GeV, which was chosen by Glück, Reya, and Vogt [10] in the so-called “dynamical approach” using only valence-like distributions at the initial μ^2 scale and relying on evolution to generate the quark and gluon distributions at higher Q^2 .

The solid and dashed curves in Fig. 1 correspond to $\bar{d}(x) - \bar{u}(x)$ calculated from the BHPS model evolved to $Q^2 = 54$ GeV² using $\mu = 0.5$ and 0.3 GeV, respectively. The x -dependence of the E866 $\bar{d}(x) - \bar{u}(x)$ data is quite well described by the five-quark Fock states in the BHPS model provided that the Q^2 -evolution is taken into consideration. It is interesting to note that an excellent fit to the data can be obtained if $\mu = 0.3$ GeV is chosen (dashed curve in Fig. 1) rather than the more conventional value of $\mu = 0.5$ GeV. Also shown in Fig. 1 are the calculations with the BHPS model evolved to $Q^2 = 2.5$ GeV² using $\mu = 0.5$ GeV and $\mu = 0.3$ GeV. The calculations are in agreement with the HERMES data within the experimental uncertainties.

We now consider the extraction of the $|uuds\bar{s}\rangle$ five-quark component from existing data. The HERMES collaboration reported the determination of $x(s(x) + \bar{s}(x))$ over the range of $0.02 < x < 0.5$ at $Q^2 = 2.5$ GeV² from

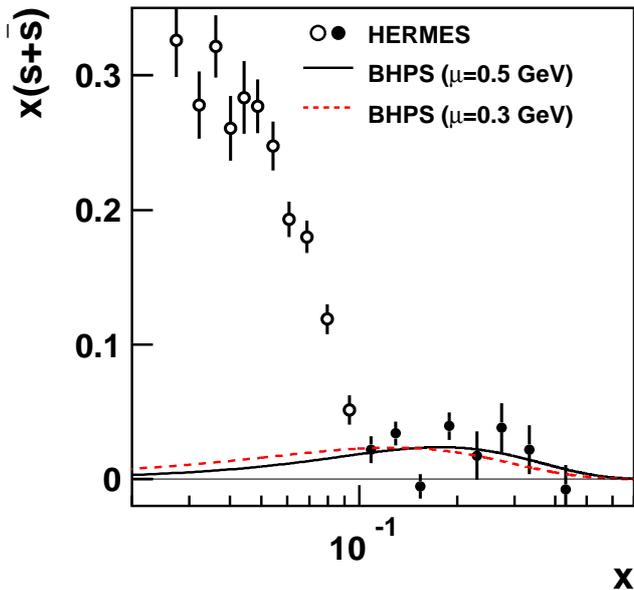

Figure 2: Comparison of the HERMES $x(s(x) + \bar{s}(x))$ data with the calculations based on the BHPS model. The solid and dashed curves are obtained by evolving the BHPS result to $Q^2 = 2.5 \text{ GeV}^2$ using $\mu = 0.5 \text{ GeV}$ and $\mu = 0.3 \text{ GeV}$, respectively. The normalizations of the calculations are adjusted to fit the data at $x > 0.1$ with statistical errors only, denoted by solid circles.

their measurement of charged kaon production in SIDIS reaction [6]. The HERMES data, shown in Fig. 2, exhibits an intriguing feature. A rapid fall-off of the strange sea is observed as x increases up to $x \sim 0.1$, above which the data become relatively independent of x . The data suggest the presence of two different components of the strange sea, one of which dominates at small x ($x < 0.1$) and the other at larger x ($x > 0.1$). This feature is consistent with the expectation that the strange-quark sea consists of both the intrinsic and the extrinsic components having dominant contributions at large and small x regions, respectively. In Fig. 2 we compare the data with calculations using the BHPS model with $m_s = 0.5 \text{ GeV}/c^2$. The solid and dashed curves are results of the BHPS model calculations evolved to $Q^2 = 2.5 \text{ GeV}^2$ using $\mu = 0.5 \text{ GeV}$ and $\mu = 0.3 \text{ GeV}$, respectively. The normalizations are obtained by fitting only data with $x > 0.1$ (solid circles in Fig. 2), following the assumption that the extrinsic sea has negligible contribution relative to the intrinsic sea in the valence region. Figure 2 shows that the fits to the data are quite adequate, allowing the extraction of the probability of the $|uuds\bar{s}\bar{s}\rangle$ state as

$$\begin{aligned} \mathcal{P}_5^{s\bar{s}} &= 0.024 \quad (\mu = 0.5 \text{ GeV}); \\ \mathcal{P}_5^{s\bar{s}} &= 0.029 \quad (\mu = 0.3 \text{ GeV}). \end{aligned} \quad (4)$$

We consider next the quantity $\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x)$. Combining the HERMES data on $x(s(x) + \bar{s}(x))$ with

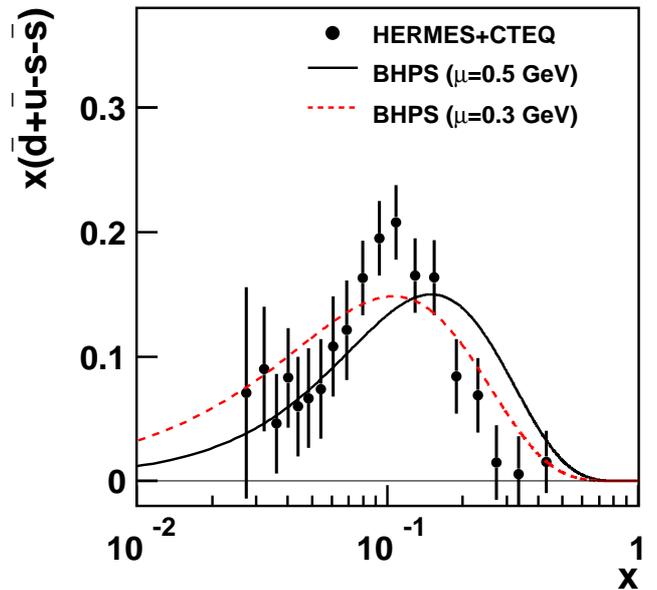

Figure 3: Comparison of the $x(\bar{d}(x) + \bar{u}(x) - s(x) - \bar{s}(x))$ data with the calculations based on the BHPS model. The values of $x(s(x) + \bar{s}(x))$ are from the HERMES experiment [6], and those of $x(\bar{d}(x) + \bar{u}(x))$ are obtained from the PDF set CTEQ6.6 [11]. The solid and dashed curves are obtained by evolving the BHPS result to $Q^2 = 2.5 \text{ GeV}^2$ using $\mu = 0.5 \text{ GeV}$ and $\mu = 0.3 \text{ GeV}$, respectively. The normalization of the calculations are adjusted to fit the data.

the $x(\bar{d}(x) + \bar{u}(x))$ distributions determined by the CTEQ group (CTEQ6.6) [11], the quantity $x(\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x))$ can be obtained and is shown in Fig. 3. This approach for determining $x(\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x))$ is identical to that used by Chen, Cao, and Signal in their recent study of strange quark sea in the meson-cloud model [12].

An important property of $\bar{u} + \bar{d} - s - \bar{s}$ is that the contribution from the extrinsic sea vanishes, just like the case for $\bar{d} - \bar{u}$. Therefore, this quantity is only sensitive to the intrinsic sea and can be compared with the calculation of the intrinsic sea in the BHPS model. We have

$$\begin{aligned} \bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x) = \\ P^{u\bar{u}}(x_{\bar{u}}) + P^{d\bar{d}}(x_{\bar{d}}) - 2P^{s\bar{s}}(x_{\bar{s}}). \end{aligned} \quad (5)$$

We can now compare the $x(\bar{u}(x) + \bar{d}(x) - s(x) - \bar{s}(x))$ data with the calculation using the BHPS model. Since $\bar{u} + \bar{d} - s - \bar{s}$ is a flavor non-singlet quantity, we can readily evolve the BHPS prediction to $Q^2 = 2.5 \text{ GeV}^2$ using $\mu = 0.5 \text{ GeV}$ and the result is shown as the solid curve in Fig. 3. It is interesting to note that a better fit to the data can again be obtained with $\mu = 0.3 \text{ GeV}$, shown as the dashed curve in Fig. 3.

From the comparison between the data and the BHPS calculations shown in Figs. 1-3, we can determine the probabilities for the $|uud\bar{u}\bar{u}\rangle$, $|uudd\bar{d}\bar{d}\rangle$, and $|uuds\bar{s}\bar{s}\rangle$ configura-

tions as follows:

$$\mathcal{P}_5^{u\bar{u}} = 0.122; \quad \mathcal{P}_5^{d\bar{d}} = 0.240; \quad \mathcal{P}_5^{s\bar{s}} = 0.024$$

$$(\mu = 0.5 \text{ GeV}) \quad (6)$$

or

$$\mathcal{P}_5^{u\bar{u}} = 0.162; \quad \mathcal{P}_5^{d\bar{d}} = 0.280; \quad \mathcal{P}_5^{s\bar{s}} = 0.029$$

$$(\mu = 0.3 \text{ GeV}) \quad (7)$$

depending on the value of the initial scale μ . It is remarkable that the $\bar{d}(x) - \bar{u}(x)$, the $s(x) + \bar{s}(x)$, and the $\bar{d}(x) + \bar{u}(x) - s(x) - \bar{s}(x)$ data not only allow us to check the predicted x -dependence of the five-quark Fock states, but also provide a determination of the probabilities for these states.

Equations 6 shows that the combined probability for proton to be in the $|uudQ\bar{Q}\rangle$ states is around 40%. It is worth noting that an earlier analysis of the $\bar{d}-\bar{u}$ data in the meson cloud model concluded that proton has $\sim 60\%$ probability to be in the three-quark bare-nucleon state [13], in qualitative agreement with the finding of this study. A significant feature of the present work is the extraction of the $|uuds\bar{s}\rangle$ component, which would be related to the kaon-hyperon states in the meson cloud model. It is also worth mentioning that in the BHPS model the $|uudQ\bar{Q}\rangle$ states have the same contribution to the proton's magnetic moment as the $|uud\rangle$ three-quark state, since Q and \bar{Q} in the $|uudQ\bar{Q}\rangle$ states have no net magnetic moment. Therefore, the good description of the nucleon's magnetic moment by the constituent quark model is preserved even with the inclusion of a sizable five-quark components in the BHPS model.

We note that the probability for the $|uuds\bar{s}\rangle$ state is smaller than those of the $|uudu\bar{u}\rangle$ and the $|uudd\bar{d}\rangle$ states. This is consistent with the expectation that the probability for the $|uudQ\bar{Q}\rangle$ five-quark state is roughly proportional to $1/m_Q^2$ [1, 4]. One can then estimate that the probability for the intrinsic charm from the $|uudc\bar{c}\rangle$ Fock state, $\mathcal{P}_5^{c\bar{c}}$ to be roughly 0.01. This is also consistent with an estimate based on the bag model [14], as well as with an analysis of the EMC charm-production data [15]. Figure 4 shows the x distribution of intrinsic \bar{c} calculated with the BHPS model using $1.5 \text{ GeV}/c^2$ for the mass of the charm quark. Also shown in Fig. 4 is the calculation which evolve the BHPS calculation from the initial scale, $\mu = 0.5 \text{ GeV}$, to $Q^2 = 75 \text{ GeV}^2$, the largest Q^2 scale reached by EMC [16]. It is interesting to note that the intrinsic charm contents at the large x ($x > 0.3$) region are drastically reduced when Q^2 evolution is taken into account. Figure 4 suggests that the most promising region to search for evidence of intrinsic charm could be at the somewhat lower x region ($0.1 < x < 0.4$), rather than the largest x region explored by previous experiments. It is worth noting that we adopt the simple assumption that the initial scale is the same for all five-quark states. It is conceivable that the initial scale for intrinsic charm is significantly higher due to the larger mass of the charmed quark. The dashed curve shows the x

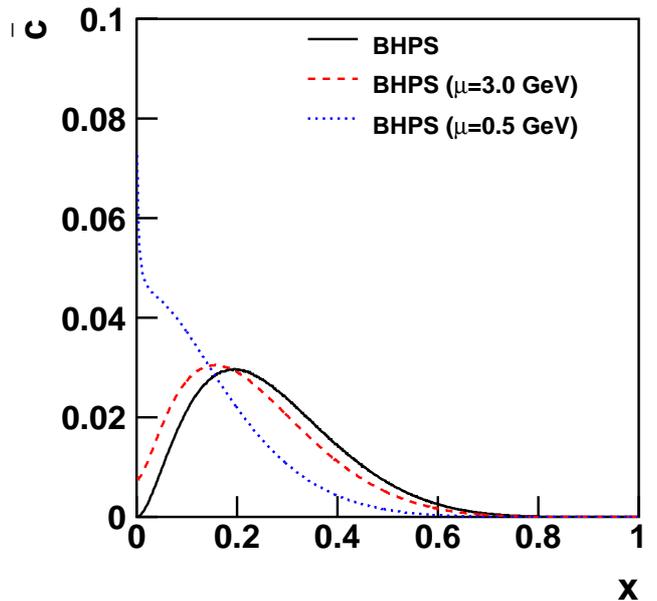

Figure 4: Calculations of the $\bar{c}(x)$ distributions based on the BHPS model. The solid curve corresponds to the calculation using Eq. 1 and the dashed and dotted curves are obtained by evolving the BHPS result to $Q^2 = 75 \text{ GeV}^2$ using $\mu = 3.0 \text{ GeV}$, and $\mu = 0.5 \text{ GeV}$, respectively. The normalization is set at $\mathcal{P}_5^{c\bar{c}} = 0.01$.

distribution of intrinsic \bar{c} at $Q^2 = 75 \text{ GeV}^2$ when the initial scale is set at $\mu = 3 \text{ GeV}$, corresponding to the threshold of producing a pair of charmed quarks. As expected, the shape of the intrinsic \bar{c} x distribution becomes similar to that of the BHPS model.

In conclusion, we have generalized the existing BHPS model to the light-quark sector and compared the calculation with the $\bar{d} - \bar{u}$, $s + \bar{s}$, and $\bar{u} + \bar{d} - s - \bar{s}$ data. The qualitative agreement between the data and the calculations provides strong support for the existence of the intrinsic u , d and s quark sea and the adequacy of the BHPS model. This analysis also led to the determination of the probabilities for the five-quark Fock states for the proton involving light quarks only. This result could guide future experimental searches for the intrinsic c quark sea or even the intrinsic b quark sea [17], which could be relevant for the production of Higgs boson at LHC energies [18].
