Mathematical properties of dynamic systems and their applications
to quantum theory

Eric Tesse

Abstract

While it is widely acknowledged that quantum theory is strange, and that the world view it implies is elusive, there is considerably less consensus as to why this is the case. This article will explore the possibility that the theory may be opaque because the mathematical language it employs is inarticulate. To address this possibility, three interconnected mathematical theories will be developed, each specifically designed to handle aspects of quantum theory’s subject matter. The first will describe dynamic systems in terms that are general enough to be applicable to any kind of dynamics, including both classical and quantum. That description will then be used to construct a theory of experiments, with the aim of understanding what types of experiments scientific methodology allows. Finally, the theory of experiments will found a theory of experimental probabilities applicable to any collection of experiments, so long as their probabilities are internally consistent. The resulting overarching mathematical language will then be applied to quantum physics. In the initial application, it will be used to explain the core nature and structure of quantum measurement and probability. Following that, it will be used to construct a large class of conceptually simple systems that are capable of displaying the full range of quantum behavior. The properties that define this class of systems will be in accord with experimental results, leaving open the possibility that the physical universe may be describable as such a system. The more immediate conclusion, however, will be that systems that possess quantum behavior may be neither strange nor elusive.

Part I

Introduction

Our fascination with quantum physics has as much do to with its strangeness as its success. This strangeness can conjure contradictory responses: on the one hand, the sense that science has dug so deep as to touch upon profound metaphysical questions, and on the other, the sense that something is amiss, as science should strive to uncover simple explanations for seemingly strange phenomena. Fans of the first response will find little of interest in the paper, for it explores the second.

Let’s start by noting that the mathematical language employed by quantum theory was not developed to investigate the types of problems addressed in the theory. Hilbert spaces, for example, were developed to investigate analogies between certain function spaces & Euclidean spaces; they were only later adopted by physicists to describe quantum systems. This is in sharp contrast with classical mechanics. The development of differential calculus was, to a large extent, driven by the desire to describe the observed motion of bodies, the very question with which classical mechanics is concerned. In consequence, it is no exaggeration to say that if a question is well defined within classical mechanics, it can be described using calculus.

In quantum physics, the mathematical language is far less articulate. For example, it leaves unclear what empirical properties a system must possess in order for the quantum description to apply. It is also unclear how, and even whether, the language of quantum theory can be used to describe the experiments employed to test the theory. It is similarly unclear whether and/or how quantum theory can be used to describe the world of our direct experience.

Some of the theory’s inexpressiveness lies closer to the field’s core subject matter. For example, particle paths can be observed in tracking detectors, and those paths can be used to determine particle position and velocity. Such measurements cannot be made with absolute precision, but modern detectors are often impressively precise. The ability to perform these measurements means that experiments are capable of determining joint position & velocity probabilities. For example, using any particle double-slit experimental set-up, together with a tracking detector, the joint position and velocity distribution can be determined up to
the experimental precision. Quantum theory, however, cannot be used to calculate such a distribution; only the unconjoined position distribution and velocity distribution can be calculated. Thus, experiments can yield results that quantum theory cannot calculate.

Considerations such as these raise the question: To what extent are the difficulties of quantum theory due to limitations in our ability to phrase relevant questions in the theory’s mathematical language? If such limitations do play a role, it would not represent a unique state of affairs. As most everyone knows, Zeno’s paradoxes seemed to challenge some of our most basic notions of time and motion, until calculus resolved the paradoxes by creating a clear understanding of the continuum. Somewhat more remotely, the drawing up of annual calendars, and other activities founded on heavenly activity, was once imbued with a mystery well beyond our current awe of quantum physics. With the slow advance of the language and theory of numbers, the mystery waned, until now such activity requires little more than arithmetic.

This article will investigate the question of whether a similar situation exists for quantum physics. Toward that end, three simple mathematical theories will be created. Each will formalize concepts required by physical theory, with the aim of clarifying them. The theories will contain no assumptions beyond those required for formalization; in particular, they will not contain any assumptions about the nature of quantum systems. The resulting mathematical language will then be applied to quantum theory.

This begins in Part II with a general theory of dynamic systems. In order to achieve the required generality, dynamic systems will be defined as any system that can be parametrized by time. To make such a rudimentary notion of dynamics sufficiently expressive, it will be enriched with cut and paste operations, an elementary concept of “knowledge”, and a notation for describing system dynamics.

The resulting language will be applied in Part III to formalize scientific experiments. Dynamic systems will be employed to describe both experimental set-ups as a whole, and the systems whose natures the experiments probe. The analysis will be somewhat analogous to that found in automata theory: A sequence of system states is “read into” the experimental equipment, and as the states are read in, the equipment’s state changes, until it ultimately enters a final state. The final state determines which outcome the sequence of states belongs to. In developing this formalization, we will strive to limit our assumptions to those properties of experiments that are required by the scientific method.
Finally, in Part IV a theory of experimental probability will be given. It will first be argued that the classic rules of probability and statistics hold for any individual experiment. Probability rules will then be derived for any collection of experiments that satisfies the constraint that, if any two experiments in the collection share outcomes, then they agree on those outcomes’ probabilities. This will prove sufficient to develop a theory applicable to both classical and quantum probabilities.

These theories will first be applied in Part V, where the structure of quantum measurements and probabilities will be considered. The focus here will be on sets of experimental outcomes that are structurally guaranteed to have a total probability of 1. The non-additivity of quantum probabilities places limits on which sets of outcomes can have this property, and that in turn limits what kinds of experiments can be performed. To see this, note that if an experiment has outcomes of \( \{X, \neg X\} \), and another has outcomes of \( \{X_1, X_2, \neg X\} \) then \( P(X) + P(\neg X) = 1 = P(X_1) + P(X_2) + P(\neg X) \), and so \( P(X) = P(X_1) + P(X_2) \); if \( P(X) \neq P(X_1) + P(X_2) \) then one of these experiments cannot be performed (the only other possibility being that the probability of a given outcome depends on the make-up of the experiment as a whole, but this is never the case for quantum systems). Applying results from the prior analysis of experiments and experimental probability, we will see that the allowed experiments, and the core structure of quantum probabilities, are precisely what that analysis has lead us to expect. As the only assumptions made in the theory of experiments will be those required by the scientific method, this will be an early indication that quantum physics may not be as wholly strange as it first appears.

In Part VI our mathematical language will be used to construct dynamic systems that display quantum behavior. This will prove to be surprisingly easy. A simple construction will yield a large class of dynamic systems that possess (or are readily compatible with) the properties of non-determinism, momentum conservation, non-additive probabilities, interference effects, observation’s ability to destroy interference, the influence of particle identity on probability, entanglement, diffraction, and tunneling, among others. A non-relativistic version of the construction will be presented first, followed by a relativistic one; the relativistic version will integrate discrete, interactive fields into its description. The final section in this part will take a closer look at quantum probability dynamics, connecting it to earlier results.

It is hoped that this material will help demonstrate that at least some of the baffle-
ment we feel in the face of quantum physics is due to the manner in which we address
the phenomenon, rather than the nature of the phenomena themselves, and that when we
seek rational understanding of perplexing scientific findings, it is helpful to first hone our
mathematical language, in the expectation that this can help bring a clean, uncluttered
perspective to the subject.

Part II

Dynamics

I. PARAMETERS

In this first part, we will consider dynamic systems. Dynamic systems are systems
that can change with time, meaning that in any mathematical description, they will be
parametrized by time. In the interest of completeness, we therefore begin by establishing
the mathematical properties of parameters. The material in this section will likely feel quite
familiar, as it never strays far from the manner in which number theories are generally
constructed. As will be seen shortly, the unusual aspects of parameter theory are that pa-
rameters include scale, and that the theory’s models correspond to all four of the canonical
number systems: the Natural numbers, Integers, Reals, and non-negative Reals. Because
this material so closely mirrors well known mathematics, only a quick sketch will be pre-
sented. If one is interested in filling in the missing details, the axiomization and development
of the Real numbers in almost any textbook on Real analysis ([1], for example) will provide
a complete description of a closely related construction. This section may be skimmed.

Parameters are structures of the form \((\Lambda, <, +, 0)\) that satisfy the following axioms:

Total Ordering:
1) For all \(\lambda \in \Lambda\), \(\lambda \not< \lambda\)
2) For all \(\lambda_1, \lambda_2, \lambda_3 \in \Lambda\), if \(\lambda_1 < \lambda_2\) and \(\lambda_2 < \lambda_3\) then \(\lambda_1 < \lambda_3\)
3) For all \(\lambda_1, \lambda_2 \in \Lambda\), either \(\lambda_1 = \lambda_2\) or \(\lambda_1 < \lambda_2\) or \(\lambda_2 < \lambda_1\)

Additivity:
4) For all \(\lambda \in \Lambda\), \(\lambda + 0 = \lambda\)
5) For all \(\lambda_1, \lambda_2 \in \Lambda\), \(\lambda_1 + \lambda_2 = \lambda_2 + \lambda_1\)
6) For all $\lambda_1, \lambda_2, \lambda_3 \in \Lambda$, $(\lambda_1 + \lambda_2) + \lambda_3 = \lambda_1 + (\lambda_2 + \lambda_3)$

Interrelationship between ordering and addition:

7) For all $\lambda_1, \lambda_2, \lambda_3 \in \Lambda$, $\lambda_1 < \lambda_2$ iff $\lambda_1 + \lambda_3 < \lambda_2 + \lambda_3$

8) For all $\lambda_1, \lambda_2 \in \Lambda$, if $\lambda_1 < \lambda_2$ then there's a $\lambda_3 \in \Lambda$ s.t. $\lambda_1 + \lambda_3 = \lambda_2$

Parameters possess a positive element:

9) There exists a $\lambda \in \Lambda$ s.t. $\lambda > 0$

Multiplication is not defined on parameters. This is because parameters generally have scale (e.g., values of “13 sec”, rather than simply “13”).

A number of basic properties follow immediately from these axioms. For example, it follows from axioms 7 & 8 that parameters are either discrete or dense; they can’t be discrete in some places, and dense in others. It follows from axioms 7, 9, and 4 that parameters are unbounded from above, and from 7 & 4 that if a parameter is bounded from below, its lower bound is 0. It can also be shown that if a parameter is unbounded from below, then every parameter value has an additive inverse.

Parameters may therefore be categorized into four broad classes, based on whether they are discrete or dense, and whether or not they are bounded from below. These four classes contain many types of parameters that will not suit our purposes. For example, the set of numbers whose decimal representation is of finite length is a parameter, as is any uncountable limit ordinal. Neither of these will be useful for parametrizing dynamic systems. We would therefore like to limit our attention to those structures that satisfy two further requirement. First, we are only interested in parameters whose values are finite; this equivalent to assuming that for any $\lambda_2 > \lambda_1 > 0$, there exists an $n \in \mathbb{N}^+$ s.t. $\lambda_1$ added to itself $n$ times is greater than $\lambda_2$. Second, among the dense parameters, we are only interested in those for which all bounded Cauchy sequences converge. Together, these two requirements are equivalent to adding the following axiom:

10) All subsets of $\Lambda$ that are bounded from above have a least upper bound.

This statement is quite strong; each of the four classes of parameters contain only a single element (up to an isomorphism) that satisfies it. These models are closely related to the four canonical number system. This can be seen by selecting a parameter value to represent “1”, and introducing the operation of multiplication by a number:

First, we assign a value to 1. If the parameter is discrete, we assign “1” to be the successor to 0; if it’s dense, we can choose “1” to be any parameter value greater than 0. The choice
of 1 sets the scale.

Now to define multiplication by a number. Define 0\lambda = 0, and for any \( n \in \mathbb{N}^+ \), and any \( \lambda \in \Lambda \), define \( n\lambda \) to be the value of \( \lambda \) added to itself \( n \) times. If the parameter is unbounded from below, then for any \( i \in \mathbb{Z}, i < 0 \), define \( i\lambda \) to be the additive inverse of \( |i|\lambda \). If the parameter is dense and unbounded from below, for any \( \frac{m}{n} \in \mathbb{Q} \), define \( \frac{m}{n}\lambda \) to be the \( \lambda' \) s.t. \( m\lambda' = n\lambda \); if the parameter is bounded from below, limit this operation to \( \frac{m}{n} \in \mathbb{Q}^+ \). Note that, with the inclusion of axiom 10, \( \frac{m}{n}\lambda \) must exist for dense parameters.

Axiom 10 further entails that all dense parameters form a continuum, which means that we ought to be able to multiply dense parameters by real numbers as well. This is defined as follows: For any \( r \in \mathbb{R}\setminus\mathbb{Q} \) (that is, \( r \) is an element of \( \mathbb{R} \), but is not an element of \( \mathbb{Q} \)), if \( r > 0 \land \lambda \geq 0 \) or \( r < 0 \land \lambda \leq 0 \) then chose any increasing sequence of rational numbers, \( q_1, q_2, q_3, ... \), that converges to \( r \), while for all other values of \( r \) and \( \lambda \) choose any decreasing sequence that converges to \( r \). Define \( r\lambda \) to be the least upper bound of \( q_1\lambda, q_2\lambda, q_3\lambda, ... \). It follows from Axiom 10 that \( r\lambda \) exists. It can also be shown that the value of \( r\lambda \) is independent of the choice of \( q_i \)’s.

This completes the definition of multiplication by the various types of numbers. Given these, it can be shown that the four types of parameters may be constructed as follows:

If \((\Lambda, <, +, 0)\) is discrete and bounded from below, then \( \Lambda = \{ n1 : n \in \mathbb{N} \} \), if it’s discrete and unbounded from below, \( \Lambda = \{ i1 : i \in \mathbb{Z} \} \), if it’s dense and unbounded from below \( \Lambda = \{ r1 : r \in \mathbb{R} \} \), and if it’s dense and bounded from below \( \Lambda = \{ r1 : r \in \mathbb{R}^+ \} \). In all cases \( x_11 + x_21 = (x_1 + x_2)1 \) and \( x_11 > x_21 \) iff \( x_1 > x_2 \).

Thus, the above 10 axioms yield precisely the 4 required parameters. In what follows, parameters will generally be represented by their set of values, \( \Lambda \), rather than by their full structure, \((\Lambda, <, +, 0)\).

II. STATE TRANSITIONS

The second, and final, step towards a formal definition of dynamic systems involves viewing system dynamics in terms of state transitions. For a dynamic system we may ask: If a system is in state \( s_1 \) at time \( \lambda_1 \), what states can it be in at time \( \lambda_2 \)? If \( s_2 \) is among the states that it may be in at \( \lambda_2 \), then the system can transition from \((\lambda_1, s_1)\) to \((\lambda_2, s_2)\). We can represent this allowed transition as \((\lambda_1, s_1) \Rightarrow (\lambda_2, s_2)\).
We can almost capture the notion of allowed transitions using this simple binary “⇒” relation, however for some dynamic systems, something may be missing. Let’s say that \((\lambda_1, s_1)\) can transition to \((\lambda_2, s_2)\), \((\lambda_2, s_2)\) can transition to \((\lambda_3, s_3)\) and \((\lambda_1, s_1)\) can transition to \((\lambda_3, s_3)\). Does this imply that \((\lambda_1, s_1)\) can transition to \((\lambda_3, s_3)\) via \((\lambda_2, s_2)\)? To extend the “⇒” notation, does \((\lambda_1, s_1) \Rightarrow (\lambda_2, s_2), (\lambda_2, s_2) \Rightarrow (\lambda_3, s_3)\), and \((\lambda_1, s_1) \Rightarrow (\lambda_3, s_3)\) imply \((\lambda_1, s_1) \Rightarrow (\lambda_2, s_2) \Rightarrow (\lambda_3, s_3)\)? Armed with only the binary transition relation, there is no way to answer (or even ask) this question. To handle it, we introduce transition chains.

If \(\Lambda\) is a system’s time parameter, and \(\mathcal{P}\) its set of states, then a transition chain, \(T\), is comprised of elements of \(\Lambda \times \mathcal{P}\) s.t. the system can pass through each element of \(T\) in succession. In the above example, if \((\lambda_1, s_1) \Rightarrow (\lambda_2, s_2) \Rightarrow (\lambda_3, s_3)\) is allowed, then \(\{(\lambda_1, s_1), (\lambda_2, s_2), (\lambda_3, s_3)\}\) is a transition chain for the system. Transition chains are subject to the restriction that if \(T\) is a transition chain, \((\lambda_1, s_1), (\lambda_2, s_2) \in T\), and \((\lambda_1, s_1) \neq (\lambda_2, s_2)\), then \(\lambda_1 \neq \lambda_2\). This means that a chain cannot contain more than one element at any one time. Note that if \(T\) is a transition chain, and \(T' \subset T\), then \(T'\) is also a transition chain.

Let’s say that \(T = \{(\lambda_1, s_1), (\lambda_2, s_2), (\lambda_3, s_3)\}\) is a transition chain, and that there does not exist any chain, \(T'\), s.t. \(T \subsetneq T'\). This must mean that at all other times, there are no states that the system can transition to, and so for this set of transitions, the system only exists at times \(\lambda_1\), \(\lambda_2\), and \(\lambda_3\). In such cases, we can enhance our set of system states to include a state for non-existence, say \(\eta\); if the system is in state \(\eta\) at time \(\lambda\), it means that the system doesn’t exist at \(\lambda\). With the inclusion this state, then in the above example, there will exist a transition chain \(T'\) s.t. \(T \subsetneq T'\), and for all \(\lambda\) not in \(T\), \((\lambda, \eta) \in T'\). Thus, if the set of states is made sufficiently inclusive, every transition chain will be a subset of some “maximal” chain that possesses an element at each time.

Define a system path as a total function from \(\Lambda\) onto \(\mathcal{P}\) (the set of states) whose graph is a transition chain. A path’s graph is a maximal transition chain, and a maximal transition chain is the graph of a path. Specifying a system’s transition chains is therefore equivalent to specifying its set of possible paths. For this reason, we will describe dynamic systems in terms of sets of paths.

11
III. DYNAMIC SETS & SPACES

**Definition 1.** A *dynamic set*, $S$, is a non-empty set of functions s.t. for some parameter, $\Lambda$, all elements of $S$ have $\Lambda$ as their domain.

Elements of dynamic sets are referred to as a *paths*. They will be distinguished by an over bar: $\bar{p}$.

If $S$ is a dynamic set:

For any $\bar{p} \in S$, $\Lambda_S \equiv Dom(\bar{p})$. That is, $\Lambda_S$ is the parameter that all elements of $S$ share.

$\mathcal{P}_S \equiv \bigcup_{\bar{p} \in S} Ran(\bar{p})$; $\mathcal{P}_S$ is the set of *states*.

For $\lambda \in \Lambda_S$, $S(\lambda) \equiv \{ p \in \mathcal{P}_S : \text{for some } \bar{p} \in S, \ \bar{p}(\lambda) = p \}$. $S(\lambda)$ is the set of possible states at time $\lambda$.

$\text{Uni}[S] \equiv \{(\lambda,p) \in \Lambda_S \otimes \mathcal{P}_S : p \in S(\lambda)\}$; $\text{Uni}[S]$ is the “universe” of $S$, the set of all allowed time-state pairs.

Dynamic sets encapsulate our basic concepts of system dynamics. They provide a broad enough foundation to encompass the various kinds of “weird” dynamics seen in quantum systems. The remainder of this part will be devoted to investigating dynamic sets. To aid in the investigation, we start by defining two rudimentary operations, the first one slices paths into pieces, while the second pastes the pieces together.

**Remark.** We will use the common representation for parameter intervals, with rounded parenthesis used for open end points, and square brackets for closed end points. Thus, $(\lambda_1, \lambda_2)$ is the set of all $\lambda$ s.t. $\lambda_1 < \lambda < \lambda_2$; $(\lambda_1, \lambda_2]$ is the set of all $\lambda$ s.t. $\lambda_1 < \lambda \leq \lambda_2$, etc.

For unbounded intervals, “$\infty$” is used in place of an endpoint; for example, $(-\infty, \lambda_1]$ is the set of all $\lambda$ s.t. $\lambda \leq \lambda_1$. If the parameter is bounded from below, $[-\infty, \lambda] = [0, \lambda]$.

**Definition 2.** For dynamic set $S$:

If $\bar{p} \in S$, and $[x_1, x_2]$ is a closed interval of $\Lambda_S$, then $\bar{p}[x_1, x_2]$ is $\bar{p}$ restricted to domain $[x_1, x_2]$ (values of $x_1 = -\infty$ and/or $x_2 = \infty$ are allowed.)

$S[x_1, x_2] \equiv \{ \bar{p}[x_1, x_2] : \bar{p} \in S \}$

If $\bar{p}_1, \bar{p}_2 \in S$, $\lambda \in \Lambda_S$, and $\bar{p}_1(\lambda) = \bar{p}_2(\lambda)$, then $\bar{p}_1[x_1, \lambda] \circ \bar{p}_2[\lambda, x_2]$ is the function on domain $[x_1, x_2]$ s.t.:

$$\bar{p}_1[x_1, \lambda] \circ \bar{p}_2[\lambda, x_2](\lambda') = \begin{cases} 
\bar{p}_1(\lambda') & \text{if } \lambda' \in [x_1, \lambda] \\
\bar{p}_2(\lambda') & \text{if } \lambda' \in [\lambda, x_2] 
\end{cases}$$
If $A$ and $B$ are sets of partial paths from $S$ then

$$A \circ B \equiv \{ \bar{p}_1[x_1, \lambda] \circ \bar{p}_2[\lambda, x_2] : \bar{p}_1[x_1, \lambda] \in A, \bar{p}_2[\lambda, x_2] \in B, \text{ and } \bar{p}_1(\lambda) = \bar{p}_2(\lambda) \}$$

We will refer to the “$\circ$” operation as concatenation. For any dynamic set, $S$, any $\lambda \in \Lambda_S$, $S \subset S[-\infty, \lambda] \circ S[\lambda, \infty]$. An interesting property that a dynamic set may possess is closure under concatenation, i.e., for all $\lambda \in \Lambda_S$, $S = S[-\infty, \lambda] \circ S[\lambda, \infty]$. A dynamic set with this property is called a dynamic space. The definition is equivalent to: If $D$ is a dynamic set, it is a dynamic space if and only if for all $\lambda \in \Lambda_D$, all $\bar{p}_1, \bar{p}_2 \in D$ s.t. $\bar{p}_1(\lambda) = \bar{p}_2(\lambda)$, $\bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in D$ (as a rule, we will denote a dynamic space with a “$D$” rather than an “$S$”). The distinguishing characteristic of dynamic spaces is that the current state always contains sufficient information to fully determine the collection of possible future paths, meaning that information from the system’s past never further restricts the system’s collection of possible futures.

Closed systems will always be assumed to be dynamic spaces. This is because, for a closed system, nothing external to the system can record information about it, so the only available information of the system’s past is contained in the present state. Note that because a system being experimented on interacts with experimental equipment, it is not closed, and so may not be a dynamic space.

Some other significant properties of dynamic sets involve how their dynamics may change with time. A dynamic set, $S$, is homogeneous if for all $\bar{p} \in S$, all $\lambda_1, \lambda_2 \in \Lambda_S$ s.t. $(\lambda_2, \bar{p}(\lambda_1)) \in \text{Uni}[S]$, there’s a $\bar{p}' \in S$ s.t. for all $\lambda \in \Lambda_S$, $\bar{p}'(\lambda) = \bar{p}(\lambda + \lambda_1 - \lambda_2)$ (if $\lambda_1 < \lambda_2$, and $\Lambda_S$ is bounded from below, then we instead demand that for all $\lambda \in \Lambda_S$, $\bar{p}(\lambda) = \bar{p}'(\lambda + \lambda_2 - \lambda_1)$). $\bar{p}'$ is a time-shifted copy of $\bar{p}$. Homogeneity therefore ensures that the system’s behavior is the same regardless of when it enters a given state. This is not quite enough to say that the dynamic set does not change with time; for that you also need to assert that the system’s states may be entered at any time. A system state, $p \in \mathcal{P}_S$, is homogeneously realized if for all $\lambda \in \Lambda_S$, $p \in S(\lambda)$. Similarly, $A \subset \mathcal{P}_S$ is homogeneously realized if every element of $A$ is homogeneously realized. Thus, a dynamic set’s dynamics does not change with time if it is homogeneous, and $\mathcal{P}_S$ is homogeneously realized.
A number of interpretations of quantum mechanics posit that quantum systems exhibit their unusual behavior because they take all available paths. The introductory material presented in the prior section is equally applicable to systems that take individual paths, and systems that simultaneously take all available paths. This will continue to be the case in all that follows.

It should be noted, however, that some difficulty is encountered in the intermediate case, systems that can simultaneously take multiple paths, but may not necessarily take every path. Such a system cannot be described in terms of a single dynamic set. Instead, it would be described by a collection of dynamic sets, each element in the collection corresponding to a set of paths that the system can simultaneously execute. Because the algebra of paths and algebra of dynamic sets are similar, extending the existing formalism to include collections of dynamics sets is fairly straightforward. For example, we can define a second concatenation operator, "·", whose action on dynamic sets is analogous to o's action on paths: If $S_1$ and $S_2$ are dynamic sets, and $S_1(\lambda) = S_2(\lambda)$, then $S_1[x_1, \lambda] \cdot S_2[\lambda, x_2] = S_1[x_1, \lambda] \circ S_2[\lambda, x_2]$; if $S_1(\lambda) \neq S_2(\lambda)$ then $S_1[x_1, \lambda] \cdot S_2[\lambda, x_2]$ is undefined. If $X$ and $Y$ are collections of dynamic sets, then $X[x_1, \lambda] \cdot Y[x_1, \lambda] \equiv \{S_1[x_1, \lambda] \cdot S_2[\lambda, x_2] : S_1 \in X, S_2 \in Y and S_1(\lambda) = S_2(\lambda)\}$.

Unfortunately, this added flexibility would come at a cost, as even seemingly simple concepts can grow complicated. For example, consider the statement "I know that the system was in state $p$ at time $\lambda". If the closed system is described by dynamic set, this is easy to interpret, it means that all paths that pass through my current state passed through system state $p$ at $\lambda$. If, however, the system is described in terms of a collection of dynamic sets, $X$, then the statement, as it stands, is unclear. It may mean that I know the system to be in an $S \in X$ s.t. $S(\lambda) = \{p\}$, or it could mean that the system in some $S \in X$ s.t. $p \in S(\lambda)$. In the second case, I may also be making the further claim that among those $S \in X$, I experience the subset of paths that pass through $p$ at $\lambda$. Each of these possible meanings may be valid in some context, in which case we would have to be able to express each of them simply and unambiguously.

To avoid such complications, system dynamics will continue to be described in terms of dynamic sets, which ought to be sufficient to cover all cases of interest.
V. KNOWLEDGE

An interesting (and important) question is, given that a system is in state \( p \), what is known about the system’s past, and what is known about its future? Let’s start by introducing some notation:

**Definition 3.** If \( S \) is a dynamic set and \( p \in \mathcal{P}_S \)

\[
S_{\rightarrow p} \equiv \{ \bar{p}[\cdot, \lambda] : \bar{p} \in S \text{ and } \bar{p}(\lambda) = p \}
\]

\[
S_{p\rightarrow} \equiv \{ \bar{p}[\lambda, \cdot] : \bar{p} \in S \text{ and } \bar{p}(\lambda) = p \}
\]

For \( X \subset \mathcal{P}_S \)

\[
S_{\rightarrow X} \equiv \{ \bar{p}[\cdot, \lambda] : \bar{p} \in S \text{ and } \bar{p}(\lambda) \in X \} = \bigcup_{p \in X} S_{\rightarrow p}
\]

\[
S_{X\rightarrow} \equiv \{ \bar{p}[\lambda, \cdot] : \bar{p} \in S \text{ and } \bar{p}(\lambda) \in X \} = \bigcup_{p \in X} S_{p\rightarrow}
\]

Thus, \( S_{\rightarrow p} \) is the set of all semi-paths that terminate at state \( p \), and \( S_{p\rightarrow} \) is the set of all semi-paths that start at \( p \). Broadly speaking, if a system is in state \( p \), \( S_{\rightarrow p} \) is what the system “knows” about its past, and \( S_{p\rightarrow} \) is what it knows about its future. Similarly, if a component of the system knows that the system must in some state in the set \( X \) (e.g., \( X \) is the set of states containing the component’s current state), then \( S_{\rightarrow X} \) is what it knows about what has happened, and \( S_{X\rightarrow} \) is what it knows about what will happen.

This will provide our formal definition of knowledge: If a component of a system is in state \( s \), and \( X \) is the set of system states that contain \( s \), then \( S_{\rightarrow X} \) is what that component “knows” about the system’s past, and \( S_{X\rightarrow} \) is what it knows about the system’s future. This definition is in keeping with the common assumptions that all “knowledge” a system possesses at a given time is encoded in its state. For example, it is generally assumed that everything a person knows about the past and future is encoded in their physical brain state. The assumption certainly holds for computers, where all memory is encoded in the states of their various memory devices.

Often, when we speak of things we know to have happened, we say things like “I know I took my keys this morning”. “\( S_{\rightarrow X} \)” alone cannot capture such a sentiment. To formalize this kind of statement, we take the above definitions one step further:

**Definition 4.** If \( S \) is a dynamic set and \( X, Y \subset \mathcal{P}_S \)

\[
S_{\rightarrow Y \rightarrow X} \equiv \{ \bar{p}[\cdot, \lambda] \in S_{\rightarrow X} : \text{for some } \lambda' \leq \lambda, \ \bar{p}(\lambda') \in Y \}
\]

\[
S_{X \rightarrow Y \rightarrow} \equiv \{ \bar{p}[\lambda, \cdot] \in S_{X \rightarrow} : \text{for some } \lambda' \geq \lambda, \ \bar{p}(\lambda') \in Y \}
\]
$S_{\rightarrow Y \rightarrow X}$ is the set of semi-paths that pass through $Y$ and terminate at $X$. If you know that the system’s current state is in $X$, and $S_{\rightarrow X} = S_{\rightarrow Y \rightarrow X}$, then you know that $Y$ happened; similarly, if $S_{X \rightarrow} = S_{X \rightarrow Y \rightarrow}$ then you know that $Y$ is going to happen. Thus, for example, if $X$ is the set of all world states that containing your current brain state (or those portions of your brain state utilized for memory), then you’d be justified is claiming that you know $Y$ happened if $S_{\rightarrow X} = S_{\rightarrow Y \rightarrow X}$. Of course, there is a conceivable scenario in which I clearly remember taking my keys this morning, and my brain is in a state it would be in if I had taken my keys, but there is a path that passes through this brain state along which I didn’t take my keys. In this case $S_{\rightarrow X} \neq S_{\rightarrow Y \rightarrow X}$ (where $X$ are world states that contain my current brain state, and $Y$ are the states in which I take my keys), and my subjective sense of certain knowledge is not justified.

Note that, while we expect there to be a correlation between our subjective sense of knowledge, and knowledge as defined here when applied to our physical state, we do not demand that the two must be identical. In so far as they are different, our subjective knowledge may be said to lack certainty.

The above notation can be extended further. For example, we can define $S_{\rightarrow (\lambda,Y) \rightarrow X} \equiv \{\bar{p}[-\infty, \lambda'] \in S_{\rightarrow X} : \lambda' \geq \lambda \text{ and } \bar{p}(\lambda) \in Y\}$, meaning that $S_{\rightarrow (\lambda,Y) \rightarrow X}$ the set of all semi-paths that pass though $Y$ at $\lambda$ and terminate at $X$. If the system’s current state is in $X$, and $S_{\rightarrow X} = S_{\rightarrow (\lambda,Y) \rightarrow X}$, then we know that $Y$ happened at time $\lambda$.

Assertions like $S_{\rightarrow X} = S_{\rightarrow Y \rightarrow X}$ will be central to our formalization of experiments. Interestingly, there is little difference between the expression for the knowledge that $Y$ has happened, $S_{\rightarrow X} = S_{\rightarrow Y \rightarrow X}$, and the expression for knowing that $Y$ will happen, $S_{X \rightarrow} = S_{X \rightarrow Y \rightarrow}$. In reality, however, these two types of knowledge are quite different. We know a great deal more about what has happened than what will happen. This is not peculiar to us; as we dig into the earth, we uncover information about prehistoric life and past civilizations, but learn next to nothing about future life and future civilizations. In a sense, like us, the earth also remembers its past, but does not know its future. Perhaps the most elemental example of this asymmetry occurs when we peer into the night time sky, and can see stars as they existed in the past, but not as they will be in the future. This is because we receive light from heavenly bodies, and so information about them, along only the backward light cone.

Why that may be the case will not concern us here. Experiments, by their nature, must reliably record events that have occurred. We will therefore be interested in what we know
of the past, given our current state. Other activities, such as setting an alarm clock, reliably cause events to occur in the future. That will be of less concern here.

A. A Final Word on Ontology

In the prior section, it was asserted that the formalism being developed will be able to describe systems that simultaneously take all available paths. In the current section, knowledge has been defined in a way that appears to require the system state to be in a subset of the set of available states. To see how this may be reconciled with the prior claim, it only needs to be noted that we don’t experience the world as a multiplicity of simultaneous states, we experience the world as a succession of individual states. In the definition of knowledge, the states used in the expressions may be understood to be the states that we experience, regardless of whether a system takes an individual path, or all available paths.

This however, raises the question of whether common experience rules out the possibility that the world may simultaneously take all available paths. While this question has little to no bearing on the concerns of this article, it may be of some general interest. For this reason, an answer will be attempted.

“Multi-path” dynamics can be squared with our experience of individual world states by making three rudimentary assumptions. The first is that everything that we experience, we experience as part our consciousness. This is so obviously true it hardly qualifies as an “assumption”, yet it may cause some discomfort, in part because, as a term, “consciousness” nearly impossible to define, while as a concept, it can be distressingly difficult to discuss. Fortunately, we only require one further assumption about consciousness, and that is that conscious states are mirrored in our brain states. That is, we assume that if you know the physical state of a person’s brain (as well as how to interpret it), then you know what that person is sensing, thinking, and feeling.

Our third assumption is that aspects of a person’s physical brain state mirror the state of the world. For example, if someone is petting her dog, we assume this fact is registered in her brain state, and if her brain state later contains the information “a few minutes ago, I petted my dog”, it is because a few minutes ago, she petted her dog.

Now imagine that the universe simultaneously takes all possible paths. In one of these paths, I’m drinking coffee, and in another, tea. These differences are reflected in different
brain states, which are in turn reflected in different conscious states. I don’t simultaneously experience drinking coffee and tea; instead, on one path I have the experience of drinking coffee, and in the other, I have the experience of drinking tea.

Taking this one step further, let’s imagine a device that measures the position of an electron. The electron and measuring device takes all possible paths. In so far as the measuring device is operational, the electron path and the device’s path are not independent; for the measurement to be correct, the state of the device must mirror the state of the electron. Say that on one path the electron is in one position, causing the measuring device to enter some state, and on another path, the electron is at a different position, causing the measuring device to enter a different state. On the first path, I will see the device in one state, on the other, in a different state. Therefore, whenever the electron’s position is measured, I always see a result corresponding to the electron being at a single position, even if the electron takes all possible paths.

VI. DYNAMIC SET NOTATION

In the prior section, a notation for describing sets of paths, such as $S \rightarrow Y \rightarrow X$, was introduced. This notation will prove to be very useful. In this section, it will be fleshed it out.

1. Single Condition Path Expressions

If $S$ is a dynamic set, and $X \subset \mathcal{P}_S$, $S \rightarrow X \rightarrow$ is the set of all elements of $S$ that pass through $X$:

$$S \rightarrow X \rightarrow \equiv \{ \bar{p} \in S : \text{for some } \lambda \in \Lambda_S, \bar{p}(\lambda) \in X \}.$$

2. Adding Conditions

Further sets of states may always be added to a chain of events. Thus, for example, $S \rightarrow X \rightarrow Y \rightarrow Z \rightarrow$ is the set of paths that pass through $X$, then $Z$, and then $Y$. Explicitly:

$$S \rightarrow X \rightarrow Y \rightarrow Z \rightarrow \equiv \{ \bar{p} \in S : \text{for some } \lambda_1 \leq \lambda_2 \leq \lambda_3, \bar{p}(\lambda_1) \in X, \bar{p}(\lambda_2) \in Y, \text{and } \bar{p}(\lambda_3) \in Z \}$$
3. **End Arrows**

We can switch between sets of paths, semi-paths, and path segments by adding and removing end arrows from the subscript. For example, if $X$ and $Y$ are sets of states, $S_{\rightarrow X \rightarrow Y}$ is the set of semi-paths that pass through $X$ and end at $Y$, while $S_{X \rightarrow Y}$ is the related set of path segments that run from $X$ to $Y$. Explicitly:

$$S_{X \rightarrow Y} \equiv \{ \bar{p}[\lambda_1, \lambda_2] : \bar{p} \in S, \bar{p}(\lambda_1) \in X, \text{ and } \bar{p}(\lambda_2) \in Y \}$$

$$S_{\rightarrow X \rightarrow Y} \equiv \{ \bar{p}[\lambda, \lambda_2] : \bar{p} \in S \text{ and for some } \lambda_1 \leq \lambda_2, \bar{p}[\lambda_1, \lambda_2] \in S_{X \rightarrow Y} \}$$

$$S_{X \rightarrow Y \rightarrow} \equiv \{ \bar{p}[\lambda_1, \infty] : \bar{p} \in S \text{ and for some } \lambda_2 \geq \lambda_1, \bar{p}[\lambda_1, \lambda_2] \in S_{X \rightarrow Y} \}$$

Note that the expressions for $S_{\rightarrow X \rightarrow Y}$ and $S_{X \rightarrow Y \rightarrow}$ given here are equivalent to the ones given in the prior section.

4. **Adding Time**

To any set of states, time may be added, indicating paths that pass through the set of states at the given time. For example $S_{X \rightarrow (\lambda,Y) \rightarrow Z}$ is the set of partial-paths that start at $X$, pass through $Y$ at time $\lambda$, and terminate at $Z$:

$$S_{X \rightarrow (\lambda,Y) \rightarrow Z} \equiv \{ \bar{p}[\lambda_0, \lambda] \in S_{X \rightarrow Z} : \lambda_0 \leq \lambda \leq \lambda_1 \text{ and } \bar{p}[\lambda_0, \lambda_1](\lambda) \in Y \}$$

5. **Extended Time Conditions**

Let’s say we want to specify that between the time a path passes through $A$, and the time it passes through $B$, it is always in the set of states $Z$. We do so by using the following notation:

$$S_{A \rightarrow |Z| \rightarrow B} = \{ \bar{p}[\lambda_1, \lambda_2] \in S_{A \rightarrow B} : \text{for all } \lambda \in (\lambda_1, \lambda_2), \bar{p}(\lambda) \in Z \}$$

For end arrows:

$$S_{A \rightarrow |Z| \rightarrow} = \{ \bar{p}[\lambda_1, \infty] \in S_{A \rightarrow} : \text{for all } \lambda > \lambda_1, \bar{p}(\lambda) \in Z \}$$

and similarly for $S_{\rightarrow |Z| \rightarrow A}$.

Thus any $\rightarrow$ can be replaced with $\rightarrow |Z| \rightarrow$, the bracketed set specifying the range of states available for the trip.

The remaining rules help to simplify the notation under various circumstances.
6. Extended Time Conditions, Pt 2

In the expression $S_{A \to |Z| \to B}$, $|Z|$ applies to open interval between $A$ and $B$. There may, however, be times when we want it to apply to one or both of the end points. To specify this, we replace “|” with “∥”.

For example: $S_{A \to |Z| \parallel \to B} \equiv \{ \bar{p}[\lambda_1, \lambda_2] \in S_{A \to B} : \text{for all } \lambda \in (\lambda_1, \lambda_2), \bar{p}(\lambda) \in Z \}$ (compare with the definition of $S_{A \to |Z| \to B}$). This may be written in terms of prior notation as $S_{A \to A \parallel \to B} = S_{A \cap B} \cup S_{A \to |Z| \to B \cap Z}$, where $S_{A \cap B}$ contains the paths in which $A$ and $B$ occur simultaneously (and so the $|Z|$ condition doesn’t apply), and $S_{A \to |Z| \to B \cap Z}$ contributes the paths in which $A$ occurs before $B$.

Similarly, $S_{A \to A \parallel \to |Z| \parallel \to B} \equiv \{ \bar{p}[\lambda_1, \lambda_2] \in S_{A \to B} : \text{for all } \lambda \in [\lambda_1, \lambda_2], \bar{p}(\lambda) \in Z \}$ is equal to $S_{A \cap B} \cup S_{A \cap Z \to |Z| \to B}$. Finally, $S_{A \to A \parallel \to |Z| \parallel \to B} \equiv \{ \bar{p}[\lambda_1, \lambda_2] \in S_{A \to B} : \text{for all } \lambda \in [\lambda_1, \lambda_2], \bar{p}(\lambda) \in Z \}$ is simply $S_{A \cap Z \to |Z| \to B \cap Z}$.

Expressions of this form will come in handy in when discussing experiments.

7. States

When a set of states contains only a single state, $X = \{p\}$, we may use $p$ rather than $\{p\}$. For example, rather than $S_{X \to (\lambda, \{p\})}$, we may write $S_{X \to (\lambda, p)}$

8. Promoting the Subscript

When the dynamic set is understood, or unimportant, we may simply denote the subscript. For example, we may write $X \to (\lambda, Y) \to p$ in place of $S_{X \to (\lambda, Y) \to p}$.

9. Negation

Sometimes we wish to specify what does not happen, rather than what does happen. This is fairly straightforward; to specify that $Z$, does not occur, simply specify that $\mathcal{P}_S \setminus Z$ does occur. For example, to say that path $\bar{p}$ doesn’t pass through $X$ simply say $\bar{p} \in \to |\mathcal{P}_S \setminus X| \to$. To make this easier to read, for any $X \subset \mathcal{P}_S$ define $\tilde{X} \equiv \mathcal{P}_S \setminus X$. The prior expression then becomes $\bar{p} \in \to |\tilde{X}| \to$. 

20
Part III

Experiments

In this part, experiments will be formalized. The formalization will be somewhat analogous to automata theory. There, a sequence of characters is read into an automata, which then determines whether the sequence corresponds to a sentence in a given language. One of the goals of automata theory is to determine what types languages the various kinds of automata are capable of deciding. Experiments are similar: System paths are “read into” an experimental set-up, which then determines which outcome each path belongs to. As in automata theory, one of our goals will be to determine the sets of outcomes that experiments are capable of deciding.

As discussed in the Introduction, if experimental probabilities are not additive, it generally means that there are limitations to what sorts of experiments that can be performed. The question of allowed experiments is therefore foundational to quantum physics. By the end of this part, we will have a strong understanding of the nature of the allowed experiments, and in Part VII we will demonstrate that these experiments are indeed the set of experiments that are consistent with quantum probability (subject to the limitations of the quantum probability calculus).

Another goal of this part will be to eliminate any mystery surrounding “external observers” in quantum measurement. In considering experiments, we will investigate the dynamics of the closed systems that includes the system being experimented on, along with the experimental equipment, the experimenter, etc. Any “external observers” are only external to the system being experimented on; they are included in the closed dynamic spaces that we will be investigating. This view will prove useful in Part VI where we will construct dynamic spaces that exhibit quantum properties.

VII. SHELLS

In this first section, we consider the closed dynamic space that encompasses both the system being experimented on and all experimental apparatus (including the experimenter). We use this dynamic space to enforce some of the basic dynamic properties of experiments,
namely, that experiments are re-runnable, have a clearly defined start, once started they must complete, and once complete, they “know” that the experiment occurred.

To formalize these requirements we can define experimental shells as triples, \((D, I, F)\), where \(D\) is a dynamic space, \(I \subseteq P_D\) is the set of initial states, and \(F \subseteq P_D\) is the set of final states. We can start by assuming that these satisfy:

1) \(D\) is homogeneous
2) \(I\) is homogeneously realized
3) \(I \rightarrow = I \rightarrow F \rightarrow\)
4) \(\rightarrow F = \rightarrow I \rightarrow F\)

The first two of the above statements ensure that the experiment is reproducible, the third ensures that when an experiment starts, it must complete, and the fourth ensures that when the experiment completes, you know that an experiment took place. This appears to be sufficient for our stated needs. However, as currently phrased, there is some ambiguity as to when the experiment starts, and what it “knows” once it completes.

As things stand, a shell can enter initial states multiple times before it enters a final state, and can enter a succession of final states at the experiment’s completion. This raises a question as to when the experiment actually starts, and when it ends. For the latter, we will make the obvious assumption that an experiment ends as soon as it enters a final state. A path may continue to be in final states after it first encounters a final state, but once the first encounter is made, the experimental run has completed.

The situation is less clear for initial states. If an experiment enters initial states multiple times before entering a final state, when does the experiment start? Let’s begin by assuming that the experiment can restart without first entering a final state; this is equivalent to assuming that the start need not correspond to the first time the shell enters an initial state. Such a restart has the effect of throwing away information - you ignore everything that happen between the first initial state, and the actual start. We may assume, without loss of generality, that the only reason to do this is if the initial data is, in some sense, bad; for example, the measuring equipment was not fully warmed up or operational, or the system being experimented on was not in a desired initial state. Any good data may always be considered as part of the experimental outcome, including any data that we may choose to ignore in our later analysis of the outcome. We therefore assume that any restart is because, at an earlier start, the data collection was flawed. But if we are not yet collecting
good data, then it’s fair to say that we have not yet entered into an experimental start state; everything being operational ought to be a prerequisite for being an experimental start state. We therefore reject our earlier assumption, and assume that the experiment starts the first time it enters an initial state.

We have not yet ruled out the possibility that the shell may enter an initial state after the experiment starts, and before it enters a final state; we have only said that this ought not correspond to the experiment restarting. However, allowing the experiment to enter initial states after it starts is awkward. This would be akin to allowing the experiment to enter a final state prior to the experiment actually ending (e.g., taking the end of the experiment to be the last time the experiment enters a final state, rather than the first time). To avoid confusion, we assume that an experiment only enters an initial state when it starts, and doesn’t enter a final state until it ends. In practice, this is not difficult to achieve. When the conditions of an experimental start is reached, the initial state can be tagged as such; for example, a clock timing the experiment may be set to 0. This tagging allows us to clearly identify when the experiment started.

Due to these considerations, we will require that after an experiment enters an initial state, it cannot re-enter the set of initial state until after it has entered a final state (any such re-entry corresponding to a new run of the experiment). This is equivalent to strengthening statement (3) from $I \rightarrow = I \rightarrow F \rightarrow$ to $I \rightarrow = I \rightarrow |\tilde{I}| \rightarrow F \rightarrow$ (see Sec VI for definitions of “$\tilde{I}$” and “$|\tilde{I}|$”). In this expression, “$|\tilde{I}|$” is used rather than “$|\tilde{I}|$” for cases in which $I \cap F \neq \emptyset$. We take $p \in I \cap F$ to represent an experimental run that stops as soon as it begins, providing a snapshot of the state of the system at the time state $p$ was entered. This is allowed, but such a state should not be reachable during a different experimental run. If we were to assume $I \rightarrow = I \rightarrow |\tilde{I}| \rightarrow F \rightarrow$, rather than $I \rightarrow = I \rightarrow |\tilde{I}| \rightarrow F \rightarrow$, then for $p_1 \in I \setminus F$, $p_2 \in I \cap F$, $p_1 \rightarrow |\tilde{I}| \rightarrow p_2 \rightarrow$ may be non-empty, in which case $p_2$ is the final state of two experimental runs, one starting at $p_1$, and the other at $p_2$. As discussed earlier, $I \rightarrow |\tilde{I}| \rightarrow F \rightarrow = (I \cap F \rightarrow) \cup (I \rightarrow |\tilde{I}| \rightarrow F \setminus I \rightarrow)$, so using “$|\tilde{I}|$” eliminates precisely this scenario.

One final, somewhat subtle, difficulty needs to be dealt with. There remain scenarios in which a final state cannot be paired with any particular experimental run. For example, consider a semi-path, $\bar{p}[\infty, 0] \in \rightarrow F$, s.t. for all $n \in \mathbb{N}^+$, $\bar{p}(\frac{1}{2n}) \in I$ and $\bar{p}(\frac{1}{2n+1}) \in F$; this satisfies all shell axioms, but the $F$ state at $\lambda = 0$ is not the final state of any particular
experiment. This is because between \( \bar{p}(0) \in F \) and any earlier \( I \), there’s another \( I \), meaning that between any run of the experiment and \( (0, \bar{p}(0)) \) there’s another experimental run. As we always want final states to “know” about the experimental run that has just completed, final states must always occur at the end of some particular experimental run. To ensure this, we strengthen statement (4) from \( \rightarrow F = \rightarrow I \rightarrow F \) to \( \rightarrow F = \rightarrow I \rightarrow I \parallel \rightarrow F \). This eliminates the above scenario. As always, the “\( \parallel \)” is for cases where \( I \cap F \neq \emptyset \).

We now have the complete definition of an experimental shell:

**Definition 5.** A shell is a triple, \( (D, I, F) \), where \( D \) is a dynamic space, \( I, F \subset \mathcal{P}_D \) are the sets of initial and final states, and these satisfy:

1) \( D \) is homogeneous

2) \( I \) is homogeneously realized

3) \( I \rightarrow = I \rightarrow |I| \rightarrow F \rightarrow \)

4) \( \rightarrow F = \rightarrow I \rightarrow |I| \rightarrow F \)

With the start and stop properties of experiments in place, we can turn our attention to what happens during an experiment. To help extract this information from the shell, we begin by defining the following set of partial paths:

**Definition 6.** If \( S \) is a dynamic set, and \( X, Y \subset \mathcal{P}_S \) then

\[
S_{X/Y} \equiv \{ \bar{p} [\lambda_1, \lambda_2] : \bar{p} [\lambda_1, \infty] \in S_{X \rightarrow Y \rightarrow}, \text{ and } \lambda_2 = \inf(\bar{p}^{-1}[\lambda_1, \infty]|Y]) \}
\]

In the above definition, \( \lambda_2 \) is either the first time \( Y \) occurs in \( \bar{p} [\lambda_1, \infty] \) or, if the “first time” can’t be obtained in the continuum, the moment before \( Y \) first appears. For shell \( (D, I, F) \), \( D_{I/F} \) is the set of partial-paths representing what can happen during the course of the experiment. As sets of this form will be of some importance, the following definition and theorem will prove useful:

**Definition 7.** If \( S \) is a dynamic set and \( X, Y \subset \mathcal{P}_S \),

\[
(X/Y) \equiv \{ p \in \mathcal{P}_S : \text{for some } \bar{p} [\lambda_1, \lambda_2] \in S_{X/Y}, \ p = \bar{p}(\lambda_2) \}
\]

This means that elements in \( (X/Y) \) are the end points of the paths in \( S_{X/Y} \).

**Theorem 8.** If \( D \) is a homogeneous dynamic space then \( D_{X/Y} = X \rightarrow |Y| \rightarrow (X/Y) \)
Proof. If \( \tilde{p}[\lambda_1, \lambda_2] \in D_{X/Y} \) then \( \tilde{p}(\lambda_1) \in X, \tilde{p}(\lambda_2) \in (X/Y) \), and for all \( \lambda \in [\lambda_1, \lambda_2] \), \( \tilde{p}(\lambda) \notin Y \), so \( D_{X/Y} \subset X \to \|\tilde{Y}\| \to (X/Y) \). (Note that this doesn’t require \( D \) to be homogeneous, or a dynamic space.)

It remains to show that \( X \to \|\tilde{Y}\| \to (X/Y) \subset D_{X/Y} \). Take \( \tilde{p}[\lambda_1, \lambda_2] \in X \to \|\tilde{Y}\| \to (X/Y) \), \( p \equiv \tilde{p}(\lambda_2) \in (X/Y) \). By the definition of \( (X/Y) \), there’s a \( \tilde{p}'[\lambda_3, \infty] \in p \) s.t. \( \lambda_3 = \inf(\tilde{p}'[\lambda_3, \infty]^{-1}[Y]) \). By homogeneity, there’s a \( \tilde{p}'' \) s.t. for all \( \lambda \in \Lambda_D \), \( \tilde{p}''(\lambda) = \tilde{p}'(\lambda + \lambda_3 - \lambda_2) \) (assuming \( \lambda_3 \geq \lambda_2 \) or \( \Lambda_D \) is unbounded from below; otherwise \( \tilde{p}'(\lambda) = \tilde{p}''(\lambda + \lambda_2 - \lambda_3) \) may be asserted for all \( \lambda \in \Lambda_D \)). By considering \( \tilde{p}[\lambda_1, \lambda_2] \circ \tilde{p}''[\lambda_2, \infty] \), it follows that \( \tilde{p}[\lambda_1, \lambda_2] \in D_{X/Y} \). \( \square \)

If \((D, I, F)\) is a shell, \( D \) is a homogeneous dynamic space, and so \( I \to \|\tilde{F}\| \to (I/F) \) represents what can happen during the course of the experiment. With this in mind, we introduce the following sets of experimental states and paths:

**Definition 9.** If \( Z = (D, I, F) \) is a shell:

\[
\text{Int}(Z) = \{ p \in \mathcal{P}_D : I \to \|\tilde{F}\| \to p \neq \emptyset \} \text{ is the shell interior.}
\]

\[
\text{Dom}(Z) \equiv F \cup \text{Int}(Z) \text{ is the shell domain}
\]

If \( A \subset \text{Dom}(Z) \), \( \omega_A \equiv (0, I) \to \|\tilde{I}\| \to A \)

If \( A \subset F \), \( \Theta_A \equiv \{ \tilde{p}[0, \lambda] \in D_{I/F} : \text{for some } \tilde{p}'[0, \lambda'] \in \omega_A, \tilde{p}'[0, \lambda] = \tilde{p}[0, \lambda] \} \)

The first two definitions identify sets of experimental states. The first set, the shell interior, consists of states that the shell can enter while the experiment is in progress. In words, \( I \to \|\tilde{F}\| \to p \) means that \( p \) can be reached from \( I \) prior to \( F \) being reached (or when \( F \) is first reached). From Thm 8 together with shell axiom 3, it follows that \( \text{Int}(Z) \) contains precisely the states in \( D_{I/F} \). The second set, the shell domain, consists of all states of interest with regard to the experiment.

The second two definitions identify sets of experimental paths. Given that our current state is in \( A \), \( \omega_A \) tells what has happened since the experiment started. Because shell dynamics are homogeneous, and \( I \) is homogeneously realized, it is sufficient only consider paths that start at \( \lambda = 0 \). Finally, given that the shell is in \( A \subset F \), \( \Theta_A \) captures what occurred during the experiment just run. It’s important to note that this is all that can be known about what happened. If, for example, we know that the initial state was in \( Y \subset I \), this is because for any \( p \in I \setminus Y, p \to \|\tilde{I}\| \to A = \emptyset \), and so this fact is reflected in \( \Theta_A \).
Note too that the experimenter herself is part of the dynamic space, so if she knows that
the experiment started in \( Y \) because she remembers it, and this ought to be reflected in \( A \).

VIII. RECORDERS

In this section, we split the shell into a system and its environment. By making several
assumptions about the interrelationship between these two, the shell will take on the char-
acter of an experiment in which the system is observed, and the environment (or parts of
the environment) performs those observations and records the results.

A. Environmental Shells

Before splitting the shell into a system and its environment, a little added notation will
be helpful. If \( X \times Y \) is a Cartesian product, and \( A \subset X \times Y \), the projection of \( A \) onto \( X \)
will be written as \( X \cdot A \), so \( X \cdot A = \{ x \in X : \text{for some } y \in Y, \ (x, y) \in A \} \); similarly for
projections onto \( Y \). For any path, \( \bar{p} \), s.t. \( \text{Ran}(\bar{p}) \subset X \times Y \), \( X \cdot \bar{p} \) is the projection of \( \bar{p} \) onto
\( X \), meaning that for all \( \lambda \in \Lambda \), \( (X \cdot \bar{p})(\lambda) = X \cdot (\bar{p}(\lambda)) \); similarly for projections onto \( Y \), and
for projections of sets of paths onto \( X \) and \( Y \). “Environmental shells” may now be defined.

Definition 10. A shell, \( Z = (D, I, F) \), is an environment shell if there exist sets, \( E \) and
\( S \), s.t.

1) \( \text{Dom}(Z) \subset S \times E \)

2) \( E \cdot \text{Dom}(Z) = E \) and \( S \cdot \text{Dom}(Z) = S \)

3) With \( F \equiv E \cdot F \), \( F = (S \times F) \cap \mathcal{P}_D \)

The first assertion states that the shell consists of a system and its environment, the
second that \( E \) & \( S \) have no excess states, and the third that whether or not you are in a
final state can be determined entirely by the environmental state, which is in keeping with
the assumption that the experimental equipment resides in the environment.

Strictly speaking, environmental shells are structures with signature \( (D, I, F, S, E) \). How-
ever, it is unwieldy to always have to specify all these sets, so we will fix a standard notation
for environmental shells. For environmental shell \( Z \), \( D \) will refer to the shell’s dynamic space,
\( I \) to its initial states, \( F \) to its final states, \( S \) to its system states, \( E \) to its environmental
states, and $\mathcal{F}$ will always be $\mathcal{E} \cdot F$. If we need to specify which shell $I$ (for example) belongs to, we add a subscript identifying the shell: $I_Z$.

Having isolated the system within the shell domain, we may now formally define experimental outcomes:

**Definition 11.** If $Z$ is an environmental shell, and $X \subset \mathcal{F}$, $\mathcal{O}_X \equiv S \cdot \Theta_{S \times X}$

If an experiment was run, a record was kept of what was measured over the course of the run, and $X \subset \mathcal{F}$ is the set of environmental states containing that record, then $\mathcal{O}_X \equiv S \cdot \Theta_{S \times X}$ is what we know to have occurred in the system during the experiment.

This raises a somewhat subtle point. One of the reasons to run an experiment is to try to discover the nature of a system’s dynamics. However, a shell contains a dynamic space that includes the system’s dynamics, which appears to imply that we already know what the system dynamics are. To resolve the apparent conflict, it is best to view $\mathcal{O}_\mathcal{F}$ as containing all system paths considered possible prior to running the experiment. When we run an experiment, we have to assume that we understand the workings of the experimental setup, otherwise we won’t know what the state of the experimental apparatus tells us about what happened in the system being experimented on. $\mathcal{D}$ only needs to reflect that understanding.

In general, we expect the actual set of allowed paths for the closed system to be a subset of the shell’s dynamic space, $\mathcal{D}$.

Returning to experimental outcomes, $\mathcal{O}_X$ tells us what happened during the experiment once it has completed. The following two sets of system paths give us a view into what is happening while the experiment is in flight:

**Definition 12.** If $A \subset \text{Int}(Z)$:

$$\Sigma_A \equiv S \cdot [(0, I) \to \| \tilde{F} \| \to A]$$

$$\Sigma_{A \to} \equiv \{ \tilde{s}[\lambda_1, \lambda_2] : \text{for some } \tilde{p}[0, \lambda_2] \in \Theta_F, \tilde{p}(\lambda_1) \in A \land \tilde{s}[\lambda_1, \lambda_2] = S \cdot \tilde{p}[\lambda_1, \lambda_2] \}.$$ 

$\Sigma_A$ gives the system paths from $I$ to $A$. It is what you know about what has transpired in the system during the experiment, given that you know that the current state of $\mathcal{D}$ is in $A$. $\Sigma_{A \to}$ gives the system paths from $A$ through to the end of the experiment.

**Theorem 13.** $\Sigma_{(I/F)} = \mathcal{O}_\mathcal{F}$

*Proof.* $\mathcal{O}_\mathcal{F} = S \cdot \Theta_F$. $\Theta_F$ is the set of $\tilde{p}[0, \lambda] \in D_{I/F}$. Since $D_{I/F} = I \to \| \tilde{F} \| \to (I/F)$, $\Theta_F = (0, I) \to \| \tilde{F} \| \to (I/F)$. Therefore $\mathcal{O}_\mathcal{F} = S \cdot [(0, I) \to \| \tilde{F} \| \to (I/F)] = \Sigma_{(I/F)}$. 

27
In order for an environmental shell to behave as a well-constructed experiment, the interactions between the system and its environment must respect some constraints. It is to these that we now turn.

B. Unbiased Conditions

In an experiment, the system’s environment ought not influence the experimental outcome; an environmental shell is unbiased if this is the case. In its strongest form, this demands that different environmental states cannot effect the system differently. Naively, this may be written: For any pair of states sharing the same system state, \((s, e_1), (s, e_2) \in \text{Int}(Z)\), \(\Sigma_{(s, e_1) \to} = \Sigma_{(s, e_2) \to}\). However, because in general \(\Sigma_{(s, e_1)} \neq \Sigma_{(s, e_2)}\), the elements of \(\Sigma_{(s, e_1) \to}\) and \(\Sigma_{(s, e_2) \to}\) may terminate at different times. A further complication is that, within \(\Theta_F\), \((s, e_1)\) and \((s, e_2)\) may not be realized at the same times; because \(\mathcal{O}_F\) does not need to be homogeneous, if \((s, e_1)\) and \((s, e_2)\) are realized at different times, they need not have similar \(\Sigma_{(s, e_i) \to}\)’s. These considerations lead to a definition whose wording is more convoluted, but whose meaning is essentially the same.

**Definition 14.** An environmental shell is strongly unbiased if for every \(\lambda \in \text{Dom}(\Theta_F)\), every \((s, e_1), (s, e_2) \in \Theta_F(\lambda)\), \(s_1[\lambda, \lambda_1] \in \Sigma_{(s, e_1) \to}\) iff there exists a \(s_2[\lambda, \lambda_2] \in \Sigma_{(s, e_2) \to}\) s.t., with \(\lambda' \equiv \text{Min}(\lambda_1, \lambda_2)\), \(s_1[\lambda, \lambda'] = s_2[\lambda, \lambda']\).

This condition means that any effect the environment may have on the system can be incorporated into the system dynamics, allowing the system to be comprehensible without having to explicitly reference its environment. The following theorem shows that if an environmental shell is strongly unbiased, \(\mathcal{O}_F\) behaves like a dynamic space.

**Theorem 15.** If an environmental shell is strongly unbiased, for every \(\bar{s}_1[0, \lambda_1], \bar{s}_2[0, \lambda_2] \in \mathcal{O}_F\), if \(\bar{s}_1(\lambda) = \bar{s}_2(\lambda)\) (\(\lambda \leq \lambda_1\) and \(\lambda \leq \lambda_2\)), then there exists a \(\bar{s}_1[0, \lambda] \circ \bar{s}_3[\lambda, \lambda_3] \in \mathcal{O}_F\) s.t., with \(\lambda_m \equiv \text{Min}(\lambda_2, \lambda_3)\), \(\bar{s}_3[\lambda, \lambda_m] = \bar{s}_2[\lambda, \lambda_m]\).

**Proof.** First note that, regardless of whether the environmental shell is unbiased, for any \(p \in \text{Int}(Z)\), if \(\bar{s}[0, \lambda] \in \Sigma_p\) and \(\bar{s}'[\lambda, \lambda'] \in \Sigma_{p \to}\) then \(\bar{s}[0, \lambda] \circ \bar{s}'[\lambda, \lambda'] \in \mathcal{O}_F\). This is because \(p\) is a state of the closed system, and the closed system is a dynamic space.

Now let’s turn to the case stated in the theorem. With \(s = \bar{s}_1(\lambda)\), for some \(e_1, e_2 \in \mathcal{E}\), \(\bar{s}_1[0, \lambda] \in \Sigma_{(s, e_1)}\) and \(\bar{s}_2[\lambda, \lambda_2] \in \Sigma_{(s, e_2) \to}\). Since the shell is unbiased, there is a \(\bar{s}_3[\lambda, \lambda_3] \in \mathcal{O}_F\),
By the considerations of the prior paragraph, $\bar{s}_1[0, \lambda] \circ \bar{s}_3[\lambda, \lambda_3] \in \mathcal{O}_F$.

There are experiments for which the strong unbiased condition fails, but the experiment is still accepted as valid. Consider the case in which a particle’s position is measured at time $\lambda_1$, and if the particle is found to be in region $A$, the particle’s spin will be measured along the y-axis at $\lambda_2$, and if particle is not in region $A$, the spin will be measured along the z-axis at $\lambda_2$. Assume that there are a pair of particle paths, $\bar{s}_1$ and $\bar{s}_2$, s.t. $\bar{s}_1$ is in region $A$ at $\lambda_1$, $\bar{s}_2$ is not in region $A$ at $\lambda_1$, and for some $\lambda \in (\lambda_1, \lambda_2)$, $\bar{s}_1(\lambda) = \bar{s}_2(\lambda)$. $\bar{s}_1[-\infty, \lambda] \circ \bar{s}_2[\lambda, \infty]$ is not a possible path because a particle can’t be in region $A$ at $\lambda_1$ and have its spin polarized along the z-axis at $\lambda_2$. Therefore the set of particle paths is not a dynamic space. Since the strong unbiased condition ensures that the system can be described by a dynamic space, that condition must have failed.

To see the problem, assume that if the particle takes path $\bar{s}_1$, the environmental shell will be in state $(s, e_1)$ at $\lambda$, whereas if it takes path $\bar{s}_2$ it will be in state $(s, e_2)$ at $\lambda$. $e_1$ and $e_2$ determine different futures for the particle: $e_1$ ensures that the spin will be measured along the y-axis at $\lambda_2$ while $e_2$ ensures that the spin will be measured along the z-axis. This violates the strong unbiased condition. However, it doesn’t necessarily create a problem for the experiment because $e_1$ and $e_2$ “know” enough about the particle’s past to know $s_1[-\infty, \lambda]$ and $s_2[-\infty, \lambda]$ must reside in separate outcomes (one belongs to the set of “in $A$ at $\lambda_1$” outcomes, the other to the set of “not in $A$ at $\lambda_1$” outcomes). Once paths have been differentiated into separate outcomes, they may be treated differently by the environment. This motivates a weak version of the unbiased condition, one that only holds when $(s, e_1)$ and $(s, e_2)$ have not yet been differentiated into separate outcomes.

To formulate this weaker version, we need to understand the conditions under which two states in $\text{Int}(Z)$ are fated to result in different outcomes. We start by capturing what is known about experimental outcomes as of some time $\lambda$. This concept will prove to be of broad value.

**Definition 16.** For environmental shell $Z$, $e \in \mathcal{F}$, $\lambda \geq 0$

- $|\mathcal{O}_e[0, \lambda]|_0 \equiv \mathcal{O}_e[0, \lambda]$
- $|\mathcal{O}_e[0, \lambda]|_{n+1} \equiv \{\bar{s}[0, \lambda] : \text{for some } e' \in \mathcal{F}, \mathcal{O}_{e'}[0, \lambda] \cap |\mathcal{O}_e[0, \lambda]|_n \neq \emptyset, \& \bar{s}[0, \lambda] \in \mathcal{O}_{e'}[0, \lambda]\}$
- $|\mathcal{O}_e[0, \lambda]| \equiv \bigcup_{n \in \mathbb{N}} |\mathcal{O}_e[0, \lambda]|_n$
If \( s[0, \lambda] \in |O_e[0, \lambda]| \) and \( s'[0, \lambda] \in O_F \setminus |O_e[0, \lambda]| \), then \( s[0, \lambda] \) and \( s'[0, \lambda] \) are heading to different outcomes. To extend this to the states in \( Int(Z) \), we use the following theorem:

**Theorem 17.** For environmental shell \( Z \), given any \( e, e' \in F \), and any \( \lambda \in \Lambda_D \) s.t. \( O_{e'}[0, \lambda] \cap |O_e[0, \lambda]| = \emptyset \), for all \( p \in Int(Z) \), if \( \Sigma_p \cap |O_e[0, \lambda]| \neq \emptyset \) then \( \Sigma_p \cap O_{e'}[0, \lambda] = \emptyset \)

**Proof.** Take any \( O_{e'}[0, \lambda] \) s.t. \( \Sigma_p \cap O_{e'}[0, \lambda] \neq \emptyset \). For this to hold, there must then be a \( \bar{p}[\lambda, \lambda'] \in (\lambda, p) \rightarrow |\bar{I}| \rightarrow e'' \). Remembering that \( \Sigma_p = S \cdot [((0, I) \rightarrow |\bar{I}|) \rightarrow p] \), and that \( \mathbb{D} \) is a dynamic space, it then follows that for any \( s[0, \lambda] \in \Sigma_p \), \( s[0, \lambda] \in O_{e'}[0, \lambda] \). Because \( \Sigma_p \cap |O_e[0, \lambda]| \neq \emptyset \), it follows from the definition of \( |O_e[0, \lambda]| \) that \( O_{e'}[0, \lambda] \subset |O_e[0, \lambda]| \). \( \square \)

Thus, a \( \Sigma_p \) can only intersect a single \( |O_e[0, \lambda]| \); all paths in \( \Sigma_p \) that are not elements of \( |O_e[0, \lambda]| \) end at times other than \( \lambda \). We can now define when two states are undifferentiated:

**Definition 18.** For environmental shell, \( Z \), \( p, p' \in Int(Z) \) are undifferentiated at \( \lambda \) if for some \( e \in F \), \( \Sigma_p \cap |O_e[0, \lambda]| \neq \emptyset \) and \( \Sigma_{p'} \cap |O_e[0, \lambda]| \neq \emptyset \).

By Thm 17, if \( p_1 \& p_2 \) are undifferentiated at \( \lambda \), and \( p_2 \& p_3 \) are undifferentiated at \( \lambda \), then \( p_1 \& p_3 \) are undifferentiated at \( \lambda \). The definition therefore divides the elements of \( \Theta_F(\lambda) \) into equivalence classes. We can now define the weak unbiased condition in the same way as the strong condition, except that it only applies to undifferentiated states.

**Definition 19.** An environmental shell is weakly unbiased if for every \( \lambda \in Dom(\Theta_F) \), every \( (s, e_1), (s, e_2) \in \Theta_F(\lambda) \) s.t. \( (s, e_1) \) and \( (s, e_2) \) are undifferentiated at \( \lambda \), \( s_1[\lambda, \lambda_1] \in \Sigma_{(s, e_1)} \) if there exists a \( s_2[\lambda, \lambda_2] \in \Sigma_{(s, e_2)} \) s.t., with \( \lambda' \equiv \text{Min}(\lambda_1, \lambda_2) \), \( s_1[\lambda, \lambda'] = s_2[\lambda, \lambda'] \).

If the weakly unbiased condition holds, the system may not behave like a dynamic space. However, the following weak version of Thm 15 does hold.

**Theorem 20.** For any weakly unbiased environmental shell, for every \( s_1[0, \lambda_1] \in O_F \), every \( \lambda \leq \lambda_1 \), if \( s_1[0, \lambda], s_2[0, \lambda] \in |O_e[0, \lambda]| \) (for some \( e \in F \)), and \( s_1(\lambda) = s_2(\lambda) \), then there exists a \( s_2[0, \lambda] \circ s_1[\lambda, \lambda_2] \in O_F \) s.t., with \( \lambda_m \equiv \text{Min}(\lambda_1, \lambda_2) \), \( s[\lambda, \lambda_m] = s_1[\lambda, \lambda_m] \).

**Proof.** Choose \( e_1, e_2 \in E \) s.t. \( s_2[0, \lambda] \in \Sigma_{(s, e_2)} \), \( s_1[\lambda, \lambda_1] \in \Sigma_{(s, e_1)} \), and \( \Sigma_{(s, e_1)} \cap |O_e[0, \lambda]| \neq \emptyset \). Note that \( \Sigma_{(s, e_2)} \cap |O_e[0, \lambda]| \neq \emptyset \). Such \( e_1 \) and \( e_2 \) must exist because \( s_1[0, \lambda], s_2[0, \lambda] \in |O_e[0, \lambda]| \). \( (s, e_1) \) and \( (s, e_2) \) are undifferentiated, and so the proof now proceeds similarly to that for Thm 15. \( \square \)
C. Recorders & Decidability

Weakly unbiased environmental shells represent our base formalization of experiment. Due to their environment’s ability to record events without actively participating in them, we refer to them as “recorders”:

**Definition 21.** A *recorder* is a weakly unbiased environmental shell.

We now consider what a recorder can tell us about its system. As things stand, recorders only give us information about what occurs in the dynamic set shard \( O_F \). As we would like to represent the system being experimented on by a full dynam ics set, we would like to be able to translate recorder outcomes into information about dynamic sets. To do so, we start with the following definitions:

For any set of partial paths, \( A \), any dynamic set, \( S \), define \( S \rightarrow A \rightarrow \equiv \{ \bar{p} \in S : \text{for some } \bar{p}[x_1, x_2] \in A, \bar{p}[x_1, x_2] = \bar{p}'[x_1, x_2] \} \), and similarly for \( S_A \rightarrow \) and \( S \rightarrow A \).

For any recorder, any \( \lambda \in \Lambda_D \), \( A \subset F \), and \( X \subset F \), define \( \Theta^\lambda_A \) and \( \Theta^\lambda_X \) to be the analogues of \( \Theta_A \) and \( \Theta_X \) for experiments that start at time \( \lambda \) rather than 0. Formally, this means \( \Theta^\lambda_A \equiv \{ \bar{p}[\lambda, \lambda'] \in I/F : \text{for some } \bar{p}'[\lambda, \lambda''] \in (\lambda, I) \rightarrow [\bar{I}] \rightarrow A, \bar{p}'[\lambda, \lambda'] = \bar{p} \} \), and \( \Theta^\lambda_X \equiv S \cdot \Theta^\lambda_S \times X \). Because \( \bar{D} \) is homogeneous and \( I \) is homogeneously realized, \( \Theta^\lambda_A \) and \( \Theta^\lambda_X \) are simply \( \Theta_A \) and \( \Theta_X \) shifted by \( \lambda \).

Finally, if \( X \) is a set, \( C \) is a covering of \( X \) if it is a collection of nonempty subsets of \( X \) and \( \bigcup C = X \). (Note: it is more common to demand that \( X \subset \bigcup C \); the restriction to \( \bigcup C = X \) will allow for some mild simplification.) \( C \) is a partition of \( X \) if it is a pairwise disjoint covering.

With these, we can state what records reveal about a system’s dynamic set:

**Definition 22.** A covering, \( K \), of dynamic set \( S \) is decided by recorder \( Z \) if for some \( \lambda \in \Lambda_S \), \( K = \{ S \rightarrow \Theta^\lambda_F : e \in \mathcal{F} \text{ and } S \rightarrow \mathcal{O}^\lambda \neq \emptyset \} \).

We do not demand that every partial path in \( \mathcal{O}^\lambda_F \) must correspond to some path in \( S \). This is because, as mentioned above, we allow \( \mathcal{O}^\lambda_F \) to be overstuffed with paths. If we wish every element of \( \mathcal{O}^\lambda_F \) to correspond to a path in \( S \), we add the condition “for every \( \bar{s} \bar{\lambda}, \lambda' \in \mathcal{O}^\lambda_F, \bar{s} \bar{\lambda}, \lambda' \in S \bar{\lambda}, \lambda' \).”

In general, recorders decide coverings rather than partitions. It is often more natural to think of experimental outcomes as partitioning the set of experimental paths, rather than
covering it. Fortunately, from any covering, a partition may be derived. To do so, we’ll extend the definition of $|O_e[0, \lambda]|$ given above.

**Definition 23.** If $K$ is a covering of a dynamic set, and $\alpha \in K$:

$$|\alpha[\lambda_1, \lambda_2]|_0 \equiv \alpha$$

$$|\alpha[\lambda_1, \lambda_2]|_{n+1} \equiv \{s[\lambda_1, \lambda_2] : \text{for some } \beta \in K, \beta[\lambda_1, \lambda_2] \cap |\alpha[\lambda_1, \lambda_2]|_n \neq \emptyset, \& s[\lambda_1, \lambda_2] \in \beta[\lambda_1, \lambda_2]\}$$

$$|\alpha[\lambda_1, \lambda_2]| \equiv \bigcup_{n \in \mathbb{N}} |\alpha[\lambda_1, \lambda_2]|_n$$

$$|K[\lambda_1, \lambda_2]| = \{|\alpha[\lambda_1, \lambda_2] : \alpha \in K\}$$

Finally, $|\alpha| \equiv |\alpha[-\infty, \infty]|$ and $|K| \equiv |K[-\infty, \infty]|$

$|\alpha[-\infty, \lambda]|$ and $|K[-\infty, \lambda]|$ will come in handy shortly, but for now we only need $|\alpha|$ and $|K|$. $|K|$ is clearly a partition, and is the most fine grained partition that can be formed from $K$. If $Z$ decides $K$, then for any $x \in |K|$, every run of $Z$ will determine whether or not $x$ occurred.

There is an important sense in which the above definition of decidability can be considered to be too broad. Closed systems are always dynamic spaces, so if a system is described by a dynamic set that is not a dynamic space, this is due to interactions with its environment. In the above definition, interactions between the system and the environment are regulated via the unbiased condition while the experiment is taking place, but before and after the experiment, any kind of interactions are allowed, even those that would undermine the autonomy of the system. It is more sensible to assume that these interactions are always unbiased. Indeed, if we make the natural assumption that the system and environment don’t interact at all outside of the experiment, then it follows immediately that the interactions are always unbiased.

To formalize this, we note that if nothing is measured prior to $\lambda$, then prior to $\lambda$ there is no distinction between being weakly & strongly unbiased and so Thm 15 ought to hold, and from $\lambda$ onward, Thm 20 ought to hold. This gives us:

**Definition 24.** If $S$ is a dynamic set, $K$ is a covering of $S$, and $\lambda \in \Lambda_S$, $S$ is unbiased with respect to $(\lambda, K)$ if

1) For all $\lambda' \leq \lambda$, $S = S[-\infty, \lambda'] \circ S[\lambda', \infty]$

2) For all $a \in K$, all $\lambda' > \lambda$, all $\bar{p}_1, \bar{p}_2 \in S[a[-\infty, \lambda']] \rightarrow$, if $\bar{p}_1(\lambda') = \bar{p}_2(\lambda')$ then $\bar{p}_1[-\infty, \lambda'] \circ \bar{p}_2[\lambda', \infty] \in S$.  

32
This effectively enforces the unbiased condition for all times. With it, we are in a position to define a more rigorous form of decidability.

**Definition 25.** A covering, \( K \), of dynamic set \( S \) is *properly decided* by recorder \( Z \) if, for some \( \lambda \in \Lambda_S \), \( S \) is unbiased with respect to \( (\lambda, K) \) and \( K = \{ S_{\rightarrow O_{\lambda_0}} : e \in F \land S_{\rightarrow O_{\lambda} e} \neq \emptyset \} \).

If \( S \) is a dynamic space then \( S \) is unbiased with respect to any \( (\lambda, K) \), so for dynamic spaces, “decidable” and “properly decidable” are identical.

The following holds trivially:

**Theorem 26.** If covering \( K \) of dynamic set \( S \) is properly decided by a recorder, then

1) There’s a \( \lambda_0 \in \Lambda_S \) s.t. for all \( \alpha \in K \), all \( \lambda \leq \lambda_0 \), \( \alpha = S[-\infty, \lambda] \circ \alpha[\lambda, \infty] \)

2) For all \( \alpha \in K \) there’s a \( \lambda_\alpha \in \Lambda_S \) s.t. \( \alpha = S_{\alpha[-\infty, \lambda_\alpha]} \rightarrow \)

**IX. IDEAL RECORDERS**

For many purposes, recorders are a weak of a construction. In particular, recorders do not allow us to draw a clean distinction between two different types of uncertainty: uncertainty about the system given complete knowledge of the environment (intrinsic uncertainty), and uncertainty about the state of the environment, particularly with regard to knowing precisely which \( e \in F \) occurred (extrinsic uncertainty). Practically speaking, it is often necessary to treat these two separately. The matter is particularly pressing in quantum theory, because there these two types of uncertainty are associated with two different methods for calculating probability.

In this section, two properties will be introduced that together will remove the ambiguity between these types of uncertainty. No further refinements to recorders that will be required.

**A. All-Reet Recorders**

It is possible for the environment to record a piece of information about the system at one time, and then later “forget” it, so that it is not ultimately reflected in the experimental outcome. This would lead to ambiguity as to how to describe the final outcome. For example, if at time \( \lambda \) the environment records whether the system is in region \( A \), \( B \), or \( C \), but by the end of the experiment, the final environmental state can only reveal whether the system
was in region $A \cup B$ or $C$, should the first outcome be understood to be “$A \cup B$” (intrinsic uncertainty), or “$A$ or $B$” (extrinsic uncertainty), or something distinct from either?

To eliminate this ambiguity, we introduce recorders that never forget. Let’s start by noting that if $\mathcal{E} \cdot \Theta_e$ has only one element, then the outcome, $\mathcal{O}_e$, has retained all the information ever gained about the system. For example, if $\mathcal{E} \cdot \Theta_e = \{ \bar{e}[0, \lambda] \}$, and $\bar{e}[0, \lambda](\lambda') = e'$, then final state, $e$, knows that the environment was in state $e'$ at time $\lambda'$, and so knows everything about the system that was known by the environment at time $\lambda'$. This rule may be generalized: if $\Theta_e = (\mathcal{S} \cdot \Theta_e) \times (\mathcal{E} \cdot \Theta_e) = \mathcal{O}_e \times (\mathcal{E} \cdot \Theta_e)$, then every environmental path contains the same information about the system, so even if final state $e$ does not know precisely which environmental path was taken, it has still retained all information that was gathered about the system (see Thm 34).

Turning this around, let’s assume that $\Theta_e \neq (\mathcal{S} \cdot \Theta_e) \times (\mathcal{E} \cdot \Theta_e)$. There are then $\bar{e}[0, \lambda], e'[0, \lambda] \in \mathcal{E} \cdot \Theta_e$ that are paired with different sets of system paths. In this case, the final state has forgotten information about the system that it gathered as it passed along one of these paths. This leads us to define recorders that never lose information about the system as:

**Definition 27.** A recorder is all-reet if for every $e \in \mathcal{F}$, $\Theta_e = (\mathcal{S} \cdot \Theta_e) \times (\mathcal{E} \cdot \Theta_e)$.

An all-reet recorder is all retaining; once an all-reet recorder records a bit of information about the system, it never forgets it. The next theorem enumerates some useful properties of all-reet recorders:

**Theorem 28.** If $Z$ is an all-reet recorder then:

1) For every $e \in \mathcal{F}$, every $\bar{s}_1[0, \lambda_1], \bar{s}_2[0, \lambda_2] \in \mathcal{O}_e$, $\lambda_1 = \lambda_2$

2) For every $p \in \text{Int}(Z)$, every $\bar{s}_1[0, \lambda_1], \bar{s}_2[0, \lambda_2] \in \Sigma_p$, $\lambda_1 = \lambda_2$

3) Assume $\bar{s}[0, \lambda_e] \in \mathcal{O}_e$. For every $e \in \mathcal{F}$, every $\lambda \in [0, \lambda_e]$, $\mathcal{O}_e = \mathcal{O}_e[0, \lambda] \circ \mathcal{O}_e[\lambda, \lambda_e]$

**Proof.** 1) Immediate from $\Theta_e = \mathcal{O}_e \times (\mathcal{E} \cdot \Theta_e)$

2) Follows from (1), and the fact that $\mathbb{D}$ is a homogeneous dynamic space

3) $\Theta_e = \mathcal{O}_e \times (\mathcal{E} \cdot \Theta_e)$, so if $\bar{s}_1[0, \lambda], \bar{s}_2[0, \lambda] \in \mathcal{O}_e$ there’s a $\bar{e}[0, \lambda] \in \mathcal{E} \cdot \Theta_e$ s.t.

$(\bar{s}_1[0, \lambda], \bar{e}[0, \lambda]), (\bar{s}_2[0, \lambda], \bar{e}[0, \lambda]) \in \Theta_e$. Since $\mathbb{D}$ is a dynamic space, if $\bar{s}_1[0, \lambda](\lambda') = \bar{s}_2[0, \lambda](\lambda'), (\bar{s}_1[0, \lambda'] \circ \bar{s}_2[\lambda', \lambda], \bar{e}[0, \lambda]) \in \Theta_e$. □

34
Using part 1 of the above theorem, for any outcome, $\mathcal{O}_e$, of an all-right recorder, we can define $\Lambda(\mathcal{O}_e)$ so that if $\bar{s}[0, \lambda] \in \mathcal{O}_e$ then $\Lambda(\mathcal{O}_e) \equiv \lambda$. Part 3 could then be written: For every $e \in \mathcal{F}$, every $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, $\mathcal{O}_e = \mathcal{O}_e[0, \lambda] \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)]$.

### B. Boolean Recorders

The most obvious example of the blurring of intrinsic and extrinsic uncertainty occurs when recorders decide coverings that are not partitions. To complete the disentanglement of intrinsic and extrinsic uncertainty, we therefore consider the property that ensures recorders decide partitions.

**Definition 29.** A recorder is **Boolean** if for any $e, e' \in \mathcal{F}$, either for all $\bar{s}[0, \lambda] \in \mathcal{O}_e$, $\bar{s}'[0, \lambda'] \in \mathcal{O}_{e'}$, $\lambda_1 \equiv \text{Min}(\lambda, \lambda')$, $\bar{s}[0, \lambda_1] \neq \bar{s}'[0, \lambda_1]$, or for all $\bar{s}[0, \lambda] \in \mathcal{O}_e \triangle \mathcal{O}_{e'}$ there’s a $\lambda' < \lambda$ s.t. $\bar{s}[0, \lambda'] \in \mathcal{O}_e \cap \mathcal{O}_{e'}$.

(“$\mathcal{O}_e \triangle \mathcal{O}_{e'}$” is the symmetric difference: $\mathcal{O}_e \triangle \mathcal{O}_{e'} = (\mathcal{O}_e \setminus \mathcal{O}_{e'}) \cup (\mathcal{O}_{e'} \setminus \mathcal{O}_e)$.)

The significance of Boolean recorders is captured in the following theorem:

**Theorem 30.** 1) If recorder $Z$ is Boolean, and it decides covering $K$, then $K$ is a partition.

2) A recorder decides a partition for any system dynamic set iff it is Boolean.

**Proof.** 1) Take any $e, e' \in \mathcal{F}$. If for all $\bar{s}[0, \lambda_1] \in \mathcal{O}_e$, $\bar{s}'[0, \lambda_2] \in \mathcal{O}_{e'}$, $\lambda_3 \equiv \text{Min}(\lambda_1, \lambda_2)$, $\bar{s}[0, \lambda_3] \neq \bar{s}'[0, \lambda_3]$, then for all $\lambda \in A_0$, $S_{\rightarrow \mathcal{O}_e} \cap S_{\rightarrow \mathcal{O}_{e'}} = \emptyset$. If for all $\bar{s}[0, \lambda_1] \in \mathcal{O}_e \triangle \mathcal{O}_{e'}$ there’s a $\lambda_0 < \lambda_1$ s.t. $\bar{s}[0, \lambda_0] \in \mathcal{O}_e \cap \mathcal{O}_{e'}$ then $S_{\rightarrow \mathcal{O}_e} = S_{\rightarrow \mathcal{O}_{e'}}$ for all $\lambda \in A_0$.

2) A recorder is not Boolean if and only if for some $e, e' \in \mathcal{F}$, and some $\bar{s}[0, \lambda_1] \in \mathcal{O}_e$, $\bar{s}'[0, \lambda_2] \in \mathcal{O}_{e'}$ ($\lambda_1 < \lambda_2$), $\bar{s}[0, \lambda_1] = \bar{s}'[0, \lambda_1]$ and $\bar{s}[0, \lambda_1] \notin \mathcal{O}_{e'}$. Under these conditions $S_{\rightarrow \mathcal{O}_e} \cap S_{\rightarrow \mathcal{O}_{e'}} = \emptyset$ requires $S_{\rightarrow \bar{s}[0, \lambda_2]} = \emptyset$, while $S_{\rightarrow \mathcal{O}_e} = S_{\rightarrow \mathcal{O}_{e'}}$ requires that for every $\bar{s}_1 \in S_{\rightarrow \bar{s}[0, \lambda_1]}$, there’s a $\lambda_3 > \lambda_1$ s.t. $\bar{s}_1[0, \lambda_3] \in \mathcal{O}_{e'}$. This clearly cannot hold for all dynamic sets. For example, there will always be dynamic sets s.t. $S_{\rightarrow \bar{s}[0, \lambda_2]} \neq \emptyset$, and for all $\lambda > \lambda_1$, there’s a $\lambda' \in (\lambda_1, \lambda]$ s.t. for some $s \in S_{\rightarrow \bar{s}[0, \lambda_1]}(\lambda')$, $s \notin \mathcal{O}_{e'}(\lambda')$.  

As the next theorem shows, the conditions under which a recorder is Boolean are simplified when the recorder is all-right:

**Theorem 31.** If a recorder is all-right, it is Boolean if and only if the following two conditions hold:
1) For every \( e, e' \in F \) either \( O_e = O_{e'} \) or \( O_e \cap O_{e'} = \emptyset \)

2) For every \( s_1[0, \lambda_1], s_2[0, \lambda_2] \in O_F \) s.t. \( \lambda_1 < \lambda_2 \), \( s_1[0, \lambda_1] \neq s_2[0, \lambda_1] \).

The first condition says that the set of outcomes partition \( O_F \), and the second says that when an experiment terminates depends entirely on what occurs in the system. One would likely expect any experiment to satisfy both conditions.

**Proof.** First, we'll show that if the above two conditions hold, then the recorder is Boolean.

If \( O_e = O_{e'} \) then \( O_e \triangle O_{e'} = \emptyset \); so “for all \( \bar{s}[0, \lambda] \in O_e \triangle O_{e'} \) there’s a \( \lambda' < \lambda \) s.t. \( \bar{s}[0, \lambda'] \in O_e \cap O_{e'} \)” holds trivially.

If \( O_e \cap O_{e'} = \emptyset \) and for every \( \bar{s}_1[0, \lambda_1], \bar{s}_2[0, \lambda_2] \in O_F \) s.t. \( \lambda_1 < \lambda_2 \), \( \bar{s}_1[0, \lambda_1] \neq \bar{s}_2[0, \lambda_1] \), then for every \( \bar{s}[0, \lambda] \in O_e \), \( \bar{s}'[0, \lambda'] \in O_{e'} \), with \( \lambda_1 \equiv \text{Min}(\lambda, \lambda') \), \( \bar{s}[0, \lambda_1] \neq \bar{s}'[0, \lambda_1] \).

To prove the two conditions, we need only apply Thm 28.1 to the Boolean condition.

If \( \Lambda(O_e) = \Lambda(O_{e'}) \), then the Boolean condition reduces to: either \( O_e = O_{e'} \) or \( O_e \cap O_{e'} = \emptyset \).

If \( \Lambda(O_e) < \Lambda(O_{e'}) \), then \( O_e \cap O_{e'} = \emptyset \) and, by the Boolean condition, for all \( \bar{s}[0, \lambda] \in O_e \), \( \bar{s}'[0, \lambda'] \in O_{e'} \), \( \bar{s}[0, \lambda] \neq \bar{s}'[0, \lambda] \).

The second condition in the prior theorem has a useful application, it helps to clarify the weak unbiased condition. As it stands, the weak unbiased condition is convoluted and difficult to apply. The above theorem allows us to extract the following simple property that is central to its meaning:

**Theorem 32.** If recorder \( Z \) is all-reet and Boolean then for all \( p_1, p_2 \in \text{Int}(Z) \), if \( \Sigma_{p_1} \cap \Sigma_{p_2} \neq \emptyset \) then \( \Sigma_{p_1} = \Sigma_{p_2} \).

**Proof.** Since \( \Sigma_{p_1} \cap \Sigma_{p_2} \neq \emptyset \), \( p_1 \) and \( p_2 \) are undifferentiated, so the theorem follows from the weak unbiased condition, together with the second condition in Thm 31.

C. **Ideal Recorders**

**Definition 33.** A recorder is **ideal** if it is Boolean and all-reet.

Ideal recorders lack the ambiguities described at the beginning of this section, and so provide our preferred formalization of experiment. It should be stressed that all the axioms for ideal recorders have been motivated solely by the requirements of the experimental
method, and not by the dictates of any particular physical theory. This means that a universe that does not allow the axioms for recorders to be realized is one in which the scientific method cannot be applied, and a universe that does not allow the axioms for ideal recorders to be realized is one in which experimental error cannot be handled systematically. However, this does not mean that ideal recorders necessarily have to be constructable within an experimentally verifiable physical theory. In particular, a theory may describe systems being experimented on, without being able to describe the closed system that includes both the system being experimented on, and the experimental equipment. “Dynamic probability spaces”, to be described in some detail in the next part, provide a template for such theories.

We now turn to the question of what experiments are capable of telling us. This entails describing the sorts of outcomes that experiments can produce. For ideal recorders, the central theorem is: If $Z$ is an ideal recorder, then for every $e \in \mathcal{F}$, $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, $\mathcal{O}_e = |\mathcal{O}_e[0, \lambda]| \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)]$.

Before proving this assertion, we note its plausibility. Just as system paths can be partitioned based on experimental outcomes, they can be partitioned based on the what the experiment has learned as of any time, $\lambda$. For all-reet recorders, these partitions are composed of the $|\mathcal{O}_e[0, \lambda]|$’s (see Defn \ref{def16}). The assertion therefore states that an ideal recorder’s outcomes are the concatenation of what has been learned as of $\lambda$ with what is learned after $\lambda$.

The remainder of this section is dedicated to establishing this result, starting with the following theorem regarding all-reet recorders:

**Theorem 34.** If $Z$ is an all-reet recorder then for every $e \in \mathcal{F}$, every $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, every $e_{\lambda} \in \mathcal{E} \cdot \Theta_e(\lambda)$, $\mathcal{O}_e[0, \lambda] = \bigcup_{s \in \mathcal{O}_e(\lambda)} \Sigma(s, e_{\lambda})$

**Proof.** First, to show that $\bigcup_{s \in \mathcal{O}_e(\lambda)} \Sigma(s, e_{\lambda}) \subset \mathcal{O}_e[0, \lambda]$. Take any $s_{\lambda} \in \mathcal{O}_e(\lambda)$. Since $Z$ is all-reet, $(s_{\lambda}, e_{\lambda}) \in \Theta_e(\lambda)$. Take any $\bar{s}[0, \lambda] \in \Sigma(s_{\lambda}, e_{\lambda})$, and any $\bar{e}[0, \lambda] \in \mathcal{E} \cdot \omega(s_{\lambda}, e_{\lambda})$. Once again, because $Z$ is all-reet, $(\bar{s}[0, \lambda], \bar{e}[0, \lambda]) \in \omega(s_{\lambda}, e_{\lambda})$. Because $(s_{\lambda}, e_{\lambda}) \in \Theta_e(\lambda)$, there must be a $\bar{p}[0, \lambda'] \in \omega_e$ s.t. $\bar{p}[0, \lambda'](\lambda) = (s_{\lambda}, e_{\lambda})$. Because $\mathbb{D}$ is a dynamic space, $(\bar{s}[0, \lambda], \bar{e}[0, \lambda]) \circ \bar{p}[\lambda, \lambda'] \in \omega_e$. It is easy to see that for all $0 \leq \lambda'' < \lambda$, $\bar{e}[0, \lambda](\lambda'') \notin \mathcal{F}$, so $(\bar{s}[0, \lambda], \bar{e}[0, \lambda]) \in \Theta_e[0, \lambda]$, and $\bar{s}[0, \lambda] \in \mathcal{O}_e[0, \lambda]$.

Next, to show that $\mathcal{O}_e[0, \lambda] \subset \bigcup_{s \in \mathcal{O}_e(\lambda)} \Sigma(s, e_{\lambda})$. If $\bar{s}[0, \lambda] \in \mathcal{O}_e[0, \lambda]$ then, because $Z$ is all-reet, for any $\bar{e}[0, \lambda] \in \mathcal{E} \cdot \Theta_e[0, \lambda]$, $(\bar{s}[0, \lambda], \bar{e}[0, \lambda]) \in \Theta_e[0, \lambda]$. Take any $\bar{e}'[0, \lambda] \in \mathcal{E} \cdot \Theta_e[0, \lambda]$...
For any recorder, any $e \in \mathcal{F}$, $[e] \equiv \{e' \in \mathcal{F} : \mathcal{O}_e = \mathcal{O}_{e'}\}$

**Corollary 36.** If $Z$ is an all-right recorder, $p, p_1, p_2 \in \text{Int}(Z)$, $e \in \mathcal{F}$, and $\lambda \in [0, \Lambda(\mathcal{O}_e)]$

1. If $(s_1, e_1), (s_2, e_2) \in \Theta_e(\lambda)$ then $(s_1, e_2) \in \Theta_e(\lambda)$

2. If $(s, e_1), (s, e_2) \in \Theta_e(\lambda)$ then $\Sigma_{(s, e_1)} = \Sigma_{(s, e_2)}$

3. If $(s, e_1), (s, e_2) \in \Theta_{[e]}(\lambda)$ then $\Sigma_{(s, e_1)} = \Sigma_{(s, e_2)}$

**Proof.** 1 and 2 are immediate from Thm 34. 3 follows from Thm 34 and the definition of $[e]$. 

We now turn to ideal recorders.

**Theorem 37.** For ideal recorder $Z$, for any $p_1, p_2 \in \text{Int}(Z)$

1. If $S \cdot p_1 = S \cdot p_2$, and for some $e \in \mathcal{F}$, $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, $p_1, p_2 \in \Theta_{[e]}(\lambda)$ then $\Sigma_{p_1} = \Sigma_{p_2}$, in all other cases $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$.

2. If $\Sigma_{p_1} = \Sigma_{p_2}$ then for all $e \in \mathcal{F}$, $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, $p_1 \in \Theta_{[e]}(\lambda)$ iff $p_2 \in \Theta_{[e]}(\lambda)$

**Proof.** 1) If the conditions hold then $\Sigma_{p_1} = \Sigma_{p_2}$ by Thm 34.

If $p_1 \cdot S \neq p_2 \cdot S$ then clearly $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$.

If there’s doesn’t exist an $e \in \mathcal{F}$ s.t. $p_1, p_2 \in \text{Ran}(\Theta_{[e]})$ then, since $Z$ is Boolean, $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$. By Thm 32 $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$

If there exits an $e \in \mathcal{F}$ s.t. $p_1, p_2 \in \text{Ran}(\Theta_{[e]})$, but no $\lambda \in [0, \Lambda(\mathcal{O}_e)]$ s.t. $p_1, p_2 \in \Theta_{[e]}(\lambda)$ then $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$ by Thm 28.

2) By Thm 32 $\Sigma_{p_1} \cap \Sigma_{p_2} = \emptyset$; since $Z$ is Boolean $p_1 \in \text{Ran}(\Theta_{[e]})$ iff $p_2 \in \text{Ran}(\Theta_{[e]})$. From Thm 28 it then follows that $p_1 \in \Theta_{[e]}(\lambda)$ iff $p_2 \in \Theta_{[e]}(\lambda)$. 

**Theorem 38.** If $Z$ is an ideal recorder then for every $e \in \mathcal{F}$, every $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, every $e_\lambda \in \mathcal{E} \cdot \Theta_{[e]}(\lambda)$, $\|\mathcal{O}_e[0, \lambda]\| = \bigcup_{s \in \mathcal{O}_e[0, \lambda]|(\lambda)} \Sigma_{(s, e_\lambda)}$

**Proof.** A: If $Z$ is an ideal recorder then for every $e \in \mathcal{F}$, every $\lambda \in [0, \Lambda(\mathcal{O}_e)]$, every $e_\lambda \in \mathcal{E} \cdot \Theta_{[e]}(\lambda)$, $\mathcal{O}_e[0, \lambda] = \bigcup_{s \in \mathcal{O}_e(\lambda)} \Sigma_{(s, e_\lambda)}$

- Immediate from Thm 34 and Thm 36.
It is sufficient to show that for every \( n \in \mathbb{N} \), \( |\mathcal{O}_e[0, \lambda]|_n = \bigcup_{s \in |\mathcal{O}_e[0, \lambda]|_n(\lambda)} \Sigma_{(s,e,\lambda)} \). By (A) this holds for \( n = 0 \). Assume it holds for \( n = i \) and consider \( n = i + 1 \).

For any \( \mathcal{O}_e' \) s.t. \( \mathcal{O}_e'[0, \lambda] \cap |\mathcal{O}_e[0, \lambda]|_i \neq \emptyset \) for every \( e_2 \in \mathcal{E} \cdot \Theta_{e'}(\lambda) \), \( \mathcal{O}_e'[0, \lambda] = \bigcup_{s \in \mathcal{O}_e'(\lambda)} \Sigma_{(s,e_2)} \). By assumption \( |\mathcal{O}_e[0, \lambda]|_i = \bigcup_{s \in |\mathcal{O}_e[0, \lambda]|_i(\lambda)} \Sigma_{(s,e,\lambda)} \), so by Thm 37.1 there’s an \( s \in |\mathcal{O}_e[0, \lambda]|_i(\lambda) \cap \mathcal{O}_e'(\lambda) \) s.t. \( \Sigma_{(s,e_2)} = \Sigma_{(s,e,\lambda)} \); by Thm 37.2 \( (s, e_\lambda) \in \Theta_{e'}(\lambda) \), so by (A) \( \mathcal{O}_e'[0, \lambda] = \bigcup_{s \in \mathcal{O}_e'(\lambda)} \Sigma_{(s,e_\lambda)} \). Since \( |\mathcal{O}_e[0, \lambda]|_i+1 = \bigcup_{s \in |\mathcal{O}_e[0, \lambda]|_i+1(\lambda)} \Sigma_{(s,e,\lambda)} \). \( \square \)

Which brings us to the desired result:

**Theorem 39.** If \( Z \) is an ideal recorder then for any \( e \in \mathcal{F} \), \( \lambda \in [0, \Lambda(\mathcal{O}_e)] \), \( \mathcal{O}_e = |\mathcal{O}_e[0, \lambda]| \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \)

**Proof.** With \( e_\lambda \in \mathcal{E} \cdot \Theta_e(\lambda) \):

\[
\mathcal{O}_e = \mathcal{O}_e[0, \lambda] \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \quad \text{(Thm 28.3)}
\]

\[
= \left( \bigcup_{s \in \mathcal{O}_e(\lambda)} \Sigma_{(s,e,\lambda)} \right) \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \quad \text{(Thm 34)}
\]

\[
= \left( \bigcup_{s \in |\mathcal{O}_e[0, \lambda]|(\lambda)} \Sigma_{(s,e,\lambda)} \right) \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \quad \text{(any path segment ending with an } s \in |\mathcal{O}_e[0, \lambda]|(\lambda) \text{)}
\]

\( \mathcal{O}_e(\lambda) \) will not be concatenated with \( \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \)

\[
= |\mathcal{O}_e[0, \lambda]| \circ \mathcal{O}_e[\lambda, \Lambda(\mathcal{O}_e)] \quad \text{(Thm 38)} \quad \square
\]

**X. IDEAL PARTITIONS**

**A. Ideal Recorders & Ideal Partitions**

Thm 39 allows us to identify the coverings that ideal recorders are capable of deciding:

**Definition 40.** A partition, \( \gamma \), of dynamic set, \( S \), is **ideal** if

1. For all \( \alpha \in \gamma \), all \( \lambda \in \Lambda_S \), \( \alpha = |\alpha[-\infty, \lambda]| \circ \alpha[\lambda, \infty] \)

2. There exists a \( \lambda_0 \in \Lambda_S \) s.t. for all \( \alpha \in \gamma \), all \( \lambda \leq \lambda_0 \), \( \alpha = S[-\infty, \lambda] \circ \alpha[\lambda, \infty] \).

3. For all \( \alpha \in \gamma \), there exists a \( \lambda_\alpha \in \Lambda_S \) s.t. \( \alpha = S_{\alpha[-\infty,\lambda_\alpha]} \).

The first condition reflects Thm 39 while the next two reflect Thm 26. The following three theorems establish the relationship between ideal recorders and ideal partitions.

**Theorem 41.** If a covering, \( K \), of dynamic set \( S \) is properly decided by an ideal recorder, \( Z \), then \( K \) is an ideal partition.
Proof. Because $K$ is properly decided by $Z$, there must be a $\lambda_0 \in \Lambda_S$ s.t. $K \equiv \{S_{\to \mathcal{O}_{e}^{\lambda_0}} : \epsilon \in \mathcal{F} \text{ and } S_{\to \mathcal{O}_{e}^{\lambda_0}} \neq \emptyset\}$, and $S$ is unbiased with respect to $(\lambda_0, K)$. For each $\alpha = S_{\to \mathcal{O}_{e}^{\lambda_0}} \in K$ define $\lambda_\alpha \equiv \lambda_0 + \Lambda(\mathcal{O}_{e})$.

A: $K$ is a partition
- Immediate from Thm $30$. 

B: For all $\alpha \in K$, $\lambda \leq \lambda_0$, $\alpha = S_{[-\infty, \lambda]} \circ \alpha[\lambda, \infty]$ 
- Follows from $\alpha = S_{\to \mathcal{O}_{e}^{\lambda_0}}$ and the fact that for all $\lambda \leq \lambda_0$, $S = S_{[-\infty, \lambda]} \circ S[\lambda, \infty]$

C: For every $\alpha \in K$, $\alpha = S_{\alpha[-\infty, \lambda_0]}$ 
- Follows from $\alpha = S_{\to \mathcal{O}_{e}^{\lambda_0}}$ and $\lambda_\alpha = \lambda_0 + \Lambda(\mathcal{O}_{e})$ -

It remains to show that for all $\alpha \in K$, $\lambda \in \Lambda_S$, $\alpha = [\alpha[-\infty, \lambda]] \circ \alpha[\lambda, \infty]$. As $\alpha \subset [\alpha[-\infty, \lambda]] \circ \alpha[\lambda, \infty]$, it only needs to be shown that $[\alpha[-\infty, \lambda]] \circ \alpha[\lambda, \infty] \subset \alpha$. To do so, it will be helpful to first establish the following:

D: For all $\lambda > \lambda_0$, $\alpha \in K$, $[\alpha[-\infty, \lambda]] = S_{[-\infty, \lambda_0]} \circ [\alpha[\lambda_0, \lambda]]$ 
- It is sufficient to show that for all $n \in \mathbb{N}$, $[\alpha[-\infty, \lambda]]_n = S_{[-\infty, \lambda_0]} \circ [\alpha[\lambda_0, \lambda]]_n$. By (B), this holds for $n = 0$. Assume it holds for $n = i$. By (B) and assumption on $i$, for all $\beta \in K$, $\beta[\lambda, \lambda_0] \cap [\alpha[-\infty, \lambda]]_i \neq \emptyset$ iff $\beta_{\lambda_0, \lambda} \cap [\alpha[\lambda_0, \lambda]]_i \neq \emptyset$. Since $[\alpha[x, \lambda]]_{i+1}$ is equal to the union over the $\beta$’s that intersect $[\alpha[x, \lambda]]_i$, and because $[\alpha[-\infty, \lambda]]_i$ & $[\alpha[\lambda_0, \lambda]]_i$ are intersected by the same set of $\beta \in K$, $[\alpha[-\infty, \lambda]]_{i+1} = S_{[-\infty, \lambda_0]} \circ [\alpha[\lambda_0, \lambda]]_{i+1}$ -

Now to complete the proof by showing that $[\alpha[-\infty, \lambda]] \circ \alpha[\lambda, \infty] \subset \alpha$

For $\lambda \leq \lambda_0$: Immediate from (B).

For $\lambda \in (\lambda_0, \lambda_0)$: Choose any $\bar{p}_1[-\infty, \lambda] \in [\alpha[-\infty, \lambda]]$ and $\bar{p}_2[\lambda, \infty] \in \alpha[\lambda, \infty]$. Since $S$ is unbiased with respect to $(\lambda_0, K)$, $\bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in S$; it remains to show that it is an element of $\alpha$. It follows from (D) that $\bar{p}_1[\lambda_0, \lambda] \in [\alpha[\lambda_0, \lambda]]$, and so from Thm $39$ that $\bar{p}_1[\lambda_0, \lambda] \circ \bar{p}_2[\lambda, \lambda_0] \in [\alpha[\lambda_0, \lambda_0]]$. It then follows from (B) that $\bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \lambda_0] \in \alpha[-\infty, \lambda_0]$. Since $\alpha = S_{\alpha[-\infty, \lambda_0]}$, and $\bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in S, \bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \lambda_0] \in \alpha$

For $\lambda \geq \lambda_0$: Because $S$ is unbiased with respect to $(\lambda_0, K)$, $\alpha[-\infty, \lambda] \circ \alpha[\lambda, \infty] \subset S$, and so by (C) $\alpha = \alpha[-\infty, \lambda] \circ \alpha[\lambda, \infty]$. By (A) & (C), $[\alpha[-\infty, \lambda]] = \alpha[-\infty, \lambda]$, giving us $\alpha = [\alpha[-\infty, \lambda]] \circ \alpha[\lambda, \infty]$.

The inverse can also be established, that all ideal partitions are decided by ideal recorders:

Theorem 42. Every ideal partition is properly decided by an ideal recorder
Proof. Assume \( \gamma \) is an ideal partition of dynamic set \( S \). We will describe an ideal recorder, \( Z \), that decides \( \gamma \).

1) Start by constructing dynamic space \( D_0 = S \times E_0 \) as follows: For every \( \lambda \in \Lambda_S \) create a set \( E(\lambda) \), and a bijection \( b_\lambda : |\gamma[\\infty, \lambda]| \to E(\lambda) \) s.t. for all \( \lambda_1 \neq \lambda_2 \), \( E(\lambda_1) \cap E(\lambda_2) = \emptyset \); \((\bar{s}, \bar{e}) \in D_0 \) iff \( \bar{s} \in S \) and with \( \bar{s} \in \alpha \in \gamma \), for all \( \lambda \in \Lambda \), \( \bar{e}(\lambda) = b_\lambda(|\alpha[\\infty, \lambda]|) \)

2) From \( D_0 \) construct \( Z \)'s dynamic space, \( \mathbb{D} \):

If \( \Lambda_S \) is unbounded from below, for every \( \lambda \in \Lambda_S \) define \( D_\lambda \equiv \{ \tilde{p} : \text{for some } \tilde{p}' \in D_0, \text{ for all } \lambda' \in \Lambda_S, \tilde{p}(\lambda') = \tilde{p}'(\lambda' + \lambda) \} \). That is, \( D_\lambda = D_0 \) shifted by \( \lambda \). \( \mathbb{D} \equiv \bigcup_{\lambda \in \Lambda} D_\lambda \).

If \( \Lambda_S \) is bounded from below, take any dynamic set, \( S^* \), s.t. \( \Lambda_{S^*} \) is unbounded from below, \( S_0[0, \infty] = S_0 \), and for all \( \lambda \leq 0 \), \( S^* = S^*[\\infty, \lambda] \circ S^*[\lambda, \infty] \). Construct \( E_0^* \) and \( D_0^* = S^* \times E_0^* \) as in the 1st step (each element of \( \gamma \) being extended to \( S^* \)). Construct \( \mathbb{D}^* \) from \( D_0^* \) as above. Take \( \mathbb{D} = \mathbb{D}^*[0, \infty] \).

3) \( I \): Select any \( \lambda_0 \in \Lambda_\mathbb{D} \) s.t. for all \( \lambda \leq \lambda_0 \), all \( \alpha \in \gamma \), \( \alpha = S[\\infty, \lambda] \circ \alpha[\lambda, \infty] \). \( I \equiv D_0(\lambda_0) \)

4) \( F \): For every \( \alpha \in \gamma \) select a \( \lambda_\alpha \in \Lambda_\mathbb{D} \) s.t. \( \alpha = S_{\alpha[\\infty, \lambda_\alpha]} \). \( F \equiv \bigcup_{\alpha \in \gamma} \alpha(\lambda_\alpha) \times \{ b_{\lambda_\alpha}(|\alpha[\\infty, \lambda_\alpha]|) \} \).

Now to show that \( Z \) is an ideal recorder that properly decides \( \gamma \).

A: \( D_0 \) is a dynamic space

- Take any \(( \bar{s}_1, \bar{e}_1 ), ( \bar{s}_2, \bar{e}_2 ) \in D_0 \) s.t. for some \( \lambda \in \Lambda_S \), \( ( \bar{s}_1(\lambda), \bar{e}_1(\lambda) ) = ( \bar{s}_2(\lambda), \bar{e}_2(\lambda) ) \).

Take \( \bar{s}_1 \in \alpha_1 \in \gamma \) and \( \bar{s}_2 \in \alpha_2 \in \gamma \); note that since \( \bar{e}_1(\lambda) = \bar{e}_2(\lambda) \), \( |\alpha_1[\\infty, \lambda]| = |\alpha_2[\\infty, \lambda]| \).

Take \(( \bar{s}, \bar{e} ) \equiv ( \bar{s}_1[\\infty, \lambda] \circ \bar{s}_2[\lambda, \infty], \bar{e}_1[\\infty, \lambda] \circ \bar{e}_2[\lambda, \infty] ) \). \( \bar{s} \in |\alpha_1[\\infty, \lambda]| \circ \alpha_2[\lambda, \infty] = |\alpha_2[\\infty, \lambda]| \circ \alpha_2[\lambda, \infty] = \alpha_2 \), so \(( \bar{s}, \bar{e} ) \in D_0 \) iff for all \( \lambda' \in \Lambda_D \), \( \bar{e}(\lambda') = b_{\lambda'}(|\alpha_2[\\infty, \lambda']|) \), which follows from the fact that \( \bar{s} \in \alpha_2 \). -

B: \( \mathbb{D} \) is a dynamic space

- For any \( p \in \mathcal{P}_{D_0} = \mathcal{P}_{\mathbb{D}} \), \( p \) is only realized at a single \( \lambda \in \Lambda_S \) in \( D_0 \). Because \( \mathbb{D} \) is a union over “shifted” copies of \( D_0 \), paths in \( \mathbb{D} \) can only intersect if the belong to the same copy; it follows that \( \mathbb{D} \) is a dynamic space if \( D_0 \) is. -

C: \( \mathbb{D} \) is homogeneous and \( I \) is homogeneously realized

- Because for any \( p \in \mathcal{P}_{\mathbb{D}} \), \( p \) is realized at a single \( \lambda \in \Lambda_S \) in \( D_0 \), \( D_0 \) must be homogeneous. From the nature of the construction of \( \mathbb{D} \) from \( D_0 \) it’s clear that \( \mathbb{D} \) is also homogeneous, and \( I \) homogeneously realized in \( D \). -

D: \( I \to = I \to |\bar{I}| \to F \) and \( \to F = \to I \to |\bar{I}| \to F \)

- \( D_0 = \to I \to |\bar{I}| \to F \) and \( I \) is only realized at \( \lambda_0 \), so for \( D_0 \), \( I \to = I \to |\bar{I}| \to F \to \)
and $\rightarrow F = \rightarrow I \rightarrow |I| \rightarrow F$. If this holds for $D_0$, it must also hold for $D$.

E: $Z$ is an environmental shell

- All elements of $\text{Dom}(Z)$ can be decomposed into system & environmental states, and $F$ has its own set of environmental states.

F: $Z$ is weakly unbiased

- Recall that $I = D_0(\lambda_0)$. Choose any $e_1 \in F$, and take $\alpha \in \gamma$, $\lambda_1 + \lambda_0 \in \Lambda_S$ s.t. $b_{\lambda_0 + \lambda_1}([\alpha[-\infty, \lambda_0 + \lambda |_|]) = e_1$. Take any $e \in \mathcal{E} \cdot \text{Int}(Z)$, $0 \leq \lambda_1 \leq \lambda_1$ s.t. $\Sigma_e \cap |O_{e_1}[0, \lambda_]| \neq \emptyset$. It follows that $e = b_{\lambda_0 + \lambda}([\alpha[-\infty, \lambda_0 + \lambda |_|])$. Therefore, if $e, e' \in \mathcal{E} \cdot \text{Int}(Z)$ and for some $\lambda \in \Lambda$, $\Sigma_e \cap |O_{e_1}[0, \lambda |] \neq \emptyset$ and $\Sigma_{e'} \cap |O_{e_1}[0, \lambda |] \neq \emptyset$ then $e = e'$. $Z$ must then be weakly unbiased.

G: $Z$ is all-reet

- For any $e \in F$ there’s only a single $\bar{e}[0, \lambda] \in \mathcal{E} \cdot \omega_F$, so naturally $\Theta_e = (\mathcal{S} \cdot \Theta_e) \times (\mathcal{E} \cdot \Theta_e)$.

H: $Z$ is Boolean

- Since $Z$ is all-reet, Thm[31] can be used.

For any $\bar{s}[0, \lambda] \in \mathcal{O}_F$ there’s only one $(\bar{s}[0, \lambda], \bar{e}[0, \lambda]) \in \Theta_F$. Since $\bar{e}(\lambda) \in F$ there’s only one $e \in F$ s.t. $\bar{s}[0, \lambda] \in \mathcal{O}_e$.

Take any $\bar{s}_1[0, \lambda_1], \bar{s}_2[0, \lambda_2] \in \mathcal{O}_F$ s.t. $\lambda_2 \geq \lambda_1$ and $\bar{s}_1[0, \lambda_1] = \bar{s}_2[0, \lambda_1]$. For $\bar{p}_1[0, \lambda_1], \bar{p}_2[0, \lambda_2] \in \Theta_F$ s.t. $\mathcal{S} \cdot \bar{p}_1[0, \lambda_1] = \bar{s}_1[0, \lambda_1]$ and $\mathcal{S} \cdot \bar{p}_2[0, \lambda_2] = \bar{s}_2[0, \lambda_2]$, $\bar{p}_1(\lambda_1) = \bar{p}_2(\lambda_1) \in F$, so $\lambda_2 = \lambda_1$.

I: $Z$ properly decides $\gamma$

- Given any $\alpha \in \gamma$, there is one $\lambda_\alpha$ s.t. $b_{\lambda_\alpha}([\alpha[-\infty, \lambda_|]) \in \mathcal{F}$. With $e = b_{\lambda_\alpha}([\alpha[-\infty, \lambda_|]),$ $\alpha = S_{\rightarrow \mathcal{O}_{\lambda_\alpha} \rightarrow}$. Thus, $Z$ decides $\gamma$. That $\gamma$ is properly decided follows from the fact that $\gamma$ is an ideal partition.

The final theorem considers the special case in which the system is described by a dynamic space:

**Theorem 43.** If $\gamma$ is an ideal partition, and $S = \bigcup \gamma$ is a dynamic space, then $\gamma$ is decided by a strongly unbiased ideal recorder.

**Proof.** Use the same construction as the prior theorem. For every $(s, e) \in \mathcal{P}_{D_0}$, there’s an $\alpha \in \gamma$ and a $\lambda \in \Lambda_S$ s.t. $e = b_{\lambda}([\alpha[-\infty, \lambda |_|])$ and $\mathcal{S} \cdot (D_0)(s, e) \rightarrow = (S_{\alpha[-\infty, \lambda |_|})_{(s, e)} \rightarrow$. If $S = \bigcup \gamma$ is a dynamic space, then for any $X \subset S$ s.t. $s \in X(\lambda)$ and $X = S_{X[-\infty, \lambda |_|}$, $X_{(\lambda, s) \rightarrow} = S_{(\lambda, s) \rightarrow}$. Therefore $\mathcal{S} \cdot (D_0)(s, e) \rightarrow = S_{(\lambda, s) \rightarrow}$. Since $\Sigma_{(s, e) \rightarrow}$ is simply $\mathcal{S} \cdot (D_0)(s, e) \rightarrow$.

42
shifted by $\lambda_0$ and truncated at the $\lambda_\alpha$’s (for definitions of $\lambda_0$ and $\lambda_\alpha$, see (3) and (4) in the proof of the prior theorem), it follows immediately that the recorder is strongly unbiased. □

These results are the culmination of our investigation into experiments. They delineate what experiments are capable of deciding, and allow us to discuss measurement & experiment entirely in terms of ideal partitions.

B. The Composition of Ideal Partitions

Remark. In continuation of prior practices, we will represent $S_{\alpha[-\infty,\lambda]} \to \alpha[-\infty,\lambda] \to$ in cases where $S$ is understood.

Given the significance of ideal partitions, it will be helpful to understand more about their structure, particularly how they unfold over time. To do so, we start with the simplest partitions, those whose outcomes are differentiated in no time at all:

**Definition 44.** For dynamic set $S$

- $\alpha \subset S$ is a forward moment at $\lambda$ if $\alpha = \bigcup_{\epsilon > 0} S_{\rightarrow \alpha[\lambda,\lambda+\epsilon]}$. 
- $\alpha \subset S$ is a backward moment at $\lambda$ if $\alpha = \bigcup_{\epsilon > 0} S_{\leftarrow \alpha[\lambda-\epsilon,\lambda]}$.

A partition of $S$, $\gamma$, is a forward/backward moment partition at $\lambda$ if it is composed entirely of forward/backward moments at $\lambda$.

Moments are measurements that are completed in an instant. Such measurements are commonly considered in calculus. For example, moment measurements on classical particles include measurements of position and/or velocity and/or acceleration, etc.

Moment partitions have a useful feature that many ideal partitions lack:

**Theorem 45.** If $\gamma$ is a forward/backward moment partition at $\lambda$, and $A \subset \gamma$, then $(\gamma \setminus A) \cup \{\bigcup A\}$ is a forward/backward moment partition at $\lambda$

**Proof.** Immediate from the definition of moment partitions □

It follows that if the measurements corresponding to $\gamma$ and $\gamma' = (\gamma \setminus A) \cup \{\bigcup A\}$ can both be performed, and the probability of an outcome occurring is independent of the set of outcomes as a whole, then $P(A) = P(\{\bigcup A\})$. Statements similar to Thm 45 do not hold in general for ideal partitions, which makes non-additive probabilities for extended
time experiments unsurprising. Note that in quantum theory, moment measurements such as individual position or momentum measurements, do have additive probabilities, while extended time measurements generally do not.

The major result of this section will be that ideal partitions are branching sequences of moment partitions. To obtain this result, we first show that branching sequences of moment partitions are ideal partitions, and then show that any ideal partition can be decomposed into such sequences.

To compose a branching sequence of moment partitions, start with a partition containing a single element, where that element is a dynamic space. This corresponds to the case where no measurements are performed at all; such a “partition” is ideal. Then sequentially append moment partitions by selecting an outcome from the current partition, splitting it by applying a moment partition at any time after the outcome has been obtained, and (optionally) repeating this operation on an element of the new partition. Because measurements can alter system dynamics, when appending moments to outcomes we need to take such changes into account. Any change to the dynamics is allowed, so long as it satisfies some minor constraints, such as not altering system dynamics prior to the measurement, and only effecting outcomes on which the measurement takes place. This is captured in the following definition:

**Definition 46.** If $\gamma$ is an ideal partition, $S = \bigcup \gamma$, and $\alpha \in \gamma$, a moment partition can be appended to $\alpha$ at $\lambda$ if $\alpha = S_{\alpha[-\infty,\lambda] \rightarrow}$, or if the moment partition is forward and for all $\lambda' > \lambda$, $\alpha = S_{\alpha[-\infty,\lambda'] \rightarrow}$. (The second condition allows us to append a forward partition at $\lambda$, even if outcome $\alpha$ ended with a forward partition at $\lambda$. The prior condition, that $\alpha = S_{\alpha[-\infty,\lambda] \rightarrow}$, allows this for backward moments.)

$\gamma'$ is the result of appending a moment partition to $\alpha$ at $\lambda$ if for some $\gamma_m \subset \gamma'$:

1) $\gamma' \setminus \gamma_m = \gamma \setminus \{\alpha\}$
2) For any $\lambda' < \lambda$, $(\bigcup \gamma_m)[-\infty,\lambda'] = \alpha[-\infty,\lambda']$
3) $\gamma_m$ is a moment partition of $\bigcup \gamma_m$ at $\lambda$
4) For all $\lambda' < \lambda$, $\bigcup \gamma_m$ is unbiased with respect to $(\lambda', \gamma_m)$

Traditional quantum theory provides one of the most dramatic examples of system dynamics being altered by moment measurements. There, the entire set of available states may change based on the measurement being performed. However, even under those cir-
cumstances, the above constraints are still respected.

We can now show that appending a moment partition to an ideal partition (including the trivial ideal partition consisting of a single dynamic space), results is a new ideal partition.

**Theorem 47.** If \( \gamma \) is an ideal partition, \( \alpha \in \gamma \), and \( \gamma' \) is the result of appending a moment partition to \( \alpha \), then \( \gamma' \) is an ideal partition:

**Proof.** We only need to show that for all \( \beta \in \gamma' \), \( \lambda \in \Lambda_{\gamma'} \), \( \beta = |\beta[-\infty, \lambda]|_{\gamma'} \circ \beta[\lambda, \infty] \), as the other aspects of ideal partitions clearly hold.

Define \( \gamma_m \equiv \gamma' \setminus \gamma \).

For all \( \beta \in \gamma' \setminus \gamma_m \), \( \lambda \in \Lambda_{\gamma'} \), \( \beta[-\infty, \lambda] \subset |\beta[-\infty, \lambda]|_{\gamma'} \subset |\beta[-\infty, \lambda]|_{\gamma} \). Therefore \( \beta \subset |\beta[-\infty, \lambda]|_{\gamma'} \circ \beta[\lambda, \infty] \subset |\beta[-\infty, \lambda]|_{\gamma} \circ \beta[\lambda, \infty] \). Because \( \beta = |\beta[-\infty, \lambda]|_{\gamma} \circ \beta[\lambda, \infty] \), \( \beta = |\beta[-\infty, \lambda]|_{\gamma'} \circ \beta[\lambda, \infty] \).

Assume the moment partition is appended to \( \alpha \) at, \( \lambda_m \).

For \( \beta \in \gamma_m \), \( \lambda < \lambda_m \): By the nature of an ideal partition, \( |\alpha[-\infty, \lambda]|_{\gamma} \circ \alpha[\lambda, \lambda_m] \circ \lambda_m = \alpha \rightarrow (\lambda_m, \alpha(\lambda)) \). Since \( \beta(\lambda) \subset \alpha(\lambda) \), \( |\alpha[-\infty, \lambda]|_{\gamma} \circ \alpha[\lambda, \lambda_m] \circ \lambda_m = \alpha \rightarrow (\lambda_m, \beta(\lambda)) \) so by (2) in the above definition, \( |\alpha[-\infty, \lambda]|_{\gamma} \circ \lambda_m = \left( \bigcup \gamma_m \right) \circ (\lambda_m, \beta(\lambda)) \). By (4), \( \bigcup \gamma_m \) is unbiased with respect to \( \lambda \), \( \gamma_m \), so \( |\alpha[-\infty, \lambda]|_{\gamma} \circ \beta[\lambda, \infty] \subset \bigcup \gamma_m \), and so by (3), \( \beta = |\alpha[-\infty, \lambda]|_{\gamma} \circ \beta[\lambda, \infty] \). Since \( |\beta[-\infty, \lambda]|_{\gamma'} \subset |\alpha[-\infty, \lambda]|_{\gamma}, \beta \subset |\beta[-\infty, \lambda]|_{\gamma'} \circ \beta[\lambda, \infty] \subset |\alpha[-\infty, \lambda]|_{\gamma} \circ \beta[\lambda, \infty] \), and so \( \beta = |\beta[-\infty, \lambda]|_{\gamma'} \circ \beta[\lambda, \infty] \).

For \( \beta \in \gamma_m \), \( \lambda \geq \lambda_m \): By the restriction on when a moment partition can be appended to an outcome, for \( \lambda \geq \lambda_m \), \( |\beta[-\infty, \lambda]|_{\gamma} = |\beta[-\infty, \lambda]|_{\gamma_m} \). By (4) in the above definition, \( |\beta[-\infty, \lambda]|_{\gamma_m} \circ \beta[\lambda, \infty] \subset \bigcup \gamma_m \). By (3) and the nature of a moment partition, for any \( s \in |\beta[-\infty, \lambda]| \circ \beta[\lambda, \infty] \), \( s \in \beta \).

Thm 47 means that branching sequences of moment partitions form ideal partitions. Strictly speaking, we have only shown this holds for finite sequences, but it is reasonable to conclude that it holds for any cardinality, so long as each of the sequences complete at a finite time.

We now seek to show the converse, that all ideal partitions are branching sequences of moment partitions. Given that outcomes of ideal partitions always satisfy \( \alpha = |\alpha[-\infty, \lambda]| \circ \alpha[\lambda, \infty] \), ideal partitions, and the recorders that generate them, are characterized by how \( |\alpha[-\infty, \lambda]| \rightarrow \) sheds paths as time progresses. This shedding is due to the environment accumulating information about the system. More general types of recorders are not wholly
characterized by this process: If a recorder is not Boolean then $|\alpha[-\infty,\lambda]| \rightarrow$ may not evolve to $\alpha$, while if a recorder is not all-right, then the recorder is characterized both by how information is gained, and how some of this information is later lost.

To understand how ideal partitions unfold with time, we start with the following definition:

**Definition 48.** If $\gamma$ is an ideal partition, $S = \bigcup \gamma$, and $\alpha \in \gamma$ then

- $\neg \alpha(\lambda,f)_{\gamma} \equiv \{ \bar{s} \in S : \bar{s}[-\infty,\lambda] \in |\alpha[-\infty,\lambda]| \text{ and for all } \lambda' > \lambda, \bar{s}[-\infty,\lambda'] \notin |\alpha[-\infty,\lambda']| \}$
- $\neg \alpha(\lambda,b)_{\gamma} \equiv \{ \bar{s} \in S : \bar{s}[-\infty,\lambda] \notin |\alpha[-\infty,\lambda]| \text{ and for all } \lambda' < \lambda, \bar{s}[-\infty,\lambda'] \in |\alpha[-\infty,\lambda']| \}$

$\neg \alpha(\lambda,b)_{\gamma}$ is the collection of paths that break off from $|\alpha[-\infty,\lambda']| \rightarrow$ at $\lambda' = \lambda$, while $\neg \alpha(\lambda,f)_{\gamma}$ is the collection of paths that break off from $|\alpha[-\infty,\lambda']| \rightarrow$ just after $\lambda' = \lambda$. The “b” subscript is for “backward”, and the “f” is for “forward”.

To relate these sets to the outcomes in $\gamma$, we use the following theorem:

**Theorem 49.** If $\gamma$ is an ideal partition and $\alpha \in \gamma$:

1) If $\bar{p} \in \neg \alpha(\lambda,b)_{\gamma}$, and $\bar{p} \in \beta \in \gamma$, then $|\beta[-\infty,\lambda]| \rightarrow \subset \neg \alpha(\lambda,b)_{\gamma}$

2) If $\bar{p} \in \neg \alpha(\lambda,f)_{\gamma}$, and $\bar{p} \in \beta \in \gamma$, then $\bigcap_{\lambda' > \lambda} |\beta[-\infty,\lambda']| \rightarrow \subset \neg \alpha(\lambda,f)_{\gamma}$

**Proof.** For all $\lambda'$, either $|\beta[-\infty,\lambda']| = |\alpha[-\infty,\lambda']|$ or $|\beta[-\infty,\lambda']| \bigcap |\alpha[-\infty,\lambda']| = \emptyset$, so if $\bar{p}[-\infty,\lambda'] \in |\alpha[-\infty,\lambda']|$ then $|\beta[-\infty,\lambda']| = |\alpha[-\infty,\lambda']|$, and if $\bar{p}[-\infty,\lambda'] \notin |\alpha[-\infty,\lambda']|$ then $|\beta[-\infty,\lambda']| \bigcap |\alpha[-\infty,\lambda]| = \emptyset$. 

This allows us to define moment partitions on the various $|\alpha[-\infty,\lambda]| \rightarrow$ based on when they shed their paths:

**Definition 50.** If $\gamma$ is an ideal partition, $S = \bigcup \gamma$, and $\alpha \in \gamma$ then

- $[\alpha]_{(\lambda,b)_{\gamma}} \equiv \{ |\beta[-\infty,\lambda]| \rightarrow : \beta \in \gamma \text{ and either } \beta = \alpha \text{ or } \beta \subset \neg \alpha(\lambda,b)_{\gamma} \}$
- $[\alpha]_{(\lambda,f)_{\gamma}} \equiv \{ \bigcap_{\lambda' > \lambda} |\beta[-\infty,\lambda']| \rightarrow : \beta \in \gamma \text{ and either } \beta = \alpha \text{ or } \beta \subset \neg \alpha(\lambda,f)_{\gamma} \}$

We can now prove the heart of the desired result:

**Theorem 51.** If $\gamma$ is an ideal partition, and $\alpha \in \gamma$, then $[\alpha]_{(\lambda,f)_{\gamma}}$ is a forward moment partition of $|\alpha[-\infty,\lambda]| \rightarrow$ at $\lambda$, and $[\alpha]_{(\lambda,b)_{\gamma}}$ is a backward moment partition of $\bigcap_{\lambda' < \lambda} |\alpha[-\infty,\lambda']| \rightarrow$ at $\lambda$.
\textbf{Proof.} It is clear that $[\alpha]_{(\lambda, f)\gamma}$ is a partition of $|\alpha[-\infty, \lambda]| \rightarrow$, and $[\alpha]_{(\lambda, b)\gamma}$ is a partition of $\bigcap_{\lambda'}\alpha[-\infty, \lambda'] \rightarrow$. It remains to show that they are moment partitions.

Let’s start with $[\alpha]_{(\lambda, b)\gamma}$. For any $\bar{p} \in |\beta[-\infty, \lambda]| \rightarrow \in [\alpha]_{(\lambda, f)\gamma}$, take any $\bar{p}' \in \bigcap_{\lambda'}\alpha[-\infty, \lambda'] \rightarrow$ s.t. for some $\epsilon > 0$, $\bar{p}'[\lambda - \epsilon, \lambda] = \bar{p}[\lambda - \epsilon, \lambda]$. Let’s say $\bar{p} \in \delta \in \gamma$ and $\bar{p}' \in \eta \in \gamma$. Note that $|\delta[-\infty, \lambda]| = |\beta[-\infty, \lambda]|$. Since $\bar{p}' \in \bigcap_{\lambda'}\alpha[-\infty, \lambda'] \rightarrow$, and by the nature of $[\alpha]_{(\lambda, b)\gamma}$, $|\eta[-\infty, \lambda - \epsilon]| = |\delta[-\infty, \lambda - \epsilon]| = |\alpha[-\infty, \lambda - \epsilon]|$. Since $\bar{p}'[-\infty, \lambda - \epsilon] \in |\delta[-\infty, \lambda - \epsilon]|$ and $\bar{p}'[\lambda - \epsilon, \lambda] = \delta[\lambda - \epsilon, \lambda]$, $\bar{p}'[-\infty, \lambda] \in |\delta[-\infty, \lambda - \epsilon]| \circ \delta[\lambda - \epsilon, \lambda] = \delta[-\infty, \lambda]$. Therefore $\bar{p}' \in |\delta[-\infty, \lambda]| \rightarrow = |\beta[-\infty, \lambda]| \rightarrow$.

The forward case is nearly identical. For any $\bar{p} \in \bigcap_{\lambda'}\alpha[-\infty, \lambda'] \rightarrow \in [\alpha]_{(\lambda, f)\gamma}$, take any $\bar{p}' \in |\alpha[-\infty, \lambda]| \rightarrow$ s.t. for some $\epsilon > 0$, $\bar{p}'[\lambda, \lambda + \epsilon] = \bar{p}[\lambda, \lambda + \epsilon]$. Let’s say $\bar{p} \in \delta \in \gamma$ and $\bar{p}' \in \eta \in \gamma$. Note that $\bigcap_{\lambda'}|\delta[-\infty, \lambda']| \rightarrow = \bigcap_{\lambda'}|\beta[-\infty, \lambda']| \rightarrow$. Since $\bar{p}'[-\infty, \lambda] \in |\alpha[-\infty, \lambda]| = |\delta[-\infty, \lambda]|$, and $\bar{p}'[\lambda, \lambda + \epsilon] \in \delta[\lambda, \lambda + \epsilon]$, $\bar{p}'[-\infty, \lambda + \epsilon] \in |\delta[-\infty, \lambda]| \circ \delta[\lambda, \lambda + \epsilon] = \delta[-\infty, \lambda + \epsilon]$. Therefore $\bar{p}' \in \bigcap_{\lambda'}|\delta[-\infty, \lambda']| \rightarrow = \bigcap_{\lambda'}|\beta[-\infty, \lambda']| \rightarrow$. \hfill $\Box$

To complete the picture, choose any $\lambda_0$ such that for all $\beta \in \gamma$, $\beta = S[-\infty, \lambda_0] \circ \beta[\lambda_0, \infty]$. The set $\{|\beta[-\infty, \lambda_0]| \rightarrow : \beta \in \gamma\}$ is a moment partition, as can be seen from the fact that, for all $\beta \in \gamma$, $|\beta[-\infty, \lambda_0]| \rightarrow = \rightarrow (\lambda_0, |\beta[-\infty, \lambda_0]|(\lambda_0)) \rightarrow$. This is the starting measurement of the ideal partition (possibly containing only a single outcome). From there, the outcomes split by applying moment partitions of the form $[\alpha]_{(\lambda, b)\gamma}$ and $[\alpha]_{(\lambda, f)\gamma}$. Thus, an ideal partition unfolds as a branching tree, each node of the tree being a moment partition that acts to split outcomes from each other.

Together, Thms 47 and 51 mean that ideal partitions are precisely the partitions that unfold in this manner, with the mild additional restriction that the branching must start an end at finite times.

\textbf{Part IV}
Experimental Probabilities

XI. DYNAMIC PROBABILITY SPACES

In this part, we will turn our attention from experiments to experimental probabilities. We start by reviewing probabilities for individual experiments, and considering probabilities for collections of experiments. It will be seen that individual experiments conform to traditional probability theory, while collections of experiments may not.

For an individual experiment, an outcome’s probability is the expected ratio of the number of times the outcome obtains, to the total number of times the experiment is run; the probability for a set of the experiment’s outcomes is assigned similarly. This is sufficient to motivate the laws of experimental probability: All probabilities have values between 0 and 1, if $\gamma$ is the collection of all outcomes for an experiment then $P(\gamma) = 1$, and if $A$ and $B$ are disjoint collections of outcomes from the same experiment then $P(A \cup B) = P(A) + P(B)$.

These rules are easily formalized. In keeping with our earlier results we assume that, for experiments of interest, the complete set of outcomes form an ideal partition. We then define an experimental probability space (eps) to be a triple, $(\gamma, \Sigma, P)$, where $\gamma$ is an ideal partition, $\Sigma$ is a set of subsets of $\gamma$, and $P$ is a function $P : \Sigma \to [0, 1]$, which satisfy:

1) $\gamma \in \Sigma$
2) If $\sigma \in \Sigma$ then $\gamma \setminus \sigma \in \Sigma$
3) If $\sigma_1, \sigma_2 \in \Sigma$ then $\sigma_1 \cup \sigma_2 \in \Sigma$
4) $P(\gamma) = 1$
5) If $\sigma_1, \sigma_2 \in \Sigma$ and $\sigma_1 \cap \sigma_2 = \emptyset$ then $P(\sigma_1 \cup \sigma_2) = P(\sigma_1) + P(\sigma_2)$

These are, of course, the traditional rules governing probabilities. In axiomatic probability theory, (3) and (5) are often extended to hold for countable subsets of $\Sigma$; that variation will be considered in Section XIII.

Conditions (2) & (3) are equivalent to the single statement: If $\sigma_1, \sigma_2 \in \Sigma$ then $\sigma_1 \setminus \sigma_2 \in \Sigma$. This allows us to replace the 5 assumptions enumerated above with:

1) $\gamma \in \Sigma$
2) If $\sigma_1, \sigma_2 \in \Sigma$ then $\sigma_1 \setminus \sigma_2 \in \Sigma$
3) $P(\gamma) = 1$
4) If $\sigma_1, \sigma_2 \in \Sigma$ and $\sigma_1 \cap \sigma_2 = \emptyset$ then $P(\sigma_1 \cup \sigma_2) = P(\sigma_1) + P(\sigma_2)$
To understand a physical system, it is rarely sufficient to only have to consider a single experiment. Because many different sorts of experiments can be performed on a physical system, more often than not we are interested in collections of eps’s. Such collections form a coherent structure when their probabilities are consistent with each other. To be precise, we say that a pair of eps’s, \((\gamma_1, \Sigma_1, P_1)\) and \((\gamma_2, \Sigma_2, P_2)\), are consistent if:

1) \(\gamma_1 \cap \gamma_2 \in \Sigma_1\) and \(\gamma_1 \cap \gamma_2 \in \Sigma_2\)
2) For any \(\sigma \subset \gamma_1 \cap \gamma_2\), \(\sigma \in \Sigma_1\) iff \(\sigma \in \Sigma_2\)
3) For any \(\sigma \in \Sigma_1 \cap \Sigma_2\), \(P_1(\sigma) = P_2(\sigma)\)

The second and third consistency conditions require that, on the set of common outcomes, the two probability spaces are identical. The first condition ensures that the two experiments are comparable on the set of common outcomes; without it, we could have a \(\sigma \in \Sigma_1\) that overlaps \(\gamma_1 \cap \gamma_2\), but does not contain any non-empty subsets that are elements of \(\Sigma_2\).

Consistency can be extended to collections of experiments by saying that a collection of eps’s, \(X\), is consistent if, for any \(x, y \in X\), \(x\) and \(y\) are consistent. Consistent collections of eps’s can be conveniently represented as dynamic probability space:

**Definition 52.** A dynamic probability space \((dps)\) is a triple, \((X, T, P)\) where \(X\) and \(T\) are sets, \(P : T \rightarrow [0, 1]\), and these satisfy:

1) If \(\gamma \in X\) then \(\gamma\) is an ideal partition
2) If \(t \in T\) then for some \(\gamma \in X\), \(t \subset \gamma\)
3) \(X \subset T\)
4) If \(t_1, t_2 \in T\) then \(t_1 \setminus t_2 \in T\)
5) If \(\gamma \in X\) then \(P(\gamma) = 1\)
6) If \(t_1, t_2 \in T\) are disjoint, and \(t_1 \cup t_2 \in T\), then \(P(t_1 \cup t_2) = P(t_1) + P(t_2)\)

All dps’s are equivalent to some consistent sets of eps’s, and vice versa. To extract the eps’s from a dps, iterate through the \(\gamma \in X\), and define \(\Sigma_\gamma \equiv \{t \in T : t \subset \gamma\}\) and \(P_\gamma \equiv P|_{\Sigma_\gamma}\). The resulting \((\gamma, \Sigma_\gamma, P_\gamma)\)’s form a consistent set of eps’s that contains all the information present in the original dps. Going the other way, starting with any consistent set of eps’s, \(Y\), define \(X_Y \equiv \{\gamma : (\gamma, \Sigma, P) \in Y\}\), \(T_Y \equiv \bigcup_{(\gamma, \Sigma, P) \in Y} \Sigma\), and \(P_Y : T_Y \rightarrow [0, 1]\) s.t. if \((\gamma, \Sigma, P) \in Y\) and \(t \in \Sigma\) then \(P_Y(t) = P(t)\). \((X_Y, T_Y, P_Y)\) is a dps that contains all the information present in the original collection of eps’s.
It’s important to stress that, if \((X, T, P)\) is a dps, and \(\{\alpha\}, \{\beta\}, \{\alpha \cup \beta\} \in T\), then condition (6) demands that \(P(\{\alpha, \beta\}) = P(\{\alpha\}) + P(\{\beta\})\); it does not mean that \(P(\{\alpha, \beta\}) = P(\{\alpha \cup \beta\})\). In quantum systems it is always the case that \(P(\{\alpha, \beta\}) = P(\{\alpha\}) + P(\{\beta\})\), though often the case that \(P(\{\alpha \cup \beta\}) \neq P(\{\alpha\}) + P(\{\beta\})\). The later is why quantum probabilities are referred to as “non-additive”. Also note that, unlike traditional probability spaces, arbitrary finite unions of elements of \(T\) cannot be expected to be elements of \(T\). Arbitrary finite intersections, on the other hand, are elements of \(T\).

In the remainder of this part, dps’s will be developed along two lines. The first will expand dps’s into a larger structure in order to render their content more accessible. That material will be presented in the next section, and will be applied in Part \([V]\) The second line of development will consider the manner in which dps’s unfold over time. That will be pursued in Sec \([XIV]\) and applied in Part \([VI]\)

XII. GENERALIZED PROBABILITY SPACES AND THE \((X_N, T_N, P_N)\) CONSTRUCTION

Given any dps, \((X, T, P)\), useful probabilistic information can be extracted from \(X\) and \(T\) alone. Preparatory to doing so, it will be helpful to generalize the definition of dps’s by removing the explicit reference to ideal partitions:

**Definition 53.** An event-algebra is a double, \((X, T)\), where \(X\) and \(T\) are collection of sets that satisfy:

1) If \(t \in T\) then for some \(\gamma \in X, t \subset \gamma\)
2) If \(\gamma \in X\) then \(\gamma \in T\)
3) If \(t_1, t_2 \in T\) then \(t_1 \setminus t_2 \in T\)

A generalized probability space (gps) is a triple, \((X, T, P)\), where \((X, T)\) is an event-algebra and \(P : T \rightarrow [0, 1]\) s.t.

1) If \(\gamma \in X\) then \(P(\gamma) = 1\)
2) If \(t_1, t_2 \in T\) are disjoint and \(t_1 \cup t_2 \in T\) then \(P(t_1 \cup t_2) = P(t_1) + P(t_2)\).

When \(X\) contains only a single element, this is equivalent to traditional probability theory. When \(X\) consists of ideal partitions, the gps is a dps.

For an event algebra, a particularly useful operation is the “not” operation, which gives the collection of complements to an element of \(T\):
**Definition 54.** For event-algebra \((X, T), t \in T, \neg t \equiv \{t' \in T : t' \cap t = \emptyset \& t' \cup t \in X\}.

For \(A \subset T, \neg A \equiv \bigcup_{t \in A} \neg t.

We can compound \(\neg\)'s to form \(\neg^{(n)}\) for any \(n\) by defining \(\neg^{(1)} A \equiv \neg A\) and \(\neg^{(n+1)} A \equiv \neg (\neg^{(n)} A)\). For any gps on an event-algebra, if \(t' \in \neg^{(n)} t\), and \(n\) is even, then \(P(t') = P(t)\), while if \(n\) is odd, then \(P(t') + P(t) = 1\). This motivates the following equivalence class:

**Definition 55.** If \((X, T)\) is an event-algebra and \(t \in T\) then \([t] \equiv \bigcup_{n \in \mathbb{N}^+} \neg^{(2n)} t\).

It’s easy to see that \([t]\) is an equivalence class, and that \(\neg [t] = \bigcup_{n \in \mathbb{N}^+} \neg^{(2n+1)} t\). These have the above mentioned property that if \(t' \in [t]\) then \(P(t') = P(t)\), and if \(t' \in \neg [t]\), \(P(t') + P(t) = 1\). Thus \([t]\) and \(\neg [t]\) yield information that may not be explicitly present in \((X, T, P)\).

We can obtain still further information by using \(\neg [t]\) to create a more expansive gps. To do so, start by defining the “\(\star\)” relation by: If \(t_1 \in \neg [t_2]\), \(t \subset t_1\), \(t' \subset t_2\), and \(t, t' \in T\) then \(t \star t'\).

**Theorem 56.** If \((X, T, P)\) is a gps, \(t_1 \star t_2, t_3 \star t_4, \text{ and } t_1 \cup t_2 = t_3 \cup t_4, \text{ then } P(t_1) + P(t_2) = P(t_3) + P(t_4) \in [0, 1].

**Proof.** Take \(t_1' = t_1 \cap t_3, t_2' = t_1 \cap t_4, t_3' = t_2 \cap t_3, t_4' = t_2 \cap t_4\). All \(t_i'\) are disjoint, all are elements of \(T\), and each \(t_i\) is a union of two of the \(t_i'\), so \(P(t_1) + P(t_2) = P(t_1') + P(t_2') + P(t_3') + P(t_4') = P(t_3) + P(t_4)\).

Since \(t_1 \star t_2\) there’s \(t_5 \in T, t_6 \in \neg [t_5]\) s.t. \(t_1 \subset t_5\), and \(t_2 \subset t_6\). Since \(t_6 \in \neg [t_5]\), \(P(t_5) + P(t_6) = 1\), and so \(P(t_1) + P(t_2) \in [0, 1]\).

\(\neg [t]\) and \(t_1 \star t_2\) can be used to construct a new, larger gps, \((X_1, T_1, P_1)\), as follows. First, define \(X_1\) by: For any \(t_1 \in T, t_2 \in \neg [t_1], t_1 \cup t_2 \in X_1\). It’s clear that \(X\) is a subset of \(X_1\). Next construct \(T_1\): For any \(t_1, t_2 \in T\) s.t. \(t_1 \star t_2, t_1 \cup t_2 \in T_1\). Since \(\emptyset = t \setminus t \in T\), and for any \(t \in T, t \star \emptyset, T\) is a subset of \(T_1\). Finally, we use the above theorem to define function \(P_1\): For any \(t \in T_1\), take any \(t_1, t_2 \in T\) s.t. \(t_1 \star t_2\) and \(t_1 \cup t_2 = t\), and assign \(P_1(t) = P(t_1) + P(t_2)\).

**Theorem 57.** 1) If \((X, T)\) is an event-algebra then \((X_1, T_1)\) is an event-algebra

2) If \((X, T, P)\) is a gps then \((X_1, T_1, P_1)\) is a gps.
Proof. 1) Event-algebra axioms (1) and (2) clearly hold.

For axiom (3), given any \( t_1, t_2 \in T_1 \), there exist \( t'_1, t''_1, t'_2, t''_2 \in T \) s.t. \( t'_1 \not\sim t''_1 \) and \( t_1 = t'_1 \cup t''_1 \). Define \( t_3 \equiv (t'_1 \setminus t''_1) \setminus t'_2 \) and \( t_4 \equiv (t''_1 \setminus t'_2) \setminus t'_2 \). Since \( t_3 \subset t'_1 \) and \( t_4 \subset t''_1 \), \( t_3 \not\sim t_4 \), so \( t_3 \cup t_4 \in T_1 \). \( t_1 \setminus t_2 = t_3 \cup t_4 \) so \( t_1 \setminus t_2 \in T_1 \).

2) Follows from (1) and Thm. 56. \( \square \)

Note that if \((X, T, P)\) is a dps then \((X_1, T_1, P_1)\) may not be a dps, because \(X_1\) may not be composed entirely of ideal partitions. This is why gps’s were introduced.

We can now define \((X_2, T_2, P_2) \equiv ((X_1)_1, (T_1)_1, (P_1)_1); \) which is to say, \((X_2, T_2, P_2)\) is formed from \((X_1, T_1, P_1)\) in precisely the same way as \((X_1, T_1, P_1)\) was formed from \((X, T, P)\). As \((X_1, T_1, P_1)\) is a gps, \((X_2, T_2, P_2)\) must also be a gps. Continuing in this vein we can construct \((X_3, T_3, P_3)\), \((X_4, T_4, P_4)\), etc. Finally, we can define \(X_N \equiv \bigcup_{n \in \mathbb{N}^+} X_n, T_N \equiv \bigcup_{n \in \mathbb{N}^+} T_n, \) and \(P_N : T_N \rightarrow [0,1] \) s.t. if \( t \in T_n \) then \( P_N(t) = P_n(t) \). \((X_N, T_N, P_N)\) is a gps (proved below); indeed, it is a simple gps:

**Definition 58.** A gps, \((X, T, P)\) is simple if for all \( t \in T, \neg t = \neg[^3]t \)

It follows that a gps is simple if and only if \( \neg t = \neg[^3]t \). For a simple gps, \((X_1, T_1, P_1) = (X, T, P)\), and so \((X_N, T_N, P_N) = (X, T, P)\).

**Theorem 59.** If \((X, T, P)\) is a gps then \((X_N, T_N, P_N)\) is a simple gps.

Proof. That \((X_N, T_N)\) is an event-algebra follows from the fact that if \( t \in T_N \) then for some \( m \in \mathbb{N}^+ \), all \( n > m \), \( t \) is an element of \( T_n \), and all \( T_n \) are event-algebras. That \((X_N, T_N, P_N)\) is a gps follows similarly.

It remains to show that \( T_N \) is simple. Take “\( \neg \)” to be “\( \neg \)” defined on \( T_n \) and “\( \neg N \)” to be “\( \neg \)” defined on \( T_N \). For \( t \in T_N \), if \( t' \in \neg N \neg N t \) then for some \( t_1, t_2 \in T_N \), \( t' \in \neg N t_2, t_2 \in \neg N t_1, \) and \( t_1 \in \neg N t, \) so for some \( m, n, p \in \mathbb{N}, t' \in \neg m t_2, t_2 \in \neg n t_1, \) and \( t_1 \in \neg n t, \) in which case, with \( q = Max\{\{m, n, p\}\} \), \( t' \in \neg q + 1 t, \) and so \( t' \in \neg N t. \) \( \square \)

\(X_N, T_N, \) and \( P_N\) have clear interpretations: Given that \((X, T)\) is an event-algebra, \(X_N\) is the set of of partitions whose total probability will be 1 for any gps on \((X, T)\). Given \(X_N, T_N\) is smallest set s.t. \((X_N, T_N)\) is an event-algebra that contains \((X, T)\). \((X_N, T_N)\) is also the largest event algebra onto which any probability function on \((X, T)\) can be uniquely extended. Given a gps on \((X, T)\), \((X, T, P)\), \(P_N\) is \(P\)’s unique extension to \(T_N\).
While \((X, T, P)\) and \((X_N, T_N, P_N)\) are in many ways equivalent, \((X_N, T_N, P_N)\) has a clearer structure, and often contains more readily accessible information, though this is achieved at the price of sacrificing knowledge of admissible experiments. If, for some system, you know the rules that govern the system’s probabilities, but do not know its allowed experiments, you are likely to form \((X_N, T_N, P_N)\) as its probability space, rather than \((X, T, P)\). It is for this reason that we need to understand probabilities before investigating quantum experiments in the next part.

XIII. CONVERGENCE

When performing probability calculations, countable additivity is generally preferred over finite additivity. Countable additivity allows for the introduction of integration, which in turn allows probabilities to be calculated by integrating over probability density functions. If \((X, T, P)\) is a gps, countable additivity is the requirement that:

1) If \(A \subset T\) is countable, pairwise disjoint, and \(\bigcup A \in T\), then \(P(\bigcup A) = \sum_{t \in A} P(t)\).

We generally also require a guarantee as to when \(\bigcup A \in T\):

2) If \(A \subset T\) is countable, and for some \(\gamma \in X\), \(\bigcup A \subset \gamma\), then \(\bigcup A \in T\).

A gps that satisfies (1) and (2) is convergent. Similarly, an event-algebra is convergent if it satisfies (2).

Reverting back to dps’s for a moment, it’s easy to see that convergent dps’s are equivalent to a consistent set of convergent eps’s, where convergent eps’s obey the 5 original axioms listed in section XI, but with axioms 3 & 5 amended to hold for countable sets.

We will now show that if gps \((X, T, P)\) is convergent, then so are \((X_1, T_1, P_1)\) and \((X_N, T_N, P_N)\). Thus, when convergence is included, the theory remains essentially unchanged.

Lemma 60. If \(t_1 \in T_1\) and \(t \in T\) then \(t_1 \cap t \in T\)

Proof. For some \(t_2, t_3 \in T\), \(t_1 = t_2 \cup t_3\). \(t_2 \cap t, t_3 \cap t \in T\) and \(t_2 \cap t, t_3 \cap t \subset t\) so \((t_2 \cap t) \cup (t_3 \cap t) \in T\). Since \(t_1 \cap t = (t_2 \cap t) \cup (t_3 \cap t), t_1 \cap t \in T\). \(\square\)

Theorem 61. If \((X, T, P)\) is a convergent gps then \((X_1, T_1, P_1)\) is a convergent gps

Proof. A: \((X_1, T_1)\) is a convergent event-algebra

- Take any countable \(A \subset T_1\) and \(t_1 \in T_1\) s.t. \(\bigcup A \subset t_1\). For some \(t_2, t_3 \in T\), \(t_1 = t_2 \cup t_3\).

By the above lemma, and the fact that \((X, T, P)\) is convergent, \(t_4 \equiv \bigcup_{t \in A} t_1 \cap t_2 \subset T\) and
\( t_5 \equiv \bigcup_{t \in A} t_3 \cap t_1 \in T \). Therefore \( t_4, t_5 \in T_1 \). Since \( t_4, t_5 \subset t_1, t_4 \cup t_5 \in T_1 \). \( \bigcup A = t_4 \cup t_5 \), so \( \bigcup A \in T_1 \). -

B: \( P_1 \) is a countable additive

- Take any countable, pairwise disjoint \( A \subset T_1 \) s.t. \( \bigcup A \in T_1 \). Because countable sums are defined as the limit of their partial sums, \( \sum_{t \in A} P(t) \leq 1 \), so \( \sum_{t \in A} P(t) \) is absolutely convergent.

As \( \bigcup A \in T_1 \), take \( t_1, t_2 \in T \). \( \bigcup A = t_1 \cup t_2 \) and \( t_1 \cap t_2 = \emptyset \). Because \( (X_1, T_1, P_1) \) is finitely additive, \( \sum_{t \in A} P_1(t) = \sum_{t \in A}(P(t \cap t_1) + P(t \cap t_2)) \). Since \( \sum_{t \in A} P(t) = \sum_{t \in A}(P(t \cap t_1) + P(t \cap t_2)) \) is absolutely convergent, \( \sum_{t \in A} P(t) = \sum_{t \in A} P(t \cap t_1) + \sum_{t \in A} P(t \cap t_2) \). Because \( (X, T, P) \) is a convergent gps, \( \sum_{t \in A} P(t \cap t_1) = P(t_1) \) and \( \sum_{t \in A} P(t \cap t_2) = P(t_2) \). Therefore \( \sum_{t \in A} P_1(t) = P(t_1) + P(t_2) = P_1(\bigcup A) \). - \( \square \)

**Corollary 62.** If \( (X, T, P) \) is a convergent gps then for all \( n \in \mathbb{N}^+ \) \( (X_n, T_n, P_n) \) is a convergent gps.

We may now prove the desired result:

**Theorem 63.** If \( (X, T, P) \) is a convergent gps then \( (X_N, T_N, P_N) \) is a simple convergent gps.

**Proof.** A: If \( t \in T_N, t' \in T_n \) and \( t \subset t' \) then \( t \in T_n \).

- Follows from Lemma [60] and simple induction -

B: \( (X_N, T_N) \) is a convergent event-algebra

- Take any countable \( A \subset T_N, t \in T_N \) s.t. \( \bigcup A \subset t \). For some \( n \in \mathbb{N}^+ \), \( t \in T_n \). It follows from (A) that for all \( t' \in A, t' \in T_n \). Since \( (X_n, T_n) \) is a convergent event-algebra, \( \bigcup A \in T_n \)

C: \( P_N \) is a countable additive

- Take any countable, pairwise disjoint \( A \subset T_N \) s.t. \( \bigcup A \in T_N \). For some \( n \in \mathbb{N}^+ \), \( \bigcup A \in T_n \). It follows from (A) for all \( t \in A, t \in T_n \). Because \( P_n \) is convergent \( P_N(\bigcup A) = P_n(\bigcup A) = \sum_{t \in A} P_n(t) = \sum_{t \in A} P_n(t) \). - \( \square \)

**XIV. STANDARD DPS’S**

In this section, we will utilize moments (defined in Sec [XIII]) to devise a standard approach to dps’s. In Sec [XIII] it was shown that ideal partitions can be viewed as branching sequences of moment partitions; this implies that to describe a dps, we may only need to concern
ourselves with probabilities on moment measurements. Pursuing this approach will allow us to introduce concepts that are basic to both probability theory and quantum theory, such as random variables and probability distributions.

While this section will be of significant conceptual value in what follows, many of the details will not be directly referenced in later sections. As a result, the presentation will be somewhat informal. We start by further developing moments.

A. More on Moments

The most elemental moments, the moments from which all other moments can be formed, are path moments. If \( \bar{p} \) is a path, its forward moment at \( \lambda \) is the set of all paths, \( \bar{p}' \), s.t. for some \( \lambda' > \lambda \), \( \bar{p}'[\lambda, \lambda'] = \bar{p}[\lambda, \lambda'] \), and its backward moment at \( \lambda \) is the set of all paths, \( \bar{p}' \), s.t. for some \( \lambda' < \lambda \), \( \bar{p}'[\lambda', \lambda] = \bar{p}[\lambda', \lambda] \). We can represent path moments by \([\bar{p}, \lambda, b/f]\), where \( \bar{p} \) is the path, \( \lambda \) is the time of the moment, and the \( b \) or \( f \) specifies whether the moment is forward or backward. It is easy to see that all moments are unions over path moments. Note that if \( \bar{p}' \in [\bar{p}, \lambda, x] \) then \([\bar{p}', \lambda, x] = [\bar{p}, \lambda, x]\).

The discussion of moments can be simplified somewhat if we introduce ordered pairs of the form \( z = (\lambda, x) \), where \( \lambda \) is the time, and \( x \) is either "b" or "f" for backward or forward. This allows us to speak of a "moment at \( z \)" rather than a "backward/forward moment at \( \lambda \)". Path moments may be represented by \([\bar{p}, z]\), and the statement “all moments are unions over path moments” can be formalized by: A is a moment if and only if, for some \( z \), \( A = \bigcup_{\bar{p} \in A} [\bar{p}, z] \). These pairs essentially represent the time of the moment, and can be time-ordered by: \((\lambda_1, x_1) > (\lambda_2, x_2)\) if \( \lambda_1 > \lambda_2 \) or \( \lambda_1 = \lambda_2, x_1 = f \& x_1 = b \). It is sometimes also useful to use an order-like relation between the pairs and time: \((\lambda_1, x_1) < \lambda \) if \( \lambda_1 < \lambda \) or \( \lambda_1 = \lambda \& x_1 = b \); \((\lambda_1, x_1) > \lambda \) if \( \lambda_1 > \lambda \) or \( \lambda_1 = \lambda \& x_1 = f \).

B. Individual Moment Measurements

The quintessential example of a moment is the set of paths with position \( \vec{x} \) and velocity \( \vec{v} \) at time \( \lambda \). This is a forward moment if \( \vec{v} \) is the forward velocity \((\lim_{\epsilon \to 0} \frac{\vec{x}(\lambda + \epsilon) - \vec{x}(\lambda)}{\epsilon})\), and a backward moment if \( \vec{v} \) is the backward velocity \((\lim_{\epsilon \to 0} \frac{\vec{x}(\lambda - \epsilon) - \vec{x}(\lambda)}{\epsilon})\). Position/velocity values are generally represented as tuples of real numbers, which is quite useful, because
it allows the full power of real analysis to be applied. In probability theory, the mapping of measurement results to real numbers is accomplished with random variables. Similar mappings can be introduced to dps’s.

To represent moment measurements by real numbers, we introduce functions, $M_z$, that map the set of paths in the dps, $\bigcup (\bigcup X)$, to $\mathbb{R}^N$ (for some $N$). Returning to the above example, if the system is a collection of classical particles, $M_z$ may map the particle paths onto their position and velocity values at “time” $z = (\lambda, b/f)$. To ensure that $M_z$ describes moments at $z$, it must satisfy the requirement that, if $\bar{s}' \in [\bar{s}, z]$, then $M_z(\bar{s}) = M_z(\bar{s}')$. A time sequence of $M_z$’s is akin to the parametrized random variables that define stochastic processes.

The restriction of these functions to a particular dynamic set, $S$, will be written as $M_{z,S}$. $M_{z,S}$ can be used to form moments on $S$ at $z$: for any subset of $\mathbb{R}^N = \text{Ran}(M_z)$, $y$, $M_{z,S}^{-1}[y]$ is a moment at $z$, and for any partition of $\mathbb{R}^N$, $Y$, $\{M_{z,S}^{-1}[y] : y \in Y\}$ is a moment partition at $z$. To enable the use of integration, it will be assumed that measurements correspond to pre-images of Borel sets. (The Borel sets on the reals is the smallest collection that includes all intervals, and is closed under complementation and countable union.)

Moment measurements, like any measurement, can alter a system’s dynamic set. If they do, $M_{z,S}$ can still be used to describe moment measurements, so long as the paths in $S$ already reflect those effects. While this alone may be sufficient under some circumstances, it will generally be helpful to include these alterations in the description of moment measurements. To do so, we must first take a closer look at an apparently unrelated question: How do we determine what the sort of quantity is being measured? That is, how do we determine whether the measurement is of position, velocity, angular momentum, etc.?

Assume we are given a dynamic set without the effects of measurement factored in, and a mapping, $M_z$. For some systems, a partition of $\text{Ran}(M_z)$ alone is sufficient to specify what sort of measurement is being performed. Classical mechanics provides a prominent example of this. If $M_z$ maps paths onto the position & velocity values of the system’s particles at time $z$, then a classical measurement corresponds to system energy, or system angular momentum, or particle velocity, depending on how the measurement partitions $\text{Ran}(M_z)$. Even if the measurement effects the system, measuring ranges of values of $m\vec{r} \times \vec{v}$ corresponds to measuring a particle’s angular momentum. Traditional quantum interpretations, on the other hand, provides a prominent example of systems where the partition of $\text{Ran}(M_z)$ alone
does not specify the type measurement being performed. For example, to know that momentum is being measured, it is not enough to specify the ranges of values being measured, you also need to specify the type of measurement being performed. We will call this kind of system \textit{typed}, because the type of measurement has to be explicitly supplied.

It was mentioned above that the partition of \( \text{Ran}(M_z) \) and the dynamic set, \( S \), are sufficient to describe a moment measurement, as long as \( S \) reflects the effect of the measurement on the system. It follows that for typed systems, the type of measurement being performed is specified by \( S \) at \( z \) (where \( S \) includes the effect of the measurement), and that the choice of measurement alters \( S \) to be in accord with the type of measurement being performed. If the second part of this statement is not the case, then given the dynamic set without the effects of measurement factored in, and the mapping, \( M_z \) the partition of \( \text{Ran}(M_z) \) alone determines the measurement being performed. Both parts of the statement certainly hold in traditional quantum theory, where if momentum is measured at time \( \lambda \) then \( S(\lambda) \) contains momentum states, while if position is measured, then \( S(\lambda) \) contains position states.

It will be helpful to have a means for describing measurements that applies to both typed and non-typed systems. To this end, if a time sequence of \( M_z \)'s is given, a moment measurement can be described by an ordered pair, \((z,Y)\), where \( z = (\lambda,b/f) \) is the time and type of moment partition, and the definition of \( Y \) depends on whether or not the system is typed. For non-typed systems, \( Y \) is a partition of \( \text{Ran}(M_z) \), while for typed systems, \( Y = (\tau,Y_P) \), where \( \tau \) is the type of measurement, and \( Y_P \) is the partition of \( \text{Ran}(M_z) \).

To help simplify the discussion, for typed measurements we overload the “\( \in \)” relation: If \( Y = (\tau,Y_P) \), \( y \in Y \) will assert that \( y = (\tau,x) \), and \( x \in Y_P \). For measurement \((z,Y)\), each \( y \in Y \) is a possible \textit{result}. To be able to discuss both typed & non-typed results seamlessly, we introduce the “\( \sim \)” operator: For typed result \( y = (\tau,x) \), \( \tilde{y} = x \), stripping out the type, while for non-typed systems, \( \tilde{y} = y \).

Returning to system paths, assume that \( \alpha \subset S \) is the outcome of some experiment (including, possibly, the empty experiment), and that after \( \alpha \) is obtained, we wish to perform measurement \((z,Y)\) on it. This measurement may effect the system dynamics, altering \( \alpha \). The altered set will be represented by \( \alpha \triangleleft (z,Y) \). If the measurement does not effect the system dynamics at all, then \( \alpha \triangleleft (z,Y) = \alpha \). Note that, because the choice of \( M_z \) effects the meaning of measurement \((z,Y)\), the nature of the \( \triangleleft \) operator can depend on the choice of \( M_z \).

57
If measurement \((z,Y)\) is performed on prior outcome \(\alpha\), the set of outcomes for this measurement is \(\{M_{z,O(z,Y)}^{-1}[y] : y \in Y\}\). This set will be represented by \(\alpha|(z,Y)\). The “|” operator appends a new moment partition to the end of the prior outcome. This operation was discussed previously in Sec X B. The constraints of Defn 46 continue to apply, and are readily seen to apply only to the “⊳” portion of the append operation. These constraints will be assumed to hold axiomatically to the “⊳” operation, regulating both when it can be applied to an outcome, and what effects it may have.

C. Compound Measurements

If measurement \((z,Y)\) is appended to prior outcome \(\alpha\), and \(\beta \in \alpha|(z,Y)\), another measurement, \((z',Y')\), may be appended to \(\beta\) to form \(\beta|(z',Y')\). This pair of measurements may be viewed as being a single, compound measurement on \(\alpha\). The results for such a compound measurement are the time sequences of results from the constituent moment measurements. Sequences of moment measurement results will be stylized as \(\langle A_z \rangle_Z\), where \(Z\) is the set of \(z = (\lambda,b/f)\) values at which moment measurements are performed, and for each \(z \in Z\), \(A_z\) is the result obtained at \(z\).

A compound measurement can in turn be identified with its collection of result sequences. In order to qualify as a compound measurement, however, a collection of result sequences must satisfy certain constraints. To simplify the wording of these constraints, two bits of notation will be helpful. First, if \(Z\) is a set of \((\lambda,b/f)\) values, \(Z \downarrow z\) is the set of all elements of \(Z\) that are less than \(z\). Second, if \(\langle A_z \rangle_Z\) is a result sequence, and \(m\) is a collection of result sequences, \(m[\langle A_z \rangle_Z]\) is the set of all sequences in \(m\) that start with \(\langle A_z \rangle_Z\).

We may now define compound measurements as follows: A set of result sequences, \(m\), is a *compound measurement* if it satisfies:

1) There’s a \(\lambda_0\) s.t., for all \(\langle A_z \rangle_Z \in m\), \(\lambda_0\) is a lower bound of \(Z\).
2) For all \(\langle A_z \rangle_Z \in m\) there’s a \(\lambda_1\) that is an upper bound of \(Z\).
3) For any \(\langle A_z \rangle_{Z_1}, \langle B_z \rangle_{Z_2} \in m\), any \(z \in Z_1\), if for all \(z' \in (Z_1 \downarrow z) \cap (Z_2 \downarrow z)\), \(\tilde{A}_{z'} \cap \tilde{B}_{z'} \neq \emptyset\), then \(\langle B_z \rangle_{Z_2} \in m[\langle A_z \rangle_{Z_1 \downarrow z}]\) and \(z \in Z_2\).
4) For any \(\langle A_z \rangle_Z \in m\), all \(z' \in Z\), \(\{\tilde{B}_{z'} : \langle B_z \rangle_{Z_1} \in m[\langle A_z \rangle_{Z_1 \downarrow z}]\}\) is a partition of \(\text{Ran}(M_{z'})\). For typed systems, all elements of the set \(\{B_{z'} : \langle B_z \rangle_{Z_1} \in m[\langle A_z \rangle_{Z_1 \downarrow z}]\}\) must be of the same type.
The first two axioms are basic start-stop conditions. The third ensures that compound measurements form a tree (or, as phrased in Sec X B, a branching sequences of moment measurements). Note that this axiom implies that if \((Z_1 \downarrow z) \cap (Z_2 \downarrow z) = \emptyset\), then \(\langle B_z \rangle_{Z_2} \in m[\langle A_z \rangle_{Z_1}]\) and \(z \in Z_2\). This means that \((Z_1 \downarrow z) \cap (Z_2 \downarrow z) = \emptyset\) if and only if \(z\) is the minimal element of both \(Z_1\) and \(Z_2\). The fourth axiom says that compound measurements partition the measurement space, which ensures that the tree contains a complete set of results.

Starting with the \(M_z\)'s, and the \(\prec\) operator for moment measurements, versions of the \(\prec\) and \(\mid\) operators can be derived with domains expanded to compound measurements. As can be seen from the results in Sec X B, if \(D\) is a dynamic space and \(m\) is a compound measurement, then \(D\mid m\) is an ideal partition. Thus, compound measurements represent ideal partitions.

**Remark.** Multiple different compound measurements may represent the same ideal partition. That is, for a given dynamic space, \(D\), it is possible to have \(m \neq m'\) and \(D\mid m = D\mid m'\). Because of this, the constructions of Sec XII cannot be reproduced using compound measurements alone; to construct the elements of \(X_N \setminus X\), we need to switch between different compound measurements that represent the same ideal partition. An explicit example of this is given in Appendix A.

### D. Standard DPS’s

Compound measurements can be utilized to greatly simplify dps probabilities. The structures that realize this simplification will be called “standard dps’s”, because they provide a standard approach to dps’s. To define them, the following will be helpful: If \(\langle B_z \rangle_Z\) is a result sequence, and \(m\) is a set of result sequences, \(m^-[\langle B_z \rangle_Z] \equiv m \setminus m[\langle B_z \rangle_Z]\); that is, \(m^-[\langle B_z \rangle_Z]\) is the set of elements of \(m\) that do not start with \(\langle B_z \rangle_Z\).

A **standard dps** is a convergent dps, \((X, T, P)\), together with a sequence of mappings, \(M_z\), operator, \(\prec\), and set of compound measurements, \(C\), that satisfy:

1) \(\gamma \in X\) iff for some \(\{D\} \in X \& m \in C\), \(\gamma = D\mid m\)
2) If \(\gamma \in X\), and \(\alpha \in \gamma\), then \(\{\alpha\} \in T\)
3) For every \(m \in C\), every \(\langle B_z \rangle_Z \in m\), every initial sequence of \(\langle B_z \rangle_Z\): \(\langle A_z \rangle_{Z_0}\), \(m^-[\langle A_z \rangle_{Z_0}] \cup \{\langle A_z \rangle_{Z_0}\} \in C\)
The first axiom says that the set of compound measurements, $C$, and the set of ideal partitions, $X$, represent the same collection of experiments. The second is a simple property that we would often desire of a dps. The third says that $C$ is closed under truncation of the measurement tree.

These axioms hold for both classical and quantum probabilities. They also yield several useful properties.

### E. Applying Axiom 3

The first useful property of standard dps’s can be drawn out with the help of a simple extension to our notation for dynamic sets. For any result sequence, $\langle A_z \rangle_Z$, any $S \subset Dom(M_z)$, $S \rightarrow \langle A_z \rangle_Z$ is the set of paths in $S$ that pass through every element in the sequence $\langle A_z \rangle_Z$. That is, $S \rightarrow \langle A_z \rangle_Z = \bigcap_{z \in Z} M_{z,Z}^{-1}[\tilde{A}_z]$. In particular, if $D$ is a dynamic space and $m$ is a compound measurement, $D|m = \{(D \triangleleft m)|\langle A_z \rangle_Z : \langle A_z \rangle_Z \in m\}$. If $\langle A_z \rangle_Z$ is the empty sequence, we take $S \rightarrow \langle A_z \rangle_Z = S$.

With that, we can consider the implications of axiom 3. Take any $\{D\} \in X$, $m \in C$, $\langle B_z \rangle_Z \in m$, and any initial sequence of $\langle B_z \rangle_Z$, $\langle A_z \rangle_Y$. Define $m_0 \equiv m^{-}\{(\langle A_z \rangle_Y) \cup \{\langle A_z \rangle_Y\}\}$, making $m_0$ the compound measurement formed by replacing the set of results $m(\langle A_z \rangle_Y)$ with the single result $\langle A_z \rangle_Y$. Both $\alpha \equiv \{(D \triangleleft m_0)|\langle A_z \rangle_Y\}$ and $A \equiv \{(D \triangleleft m)|\langle C_z \rangle_X : \langle C_z \rangle_X \in m(\langle A_z \rangle_Y)\}$ are elements of $T$ and, due to the restrictions on $\triangleleft$ from Defn 46, $(D|m) \setminus A = (D|m_0) \setminus \{\alpha\}$. It follows that $P(\{\alpha\}) = P(A)$. In other words, standard dps probabilities are not effected by later measurements.

Continuing with this example, consider the sequence, $\langle D_z \rangle_W$, containing all elements of $\langle B_z \rangle_Z$ that follow $\langle A_z \rangle_Y$. We may ask, what’s the probability of $\langle D_z \rangle_W$ occurring, given that $\langle A_z \rangle_Y$ has occurred? In general, this is the probability of $\langle B_z \rangle_Z$ occurring, divided by the probability that any outcome starting with $\langle A_z \rangle_Y$ occurs. With $S \equiv D \triangleleft m$ and $S^0 \equiv D \triangleleft m_0$, the general expression for this conditional probability is then:

$$P\left(S \rightarrow \langle D_z \rangle_W \mid S^0 \rightarrow \langle A_z \rangle_Y \right) = P\left(S \rightarrow \langle B_z \rangle_Z \right) / P\left(S \rightarrow \langle C_z \rangle_X : \langle C_z \rangle_X \in m(\langle A_z \rangle_Y)\right)$$

The probability in the denominator is for the set $A$, defined above, meaning that for standard dps’s, this reduces to the more intuitive (and simpler) expression:

$$P\left(S \rightarrow \langle D_z \rangle_W \mid S^0 \rightarrow \langle A_z \rangle_Y \right) = P\left(S \rightarrow \langle B_z \rangle_Z \right) / P\left(S^0 \rightarrow \langle A_z \rangle_Y \right)$$
If \( \langle D_z \rangle_W \) contains only a single element, \( (z, D) \), this last equation can be written:

\[
P \left( \left\{ S \rightarrow \langle B_z \rangle_x \right\} \right) = P \left( S \rightarrow (z, D) \rightarrow \langle S^0 \rangle_y \right) \cdot P \left( \left\{ S^0 \rightarrow \langle A_z \rangle_y \right\} \right)
\]

The same formula can, in turn, be applied to the last element in the sequence \( \langle A_z \rangle_Y \) to calculate \( P(\{S^0 \rightarrow \langle A_z \rangle_y \}) \), and so forth. Thus, we can calculate the probability of any result sequence by multiplying the conditional probabilities of its constituent moments. This means that for standard dps’s, we only need to concern ourselves with the probabilities of moment measurements, as all other probabilities can be expressed in terms of these.

### F. Consistency

In order to handle these moment probabilities more systematically, it will be helpful to delve into an issue that has, until now, been glossed over. If \( (z, Y) \) and \( (z, Y') \) are moment measurements, and \( x \in Y \cap Y' \), we have not demanded that \( M^{-1}_{z,\alpha \circ (z,Y)}[\tilde{x}] = M^{-1}_{z,\alpha \circ (z,Y')}[\tilde{x}] \). This is because the effect of a measurement on a system’s dynamic set may depend on the measurement as a whole, and not simply on the given result. In consequence, the probability of obtaining a result may depend on the measurement as a whole, even within the confines of a single dps.

To address this, we say a collection of moment measurements at \( z \), \( \mathcal{M} \), is consistent on prior outcome, \( \alpha \), if for any \( (z, Y), (z, Y') \in \mathcal{M} \), any \( x \in Y \cap Y' \), \( P(M^{-1}_{z,\alpha \circ (z,Y)}[\tilde{x}]) = P(M^{-1}_{z,\alpha \circ (z,Y')}[\tilde{x}]) \). If the system is typed, we assume that all measurements in \( \mathcal{M} \) are of the same type. Consistent collections allow us to simplify the representation of conditional moment probabilities. If collection \( \mathcal{M} \) is consistent on \( \alpha \), \( (z, Y) \in \mathcal{M} \), and \( x \in Y \), then we may write \( P_{\mathcal{M}}(x, z | \alpha) \) for \( P((\alpha \circ (z, Y)) \rightarrow (z, x) \rightarrow (z, x)) / P(\{\alpha\}) \).

Standard dps’s can always be chosen to only contain a single consistent collection for any prior result and time (and type, for typed systems). Indeed, we can take that a step further and define “measurement probability spaces” in analogy to dynamic probability spaces, but with compound measurements replacing ideal partitions. That will not be pursued here, however, as it will only aid in handling edge cases.
G. Probability Distribution

For standard dps \((X, T, P, ... )\), take any outcome, \(\alpha \in \gamma \in X\), and any time, \(z\), at which a new moment measurement may be appended to \(\alpha\). A consistent collection of measurements on \(\alpha\) at \(z\), \(\mathcal{M}\), is complete if for any countable, pairwise disjoint set of results in \(\mathcal{M}, A\), there are \((z,Y), (z,Y') \in \mathcal{M}\), s.t. \(A \subset Y\), and \(Y' \equiv (Y \setminus A) \cup \{\bigcup A\}\). \(\mathcal{M}\) is countably additive if for any such \(A\) there’s a \((z,Y) \in \mathcal{M}\), s.t. \(\bigcup A \in Y\), and \(P_M(\bigcup A, z|\alpha) = \sum_{y \in A} P_M(y, z|\alpha)\).

A complete consistent collection will always be countably additive, but a countably additive consistent collection need not be complete.

A conditional probability function, \(P_M(y, z|\alpha)\), over a countably additive consistent collection of measurements, \(\mathcal{M}\), is a countably additive function on the Borel sets in \(\mathbb{R}^N\). If the function’s domain does not include all Borel sets, it can always be expanded to a countably additive probability function over all Borel sets, \(P'_M(y, z|\alpha)\) (for all \((z,Y') \in \mathcal{M}\), \(y' \in Y'\), \(P'_M(y', z|\alpha) = P_M(y', z|\alpha)\)). There may be more than one such function, but there is always at least one. Any such \(P'_M(y, z|\alpha)\) is in turn equivalent to some probability distribution function, \(\rho_{z,\alpha;\mathcal{M}} : \mathbb{R}^N \to \mathbb{R}\), s.t. for any Borel set, \(X\), \(P'_M(y, z|\alpha) = \int_X \rho_{z,\alpha;\mathcal{M}} d^N x\). For any result in \(\mathcal{M}\), the related integral will yield the correct probability. Thus, if consistent collections are countably additive, these \(\rho_{z,\alpha;\mathcal{M}}\) completely specify the conditional moment probabilities, and so all probabilities for the standard dps.

Note that if \(P_M(y, z|\alpha)\) is not defined for every Borel set, then there may be sufficient freedom in the choice \(P'_M(y, z|\alpha)\) to be able to choose a \(\rho_{z,\alpha;\mathcal{M}}\), that is not non-negative almost everywhere. This would render it a pseudo-probability distribution. We will, however, always assume that \(\rho_{z,\alpha;\mathcal{M}}\) is a proper probability distribution.

H. Time Evolution

\(\rho_{z,\alpha}\) is, essentially, a time dependent conditional probability distribution, where \(z\) gives the time dependence, and \(\alpha\) the condition. For a standard dps, one would naturally be interested in how \(\rho_{z,\alpha}\) changes as \(z\) changes.

If there are no measurements in the interval \([z, z']\) then the distribution at \(z\) will likely determine the distribution throughout this interval. In this way, we obtain the distribution, \(\rho\), as a function of time. Commonly, \(\rho\) as a function of time can be derived from a universal
Quantum systems possess such equations of motion, but it is interesting to note that in most formulations, knowing $\rho$ at a given time is not enough to know it at all times. The probability current is also required; the probability distribution & current being equivalent to the wave function. This may be because, in these formulations, the probability distribution is a function of the system state, but is not a function of the changes to the state that moments can also describe. The probability current supplies the missing information.

We say a standard dps is *wholly physical* if the effect of measurement on the dynamic set and the probability distribution can be derived by expanding the system to include the measuring devices, and applying the equation of motion to the new, larger system. For such systems, the effects of measurement can be understood according to the same rules that drive all other aspects of the physical system’s dynamics. Classical systems can always be described in terms of wholly physical standard dps’s. Quantum systems can be described in terms of standard dps’s, but whether any such dps’s are wholly physical is an open question. In one form or another, this has been one of the enduring mysteries of quantum theory.

**Part V**

**Quantum Partitions of Unity**

Here, results of the prior part will be utilized to explain core characteristics of quantum probabilities, and deduce the sorts of experiments that quantum theory describes. We start by further considering the $(X_N, T_N, P_N)$ construction on dps’s.

**XV. DPS’S ON AN INDIVIDUAL DYNAMIC SET**

As indicated earlier, if $(X, T, P)$ is a dps, we do not expect $X_N$ to be composed entirely of ideal partitions. To understand the makeup of $(X_N, T_N, P_N)$, we need to identify aspects of ideal partitions that continue to hold for $t_1 \cup t_2$ when $t_2 \in \neg^{(3)} t_1$. In this section, we concentrate on dps’s on a single dynamic set, meaning that for all $\gamma_1, \gamma_2 \in X$, $\bigcup \gamma_1 = \bigcup \gamma_2$. In such cases, *nearly ideal partitions* provide what we’re looking for:
Definition 64. A partition, $\gamma$, of dynamic set, $S$, nearly ideal if

1) For every $\alpha, \beta \in \gamma$, every $(\lambda, p) \in Uni[\bigcup \gamma]$ either $\alpha \rightarrow_{(\lambda, p)} \beta = \beta \rightarrow_{(\lambda, p)}$ or $\alpha \rightarrow_{(\lambda, p)} \bigcap \beta = (\lambda, p) = \emptyset$

2) For every $\alpha \in \gamma$, every $\lambda \in \Lambda_S$, $\alpha = \alpha[-\infty, \lambda] \circ \alpha[\lambda, \infty]$.

3) There exists a $\lambda_0 \in \Lambda_S$ s.t. for all $\alpha \in \gamma$, all $\lambda \leq \lambda_0$, $\alpha = S[-\infty, \lambda] \circ \alpha[\lambda, \infty]$.

4) For all $\alpha \in \gamma$, there exists a $\lambda_\alpha \in \Lambda_S$ s.t. $\alpha = S_{\alpha[-\infty, \lambda_\alpha]}$.

For every $\gamma \in X_N$, properties 2 and 4 must hold, because they hold for elements of ideal partitions, and every element of $\gamma$ is the element of some ideal partition. Property 3 holds for ideal partitions, and will hold for sets formed out of any finite collection of ideal partitions; it will therefore hold for $\gamma \in X_N$. Property 1 is a weakened version of the 1st property of ideal partitions, rendering it transitive across the $\neg$ relation. It is easy to see that this property holds when $\gamma$ is an ideal partition: If $p \in \alpha(\lambda) \bigcap \beta(\lambda)$, and $|\alpha[-\infty, \lambda]| = |\beta[-\infty, \lambda]|$, then $\alpha \rightarrow_{(\lambda, p)} \beta = \beta \rightarrow_{(\lambda, p)}$, otherwise $\alpha \rightarrow_{(\lambda, p)} \bigcap \beta = (\lambda, p) = \emptyset$. Thus, all ideal partitions are nearly ideal. To show that all elements of $X_N$ are nearly ideal, we start by showing that the property of being nearly ideal is transitive across $\neg$.

Theorem 65. If $S$ is a dynamic set and $t_1 \bigcup t_2$, $t_2 \bigcup t_3$, and $t_3 \bigcup t_4$ are nearly ideal partitions of $S$, and $t_1 \bigcap t_2 = t_2 \bigcap t_3 = t_3 \bigcap t_4 = \emptyset$, then $t_1 \bigcup t_4$ is a nearly ideal partition of $S$.

Proof. It’s clear that $t_1 \bigcup t_4$ is a partition of $S$, and that properties (2) through (4) of nearly ideal partitions hold for $t_1 \bigcup t_4$. We concentrate on the first property.

Take $\alpha \in t_1$, $\beta \in t_4$, and assume that for $(\lambda, p) \in Uni[\bigcup A], \alpha \rightarrow_{(\lambda, p)} \bigcap \beta \rightarrow_{(\lambda, p)} \neq \emptyset$. With $s[-\infty, \lambda] \in \alpha \rightarrow_{(\lambda, p)} \bigcap \beta \rightarrow_{(\lambda, p)}$, there must be an $\eta \in t_2$ and a $\nu \in t_3$ s.t. $s[-\infty, \lambda] \in \eta \rightarrow_{(\lambda, p)}$ and $s[-\infty, \lambda] \in \nu \rightarrow_{(\lambda, p)}$. Since $t_1 \bigcup t_2$, $t_2 \bigcup t_3$, and $t_3 \bigcup t_4$ are nearly ideal, $\alpha \rightarrow_{(\lambda, p)} = \eta \rightarrow_{(\lambda, p)} = \nu \rightarrow_{(\lambda, p)} = \beta \rightarrow_{(\lambda, p)}$.

It is because this theorem only holds when $t_1 \bigcup t_2$, $t_2 \bigcup t_3$, and $t_3 \bigcup t_4$ are partitions of the same dynamic set that we concentrate on dps’s on a single dynamic set.

We can now show that nearly ideal partitions play a role in $(X_N, T_N, P_N)$ similar to that played by ideal partitions in dps’s:

Theorem 66. If $(X, T, P)$ is a dps on a single dynamic space, $S$, and $\gamma \in X_N$, then $\gamma$ is nearly ideal.
Proof. Let’s use \( \neg_N \) and \([t]_N\) to signify the “\(\neg\)” relation and \([t]\) equivalence class for \((X_N, T_N, P_N)\). The theorem is then equivalent to: If \(t' \in \neg_N[t]_N\), then \(t' \cup t\) is a nearly ideal partition.

For \(t_1, t_2 \in T\), if \(t_1 \in \neg t_2\) then \(t_1 \cap t_2 = \emptyset\) and \(t_1 \cup t_2\) is a nearly ideal partition, so it follows from Thm 65 that if \(t' \in \neg [t]\), then \(t' \cup t\) is a nearly ideal partition.

Using \(\neg_n\) and \([t]_n\) to signify the “\(\neg\)” relation and \([t]\) equivalence class for \((X_n, T_n, P_n)\), we now wish to show that, for \(t, t' \in T_n\), if \(t' \in \neg_n[t]_n\), then \(t' \cup t\) is a nearly ideal partition. We have just shown that it holds for \(n = 0\). Assume it holds for \(n = m\). For \(n = m + 1\), if \(x_2 \in \neg_{m+1}x_1\) then \(x_1 \cup x_2\) is a partition of \(S\) in \(T_m\), and so by assumption, it is nearly ideal. Applying Thm 65 it follows that if \(x_2 \in \neg_{m+1}[x_1]_{m+1}\) then \(x_1 \cup x_2\) is nearly ideal.

If \(t' \in \neg_N[t]_N\) then for some \(n\), \(t' \in \neg_n[t]_n\), so \(t' \cup t\) is a nearly ideal partition. \(\Box\)

Note that this result only relies on the fact that ideal partitions are nearly ideal, and that nearly ideal partitions possess the property stated in Theorem 65. This result will prove quite useful in the next section.

An example of a nearly ideal partition that is not an ideal partition, together with a description of how it can be derived from ideal partitions via the \(\neg\) operation, is provided in Appendix A.

XVI. QUANTUM PROBABILITY

In a gps, \(X_N\) contains the sets that have a total probability of 1 for any allowed probability function. In this section, we take a look at the corresponding quantum property: the sets of quantum outcomes whose total probability must be 1. We will first identify which sets have this property, then apply prior results to understand why those particular sets must have a total probability of 1, while all others need not.

A. The Basics

In traditional quantum theory, an experimental outcome may be represented as a function mapping a set of times onto a set of projection operators. If \(Q\) is a quantum outcome, \(\text{Dom}(Q)\) is the set of times at which measurements took place, and for
each \( \lambda \in \text{Dom}(Q) \), \( Q(\lambda) \) is the projection operator representing a result of the measurement performed at time \( \lambda \). To calculate the probability of obtaining this outcome in an experiment, take the time-ordered product of projection operators in \( Q \), with the earliest time to the right, \( \Pi_Q = \ldots Q(\lambda_j) \ldots Q(\lambda_0) \). (Note: For notational simplicity, we use the Heisenberg representation; in the Schrödinger representation, this would be \( \Pi_Q = \ldots U(\lambda_{j+1}; \lambda_j)Q(\lambda_j)U(\lambda_j; \lambda_{j-1}) \ldots U(\lambda_2; \lambda_1)Q(\lambda_1) \), where the \( U \)'s are propagators.) If the initial state of the wave function is \( \lambda \) the earliest time to the right, \( \Pi_Q \) the earliest time to the right, \( \Pi_Q \), then the probability of outcome \( \lambda \) is \( \langle \psi, \lambda_0 | \Pi_Q^\dagger \Pi_Q | \psi, \lambda_0 \rangle \). A set of outcomes, \( A \), has a total probability of 1 if \( \sum_{Q \in A} \langle \psi, \lambda_0 | \Pi_Q^\dagger \Pi_Q | \psi, \lambda_0 \rangle = 1 \). For this to hold for any allowed probability function, it must hold for any initial wave function; we are therefore interested in sets of outcomes that satisfy \( \sum_{Q \in A} \Pi_Q^\dagger \Pi_Q = I \), where \( I \) is the identity operator. For the obvious reasons, we are only interested in cases where \( \sum_{Q \in A} \Pi_Q = I \); the question of whether it is possible to have \( \sum_{Q \in A} \Pi_Q^\dagger \Pi_Q = I \) and \( \sum_{Q \in A} \Pi_Q \neq I \) will not be pursued. A set of outcomes that satisfies \( \sum_{Q \in A} \Pi_Q^\dagger \Pi_Q = I \) and \( \sum_{Q \in A} \Pi_Q = I \) will be called a partition of unity.

If \( A \) is a partition of unity, then for each \( Q \in A, \lambda \in \text{Dom}(Q) \), we may choose a basis that diagonalizes \( Q(\lambda) \). The assumption that \( \sum_{Q \in A} \Pi_Q = I \) means that these choices determine a collection of complete bases. We’ll refer to the vectors in these bases by \( |s, \lambda \rangle \), the parameter “\( s \)” referring to the states being measured at \( \lambda \).

To go much further, we’ll need to know which state transitions are allowed; if a transition \( (\lambda_1, s_1) \to (\lambda_2, s_2) \) is not allowed, this means that \( \langle s_1, \lambda_1 | s_2, \lambda_2 \rangle \) must be zero, and this will effect which sets of outcomes qualify as partitions of unity. If \( \langle s_2, \lambda_2 | s_1, \lambda_1 \rangle \neq 0 \), then it is clear that the system can transition from \( (\lambda_1, s_1) \) to \( (\lambda_2, s_2) \). However, if \( \langle s_2, \lambda_2 | s_1, \lambda_1 \rangle = 0 \), it is not clear whether the value is 0 for a particular choice of the probability function, but may be non-zero for others, or if the system simply cannot transition from \( (\lambda_1, s_1) \) to \( (\lambda_2, s_2) \). Looking at this from another perspective, \( \langle s_2, \lambda_2 | s_1, \lambda_1 \rangle \), may be 0 because the transition cannot take place, or because transition can take place, but is exceedingly unlikely. There is therefore some freedom in choosing the allowed transitions.

With this freedom in mind, we would like to identify a minimal set of allowed transitions; transitions that will always be assumed to be allowed. To do so, we resurrect the notion of a transition chain (see Sec \( \boxed{\Pi} \)). We’ll say that a transition chain \( (\lambda_1, s_1) \to (\lambda_2, s_2) \to \ldots (\lambda_n, s_n) \) must be allowed if all \( k < n, \langle x_k, \lambda_k | x_{k+1}, \lambda_{k+1} \rangle \neq 0 \). If a transition chain is allowed, we further assume that all subsets are also allowed. This assumption is normal for transition
chains, and handles a peculiar issue that arises because quantum probabilities are non-additive. It is possible to have \( \langle s_1, \lambda_1|s_2, \lambda_2 \rangle = 0 \), but for some \( |x, \lambda \rangle \), \( \lambda_1 < \lambda < \lambda_2 \), have \( \langle s_1, \lambda_1|x, \lambda \rangle \langle x, \lambda|s_2, \lambda_2 \rangle \neq 0 \). In such cases, we assume that the transition \((\lambda_1, s_1) \rightarrow (\lambda_2, s_2)\) is allowed. This assumption is also made in the path-integral formalism of quantum mechanics.

Note that if \( T \) is one of these allowed transition chains, and \( \lambda \) is not in the domain of \( T \), there’s a state \( s \) s.t. \( T \cup \{ (\lambda, s) \} \) is also an allowed transition chain. This is because, if \( \langle s_2, \lambda_2|s_1, \lambda_1 \rangle \neq 0 \), then it follows from \( \langle s_2, \lambda_2|s_1, \lambda_1 \rangle = \int \langle s_1, \lambda_1|x, \lambda \rangle \langle x, \lambda|s_2, \lambda_2 \rangle dx \) that there must be an \( s \) s.t. \( \langle s_1, \lambda_1|x, \lambda \rangle \langle x, \lambda|s_2, \lambda_2 \rangle \neq 0 \).

Given any particular quantum outcome, \( Q \), we can now define the minimal set of transition chains that are consistent with it.

**Definition 67.** If \( Q \) is an outcome, \( T \) is a \( Q \)-transition_chain if there exists a set of vectors, \( V \), s.t.

1) If \( |s_1, \lambda_1\rangle, |s_2, \lambda_2\rangle \in V \), and \( \lambda_1 = \lambda_2 \), then \( s_1 = s_2 \). (That is, \( V \) does not contain more than one vector at any time.)

2) For all \( \lambda \in \text{Dom}(Q) \), there’s a vector \( |s, \lambda\rangle \in V \), and \( Q(\lambda)|s, \lambda\rangle = |s, \lambda\rangle \)

3) For all \( |s, \lambda\rangle \in V \), all \( |s', \lambda'\rangle \in V \) s.t. \( \lambda' < \lambda \), there’s \( |s_1, \lambda_1\rangle \in V \) s.t. \( \lambda' \leq \lambda_1 < \lambda \) and \( \langle s_1, \lambda_1|s, \lambda \rangle \neq 0 \). (If all elements of \( V \) have an immediate predecessor, this states the condition discussed above. Note that if there is no \( |s', \lambda'\rangle \in V \) s.t. \( \lambda' < \lambda \), then the condition is vacuously true.)

4) For all \( (\lambda, s) \in T \), \( |s, \lambda\rangle \in V \). (That is, \( T \), the \( Q \)-transition_chain, is any subset of \( V \).)

A \( Q \)-transition_chain with an element at every \( \lambda \in \Lambda \) is a \( Q \)-path. Every \( Q \)-transition_chain is a subset of some \( Q \)-path. Note that for any outcome, \( Q \), and any choice of bases, the set of \( Q \)-path's is closed under concatenation.

**B. Characterizing Quantum Partitions of Unity**

We now seek to understand the conditions under which \( \sum_{Q \in \Lambda} \Pi_Q \Pi_Q = I \). This will require expanding the \( \Pi_Q \Pi_Q = Q(\lambda_0)\ldots Q(\lambda_j)\ldots Q(\lambda_M)\ldots Q(\lambda_j)\ldots Q(\lambda_0) \), and summing over the necessary transition chains. We will only need to sum over \( Q \)-transition_chain's,
as all other transition chains will not add anything to the sum. Defining $Dom(A) \equiv \bigcup_{Q \in A} Dom(Q)$, for $\sum_{Q \in A} \Pi_Q \Pi_Q^\dagger$ to be calculable, $Dom(A)$ must satisfy a couple of restrictions. Namely, $Dom(A)$ must have a maximal element, and every non-minimal element must have an immediate predecessor. Without these restrictions, we would not be able evaluate the inner products implicit in $\sum_{Q \in A} \Pi_Q \Pi_Q^\dagger$. (The expansion $\Pi_Q \Pi_Q^\dagger = Q(\lambda_0) ... Q(\lambda_j) ... Q(\lambda_M) ... Q(\lambda_j) ... Q(\lambda_0)$ cannot even be explicitly written without enforcing these restrictions on $Dom(Q)$.) As this appears to be an artifact of the quantum formalism, it may not imply anything of purely physical significance.

In order to be able to calculate actual probabilities for all of the outcomes in $A$, we need to be able to apply an initial wave function (or density matrix) to each of them. This means that $Dom(A)$ must be bounded from below. While this does not demand that $Dom(A)$ must have a minimal element, because we can always add a time to an outcome by assigning $Q(\lambda) = \mathbb{I}$, being bounded from below does mean that we can always append a minimal element to $Dom(A)$.

Finally, to describe the range of sums required to evaluate $\sum_{Q \in A} \Pi_Q \Pi_Q^\dagger$, we will need a somewhat peculiar binary relation on $Q_{transition \_chains}$, $\Xi(A; \lambda)$. It is defined as follows: If $A$ is a set of outcomes, then $\Xi(A; \lambda)$ is the set of all pairs, $(x, y) \in \Xi(A; \lambda)$, s.t. (1) for some $Q \in A$, both $x$ and $y$ are $Q_{transition \_chains}$, (2) $Dom(x) = Dom(y) = Dom(A)$, and (3) For all $\lambda' \in Dom(A)$, if $\lambda' \geq \lambda$ then $x(\lambda') = y(\lambda')$.

Taking $\lambda_M = Max(Dom(A))$, $\lambda_{M-1}$ to be the predecessor of $\lambda_M$, $\lambda_{M-2}$ to be the predecessor of $\lambda_{M-1}$, and $\lambda_0$ to be the minimal element, $\sum_{Q \in A} \Pi_Q \Pi_Q^\dagger$ can now be expanded as:

$$\int_{\Xi(A; \lambda_M)} ds_0 ds'_0 ... ds_M |s_0, \lambda_0| ... \langle s_{M-1}, \lambda_{M-1} | s_M, \lambda_M \rangle \langle s_M, \lambda_M | s'_{M-1}, \lambda_{M-1} \rangle ... \langle s'_0, \lambda_0 |$$

To understand the conditions under which this integral equals $\mathbb{I}$, we start by integrating over $s_M$. We must perform this integral for each value of $s_0, ..., s_{M-2}, s_{M-1}$ and $s'_0, ..., s'_{M-2}, s'_{M-1}$. We therefore take pairs of $Q_{transition \_chains}$ ($Q \in A)$, $x$ and $x'$, with domains of $Dom(A) \setminus \{\lambda_M\}$, and integrate over the $s_M$ that satisfy $(x \cup \{s_M, \lambda_M\}), (x' \cup \{s_M, \lambda_M\}) \in \Xi(A; \lambda_M)$. For $\sum_{Q \in A} \Pi_Q \Pi_Q^\dagger = \mathbb{I}$ each of these integrals over $s_M$ must either equal $\mathbb{I}$ or 0. This means that for each such $x$ and $x'$, either all pairs of transition-chains of the form $x \cup \{s_M, \lambda_M\}$ and $x' \cup \{s_M, \lambda_M\}$ are elements of the same outcome, or all such pairs are elements of distinct outcomes. Note that when $x = x'$, the integral is $\mathbb{I}$.
If this rule is obeyed, then after we integrate over \( s_M \) we get:

\[
\int_{\Xi(A;\lambda_{M-1})} ds_0 ds'_0 ... ds_{M-1}|s_0, \lambda_0 \rangle ... \langle s_{M-2}, \lambda_{M-2}|s_{M-1}, \lambda_{M-1} \rangle \langle s_{M-1}, \lambda_{M-1}|s'_{M-2}, \lambda_{M-2} \rangle ... \langle s'_0, \lambda_0 |.
\]

Which is of the same form as the prior equation, and so the same condition applies for \( s_{M-1} \). With this, the general condition that the set of outcomes must obey in order to be a partition of unity comes into view. For convenience in expressing the condition, let’s introduce the shorthand \( l_\lambda \equiv \{ \lambda' \in \text{Dom}(A) : \lambda' < \lambda \} \) for the lower set corresponding to all values of \( \text{Dom}(A) \) less than \( \lambda \), and \( u_\lambda \equiv \{ \lambda' \in \text{Dom}(A) : \lambda' \geq \lambda \} \) for the upper set of all values of \( \text{Dom}(A) \) greater than or equal to \( \lambda \). The general condition is then: For every \( \lambda \in \text{Dom}(A) \), every pair of transition-chains on \( l_\lambda \), \( x \) and \( x' \), if there is a transition-chain, \( y \), on \( u_\lambda \) s.t. \( \{ x \cup y, x' \cup y \} \in \Xi(A;\lambda) \), then for all transition-chains on \( u_\lambda \), \( y' \), s.t. \( x \cup y' \) and \( x' \cup y' \) are transition-chains, \( \{ x \cup y', x' \cup y' \} \in \Xi(\lambda) \). As has been argued, if \( A \) does not obey this condition, then \( \sum_{Q \in A} \Pi_Q^\dagger \Pi_Q \neq I \). It is also relatively easy to see that if \( A \) does obey it, then \( \sum_{Q \in A} \Pi_Q^\dagger \Pi_Q = I \). Perhaps the easiest way to see this is, if \( \lambda_0 \) has a successor, \( \lambda_1 \), and we continue these integrals down to \( \lambda_1 \), we get \( \int_{\Xi(A;\lambda_1)} ds_0 ds'_0 ds_1 |s_0, \lambda_0 \rangle \langle s_0, \lambda_0|s_1, \lambda_1 \rangle \langle s_1, \lambda_1|s'_0, \lambda_0 \rangle \langle s'_0, \lambda_0 |. \) Because \( \sum_{Q \in A} \Pi_Q = I \), and because it is always the case that \( (x, x) \in \Xi(A;\lambda) \), this integral yields \( I \).

Taking into account the definition of \( \Xi(A;\lambda) \), the condition under which a collection of outcomes qualifies as a partition of unity can be more simply written as: For any initial segment of \( \text{Dom}(A) \), and for any pair of transition chains on that initial segment, \( x \) and \( x' \), either all pairs of transition chains on \( \text{Dom}(A) \) of the form \( x \cup y \) and \( x' \cup y \) are elements of the same outcome, or all such pairs are elements of distinct outcomes. This will be referred to as the partition of unity condition. We will now apply the language of dynamic sets & gps’s to understand why this condition would hold.

**C. Recasting in Terms of Paths**

The partition of unity condition represents perhaps the most basic structure in quantum probabilities, it is the sets of experimental outcomes guaranteed to have a total probability of 1. We will try to understand it by applying the language of dynamic probability spaces, which will require recasting the condition into the language of paths. To accomplish this, we
make the same assertion that we made in Section III, that every transition-chain is a subset of a maximal transition chain, meaning that for every transition-chain there is a path that passes through all its points. This will result in a dynamic set for every partition of unity and choice of bases. These dynamic sets may consist entirely of Q-path’s, though as discussed, the possibility that further paths exist is not ruled out. Whatever their composition, given the dynamic sets, we would like to understand which partitions satisfy the partition of unity condition. To find out, we start by defining the class of experimental outcomes that the quantum formalism is capable of describing.

Definition 68. If S is a dynamic set, and \( L \subset \Lambda_S \), \( \alpha \subset S \) is determined on \( L \) if \( \alpha = \bigcap_{\lambda \in L} S_{\rightarrow (\lambda, \alpha(\lambda))} \). If \( L \) is finite, this is equivalent to saying that \( \alpha = S_{\rightarrow (\lambda_1, \alpha(\lambda_1))} \circ \ldots \circ S_{\rightarrow (\lambda_N, \alpha(\lambda_N))} \). A collection of subsets of \( S \) is determined on \( L \) if every element is.

We use this to define the set of partitions on which quantum calculational techniques can be applied. These are the partitions determined on some \( L \subset \Lambda \) that satisfies restrictions previously described for \( \mathrm{Dom}(A) \).

Definition 69. For dynamic set, \( S \), \( \mathcal{\Pi}_S \) is the set of partitions of \( S \) satisfying: If \( \gamma \in \mathcal{\Pi}_S \) then \( \gamma \) is determined on some \( L \subset \Lambda_S \) s.t. \( L \) is bounded from below, and every subset of \( L \) has a maximum element.

For \( \gamma \in \mathcal{\Pi}_S \), \( \Lambda_\gamma(\gamma) \) is the set of all such \( L \subset \Lambda_S \). If \( L \in \Lambda_\gamma(\gamma) \), and \( \lambda \in L \setminus \{\inf(L)\} \), we’ll designate the predecessor of \( \lambda \) as \( \lambda_p \).

We are now in a position to define the set partitions that qualify as partitions of unity.

Definition 70. For dynamic set, \( S \), \( Q_S \) is comprised of the elements of \( \mathcal{\Pi}_S \), \( \gamma \), s.t. for some \( L \in \Lambda_\gamma(\gamma) \), \( \lambda_M = \text{Max}(L) \):

For all \( \alpha \in \gamma \), all \( \bar{p}_1, \bar{p}_2 \in \alpha \), if for some \( \lambda \in L \setminus \{\inf(L)\} \), \( \bar{p}_1[\lambda, \lambda_M] = \bar{p}_2[\lambda, \lambda_M] \) then for any \( \bar{p}_1', \bar{p}_2' \in S \) s.t. \( \bar{p}_1'[-\infty, \lambda_p] = \bar{p}_1[-\infty, \lambda_p] \), \( \bar{p}_2'[-\infty, \lambda_p] = \bar{p}_2[-\infty, \lambda_p] \), and \( \bar{p}_1[\lambda, \lambda_M] = \bar{p}_2[\lambda, \lambda_M] \), there is a \( \beta \in \gamma \) s.t. \( \bar{p}_1', \bar{p}_2' \in \beta \).

\( Q_S \) is precisely the collection of partitions of unity derived above. It simply renders the condition in terms of paths rather than transition chains.

As things stand, we’ve placed almost no restrictions on the dynamic sets. To be bring order to the collection of dynamic sets, and to bring our analysis of quantum measurements...
more in line with that for recorders, we’ll assume that the dynamic sets of interest are unbiased, meaning they satisfy:

1) There’s a \( \lambda \) s.t. for all \( \lambda' < \lambda \), \( S = S[-\infty, \lambda'] \circ S[\lambda', \infty] \)

2) For any allowed outcome on the set, \( \alpha \), all \( \lambda' \), all \( \bar{p}_1, \bar{p}_2 \in S_{\alpha[-\infty, \lambda']}, \) if \( \bar{p}_1(\lambda') = \bar{p}_2(\lambda') \) then \( \bar{p}_1[-\infty, \lambda'] \circ \bar{p}_2[\lambda', \infty] \in S. \)

Dynamic sets composed entirely of \( \mathcal{Q}_{-path} \)'s obey these conditions. Such dynamic sets may not, however, obey the stronger condition of being closed under all concatenation. This is because the choice of bases may depend on the outcome of earlier measurements. For example, we allow experiments of the form: If the system is in region X at time \( \lambda \), measure linear momentum at time \( \lambda_1 \), and if it’s not in region X at time \( \lambda \), measure angular momentum at time \( \lambda_1 \).

In Section [VIII.C] the second condition was on \( |\alpha[-\infty, \lambda]| \) rather than \( \alpha[-\infty, \lambda'] \). However, if \((X, T, P)\) is a dps, and \( \gamma \in X_N \) (as opposed to \( X \)), we do not expect the condition to hold for \( |\alpha[-\infty, \lambda]| \), but we do expect it to hold for \( \alpha[-\infty, \lambda] \). Since the partitions of unity are akin to elements of \( X_N \), we use the weaker form.

We add these conditions to the definition of \( Q_S \) to form \( q_S \):

**Definition 71.** For any dynamic set, \( S \), s.t. for some \( \lambda \), all \( \lambda' < \lambda \), \( S = S[-\infty, \lambda'] \circ S[\lambda', \infty] \), \( q_S \) is comprised of the elements of \( \bar{T}_S \), \( \gamma \), s.t.

1) For all \( \alpha \in \gamma \), all \( \lambda' \), all \( \bar{p}_1, \bar{p}_2 \in S_{\alpha[-\infty, \lambda']}, \) if \( \bar{p}_1(\lambda') = \bar{p}_2(\lambda') \) then \( \bar{p}_1[-\infty, \lambda'] \circ \bar{p}_2[\lambda', \infty] \in S. \)

2) For some \( \lambda \) \( \in \Lambda_q(\gamma) \), \( \lambda_M \equiv \text{Max}(L) \), for all \( \alpha \in \gamma \), all \( \bar{p}_1, \bar{p}_2 \in \alpha \), if for some \( L \in \Lambda_q(\gamma) \), \( \lambda_M \equiv \text{Max}(L) \), for all \( \alpha \in \gamma \), all \( \bar{p}_1, \bar{p}_2 \in \alpha \), if for some \( \lambda \in L \setminus \{\inf(L)\} \), \( \bar{p}_1[\lambda, \lambda_M] = \bar{p}_2[\lambda, \lambda_M] \) then for any \( \bar{p}_1', \bar{p}_2' \in S \), s.t. \( \bar{p}_1'[-\infty, \lambda_p] = \bar{p}_1[-\infty, \lambda_p], \)
\[ \bar{p}_2'[-\infty, \lambda_p] = \bar{p}_2[-\infty, \lambda_p], \]
and \( \bar{p}_1[\lambda, \lambda_M] = \bar{p}_2[\lambda, \lambda_M] \), there’s a \( \beta \in \gamma \) s.t. \( \bar{p}_1', \bar{p}_2' \in \beta. \)

\( q_S \) is the quantum analogue of \( X_N \). We will now attempt to understand what sort of partitions \( q_S \) is comprised of.

**D. Understanding \( q_S \)**

We start by showing that all elements of \( q_S \) are nearly ideal.

**Theorem 72.** For dynamic set \( S \), if \( \gamma \in q_S \) then \( \gamma \) is a nearly ideal partition
Proof. We need to show that 1-4 in the definition of nearly ideal partitions holds.

Conditions (3) and (4) are immediate from the definitions of \( q_\mathcal{S} \) and \( \Lambda_\mathcal{S} \), respectively.

That (2) holds can be seen as follows: For any \( \alpha \in \gamma \), if \( \bar{p}, \bar{p}' \in \alpha \) and \( \bar{p}'(\lambda) = \bar{p}(\lambda) \) then \( \bar{p}_1 \equiv \bar{p}'[-\infty, \lambda] \circ \bar{p}[\lambda, \infty] \in S \). Because \( \alpha \) is determined on some \( L \in \Lambda_\mathcal{S}(\gamma) \), and for all \( \lambda' \in L \), \( \bar{p}_1(\lambda') \in \alpha(\lambda') \), \( \bar{p}_1 \in \alpha \).

That leaves (1) - For every \( \alpha, \beta \in \gamma \), every \( (\lambda, p) \in \text{Uni}[\bigcup \gamma] \) either \( \alpha \rightarrow_{(\lambda, p)} = \beta \rightarrow_{(\lambda, p)} \) or \( \alpha \rightarrow_{(\lambda, p)} \bigcap \beta \rightarrow_{(\lambda, p)} = \emptyset \).

For \( \alpha, \beta \in \gamma \) assume \( \alpha \rightarrow_{(\lambda, p)} \bigcap \beta \rightarrow_{(\lambda, p)} \neq \emptyset \), and \( \alpha \neq \beta \). \( \lambda \) cannot be an upper-bound on any \( \Lambda_\mathcal{S}(\gamma) \). Take any \( \bar{p}[-\infty, \lambda] \in \alpha \rightarrow_{(\lambda, p)} \bigcap \beta \rightarrow_{(\lambda, p)} \), \( \bar{p}'[-\infty, \lambda] \in \alpha \rightarrow_{(\lambda, p)} \), \( \bar{p}_1[\lambda, \infty] \in \alpha_{(\lambda, p)\rightarrow} \), \( \bar{p}_2[\lambda, \infty] \in \beta_{(\lambda, p)\rightarrow} \). The result is proved if \( \bar{p}'[-\infty, \lambda] \in \beta \rightarrow_{(\lambda, p)} \).

Because condition (2) for nearly ideal partitions holds:
\[
\bar{p}_1 \equiv \bar{p}[-\infty, \lambda] \circ \bar{p}_1[\lambda, \infty] \in \alpha \\
\bar{p}'_1 \equiv \bar{p}'[-\infty, \lambda] \circ \bar{p}_1[\lambda, \infty] \in \alpha \\
\bar{p}_2 \equiv \bar{p}[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in \beta \\
\bar{p}'_2 \equiv \bar{p}'[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in S.
\]

Since \( \bar{p}_1[-\infty, \lambda], \bar{p}'[-\infty, \lambda] \in \alpha \rightarrow_{(\lambda, p)}, \bar{p}'_2 \equiv \bar{p}'[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in S \). Applying condition (2) in the definition of \( q_\mathcal{S} \) to any \( \lambda' \in L \in \Lambda_\mathcal{S}(\gamma) \) s.t. \( \lambda' > \lambda \), since \( \bar{p}_1 \) and \( \bar{p}'_1 \) are elements of the same outcome, \( \bar{p}_2 \) and \( \bar{p}'_2 \) must elements of the same outcome. Therefore \( \bar{p}'[-\infty, \lambda] \in \beta \rightarrow_{(\lambda, p)} \).

Interestingly, Thm 66 only requires \( \mathcal{X}_N \) to be entirely composed of nearly ideal partitions when a dps is on a single dynamic set. When there is more than one dynamic set, the other sets can add further information, relieving the restriction that the partitions have to be nearly ideal. Traditional quantum theory allows for huge collections of dynamic sets, yet these other sets apparently do not add any information. This is likely because the multiplicity of dynamic sets is due to different measurable quantities corresponding to different types of states. In the language of standard dps’s, the systems are typed. Under those circumstances, we would not expect the various dynamic sets to shine new light on each other.

Even with that, we would still generally expect a collection of partitions of unity to be more inclusive. For example, if probabilities are additive, all partitions are partitions of unity. Thm 72 shows that quantum probabilities are on the extreme opposite end of the spectrum; they make no demands on partitions of unity beyond those required by the dps.

It may be surprising to note that not all ideal partitions in \( \Lambda_\mathcal{S} \) are included in \( q_\mathcal{S} \). The
reason revolves around the ability to learn something about a system’s past when making a measurement. The issue is easiest to see when system time is discrete. Consider a situation in which, if state \((e_1, s_1)\) at time \(\lambda = 1\) \((e_1\) being the environmental state, and \(s_1\) being the system state) transitions to system state \(s\) at \(\lambda = 2\), then the environmental state will be \(e\) at \(\lambda = 2\), and if \((e_1, s_2)\) at \(\lambda = 1\) transitions to system state \(s\) at \(\lambda = 2\), then the environmental state will be \(e'\) at \(\lambda = 2\), where \(e \neq e'\). At \(\lambda = 1\), the environment doesn’t know whether the system is in state \(s_1\) or \(s_2\), but at \(\lambda = 2\) it learns which state the system was in; the transmission of the system information to the environment was simply delayed by one tick of the clock. Such a scenario is clearly possible, and is consistent with all assumptions for ideal recorders. A complication arises, however, if we add one more detail. Let’s further assume that there is a system state, \(s'\), s.t. if the transition is from either \((e_1, s_1)\) or \((e_1, s_2)\) at \(\lambda = 1\) to \(s'\) at \(\lambda = 2\), then the environmental state is \(e''\) at \(\lambda = 2\). Thus, if the system transitions to \(s\) at \(\lambda = 2\), the environment will discover the system state at \(\lambda = 1\), but if it transitions to \(s'\), it will not. This scenario still does not appear to be inherently problematic, and is allowed by ideal recorders, but it violates the condition for a quantum partition of unity, and so is not allowed for any element in \(q_S\).

The scenario can be understood in terms of moment measurements by saying that, at \((2, s')\), only the state is measured, whereas at \((2, s)\), the backward moment is measured. When phrased like this, it is clear that the same situation can occur when time is continuous, so long as the system dynamics are such that the backward moment at \((2, s)\) reveals information about the state at \(\lambda = 1\). This would happen if the path segments going from \((1, s_1)\) to \((2, s)\) do not cross those going from \((1, s_2)\) to \((2, s)\) prior to \(\lambda = 2\). Thus, when time is continuous, such a partition can be ideal if the system dynamics between \(\lambda = 1\) and \(\lambda = 2\) are just right.

Because the quantum formalism can only describe state measurements made at discrete times, and cannot describe more general moment measurements, the exclusion of these ideal partitions from \(q_S\) is natural. The question is whether any further ideal partitions are also excluded. To find out, we define the set of ideal partitions that can be understood entirely in terms of measurements of the system state at discrete times, rather than requiring more general backward or forward moment measurement. We start by noting that if \(\alpha\) is any outcome of any ideal partition, nothing about \(\alpha\)'s paths is learned between times \(\lambda_1\) and \(\lambda_2\) if and only if \(\alpha = |\alpha[-\infty, \lambda_1]| \rightarrow \alpha[\lambda_2, \infty]\). This gives us:
Definition 73. If \( \gamma \) is an ideal partition, \( S \equiv \cup \gamma \), and \( L \subset A_S \) s.t. every non-minimal element of \( L \) has an an immediate predecessor, then \( \gamma \) is comprised of state measurements at \( L \) if for all \( \alpha \in \gamma \), \( \lambda \in L \setminus \{ \inf(L) \} \), \( \alpha = |\alpha[-\infty, \lambda_p]| \rightarrow \alpha[\lambda, \infty] \).

Limitation to state measurements eliminates precisely the scenario described above. Note that, in the above scenario, if backward moments at \((2, s)\) and \((2, s')\) both reveal whether the system was in \((1, s_1)\) or \((1, s_2)\), then the experiment can be represented by state measurements at \( L \). We can now prove the desired theorem:

Theorem 74. If \( \gamma \in \gamma_S \) is ideal, and for some \( L \in \Lambda_{\gamma}(\gamma) \), \( \gamma \) is comprised of state measurements at \( L \), then \( \gamma \in q_S \)

Proof. Assume \( \gamma \in \gamma_S \) is ideal. Take any \( L \in \Lambda_{\gamma}(\gamma) \) s.t. \( \gamma \) is comprised of state measurements at \( L \), and any \( \lambda \in L \) s.t. \( \lambda \) is not the minimal element of \( L \). Assume that for \( \alpha \in \gamma \), \( \bar{p}_1, \bar{p}_2 \in \alpha \), \( \bar{p}_1(\lambda) = \bar{p}_2(\lambda) \). Take \( \bar{p}_1', \bar{p}_2' \in S \) such that \( \bar{p}_1'[-\infty, \lambda_p] = \bar{p}_1[-\infty, \lambda_p] \), \( \bar{p}_2'[-\infty, \lambda_p] = \bar{p}_2[-\infty, \lambda_p] \), and \( \bar{p}_1'[\lambda, \infty] = \bar{p}_2'[\lambda, \infty] \). If \( \bar{p}_1' \in \beta \in \gamma \), the theorem is proved if \( \bar{p}_2' \in \beta \).

As \( |\alpha[-\infty, \lambda_p]| = |\beta[-\infty, \lambda_p]| \), \( \bar{p}_2'[-\infty, \lambda_p] \in |\alpha[-\infty, \lambda_p]| \). Since \( \bar{p}_2'[\lambda, \infty] \in \beta[\lambda, \infty] \), it follows that \( \bar{p}_2' \in \beta \).

Thus, \( q_S \) contains all ideal partitions that the quantum formalism is capable of describing. Taken together, Thms 72 and 74 show that, although quantum probability may appear peculiar, its core structure can be understood entirely in terms of elementary dps concepts.

Part VI

Quantum Dynamic Spaces

The framework developed in Parts 2-4 will now be used to give a conceptually simple account of quantum phenomenon. The initial presentation will be non-relativistic, with a relativistic version following.
XVII. POSITIONAL SYSTEMS

In this section, we will attempt to demonstrate that quantum systems may be wholly intelligible by describing a large class of systems that display a wide range of quantum behavior. The description will be qualitative rather than quantitative. This ought to be sufficient, as the conceptual difficulties that quantum systems present are due to their qualitative properties, rather than the quantitative details of the behavior.

The class of systems will be described by enumerating a handful of elementary properties that all members of the class will be assumed to possess. Systems that possess these properties will be referred to as “positional systems”. All of the properties will be in accord with both currently available experimental evidence, and direct observation, though some may run afoul of traditional quantum interpretations. While this leaves open the possibility that the physical universe may itself be representable as a positional system, no such claim will be made. It is only claimed that positional systems are conceptually simple, and can behave like quantum systems.

The first property of positional systems conforms to both classical and quantum theory: positional systems are composed of particles, and the fields with which they interact. This statement implies a bit of nomenclature that will prove useful. While the fields will be assumed to be discrete, their elemental constituents will not be referred to as “particles”. That term will be reserved for objects such as electrons and quarks. Naturally, “fermion” could have been used in place of “particle”, but the term “particle” will prove more fitting.

The next two properties of positional systems are that particles follow continuous, piecewise differentiable paths through space, and given a particle path, the particle’s linear momentum is equal to its mass times its path’s tangent vector. These properties are consistent with results from tracking detectors, where particles are observed following paths, and their momentum can be determined in the same manner as for classical particles. For positional systems, we essentially assume that if direct observations reveal that particles follow continuous paths through space, then they follow continuous paths through space regardless of whether or not they are being observed. Though this breaks with quantum orthodoxy, it is a common variety of scientific assertion. Later properties will imply that particle paths cannot be measured to arbitrarily high precision. Within the context of this section, this will be of only peripheral importance.
Turning from paths to states, particle states include position, but not velocity; velocity is derived from the particle path. Particle states also contain identifying characteristics of the particle, such as its mass and charge. They may also contain internal variables, such as spin. The particle portion of a system state is the set of its individual particle states, one element of the set for each particle in the system. It is because multiparticle states are comprised of sets of particle states, rather than tuples, that particle’s identifying characteristics are included with their state. The particle portion of a system path is then a succession of these sets. Having assumed that the particle positions do not undergo jumps, the system path can be used to construct individual particle paths.

Positional system states will also include the state of the interactive fields. However, because the dynamics in this section are non-relativistic, interactive field states will not be explicitly described. This is because, in non-relativistic systems, fundamental interactions are action at a distance. For example, non-relativistically, photons would be created and absorbed at the same moment in time. Field states will be taken up in the following section, where the dynamics will be relativistic. Even if they are not explicitly described in this section, it will be helpful keep in mind that fields do not only help drive dynamics, they also carry information, and so effect which paths can be concatenated. For example, the field state may imply information about particle velocity, information that the particle states themselves lacks.

The final two properties will further describe system dynamics. For a closed system (a system that never interacts with anything outside the system), define the system’s “r-set” to be the subset of system paths consisting of all paths that satisfy the condition: if any subsystem does not interact with its environment over some interval of time, the subsystem’s total momentum is conserved throughout that interval. This implies that, in the r-set, free particles have constant velocity, and the momentum of the system as a whole is conserved. For positional systems, a closed system’s full set of possible paths is equal to the closure of its r-set under concatenation. (To be explicit: if \( R_0 \) is a closed system’s r-set, define \( R_{n+1} \) to be the smallest set of paths s.t. for any \( p_1, p_2 \in R_n \), and any time \( t \) s.t. \( p_1(t) = p_2(t) \), \( \tilde{p}_1[\infty, t] \circ \tilde{p}_2[t, \infty] \in R_{n+1} \). The system’s set of possible paths is \( \bigcup_{n \in \mathbb{N}} R_n \).) Because all knowledge in encoded in the system state, it follows that direct observation cannot disclose whether or not the closed system is following a path in its r-set.

There is a useful, alternate way to view this closure operation. As a closed system moves
along an r-set path it can, at any random time, select a new r-set path from among the paths that share its current state. If a new path is chosen, the change will be difficult to detect, because all aspects of the newly chosen path will be consistent with all that is known about the prior path.

The choice of particle state significantly impacts concatenation. Consider the paths of a classical system. If classical particle states contain both position and velocity, then for a closed system, each path can only be concatenated with itself. However, if velocity is removed from the state, then a system path can be concatenated with many different paths, and so after closure under concatenation, the classical system’s dynamics will become non-deterministic.

Finally, we assert a broad property about the nature of particle interaction. In the textbook description of quantum electromagnetism, particles interact by exchanging photons over light-like separations. To make that description non-relativistic, we flatten the light-cone into a time slice. Particles now interact instantaneously at a distance through discrete, non-deterministic kicks. These kicks are mediated by the interactive fields. Note that in the r-set, kicks conserve momentum, and particles move with constant velocity except at those discrete times in which they interact. For more general system paths, particles move at constant velocity except at the discrete times in which they either interact, or there is a concatenation (or both).

These few simple assumptions are sufficient to motivate many of the signature behaviors of quantum systems, as we will now see.

We start by considering two properties of quantum systems that may appear to be mutually exclusive: quantum systems are both non-deterministic and momentum conserving. They are non-deterministic in that, given any amount of information about a system at any given time, at any later time there will be measurements whose results cannot be predicted. Quantum systems are momentum conserving in that, if a system’s momentum is known to be in some range at some time, and the system does not interact with its environment, then the result of any later momentum measurement will be consistent with the known range.

Positional systems also possess these two properties. To see this, start by noting that for the statement “it is known that a subsystem’s momentum was measured to be in range \( R \)” to be true, it must be the case that in all paths that pass through the current state of the subsystem and its environment, the subsystem’s momentum was measured and found to
be in range \( R \). Similarly, it can only be known that the subsystem has not interacted with its environment since such a measurement took place if, in all paths that pass through the current state of the subsystem and its environment, the subsystem has not interacted with its environment since the measurement took place. We finally note that, because a closed system is a dynamic space, for these things to be known in state \( p \), they must be known in every state that the closed system can pass through when evolving from the measurement to \( p \).

Let’s assume that is known that such a measurement took place, and that the measured subsystem has not interacted with its environment since the measurement took place. In any r-set path, the subsystem’s total momentum will be conserved, and so will continue to be in \( R \). If the system has not followed an r-set path, then there have been concatenations, which are equivalent to choosing a succession of new r-set paths, each sharing the state of the existing path at the time that the new path is chosen. Since in any such path, the subsystem was measured to have a momentum in \( R \), and the subsystem’s momentum has been conserved since the measurement took place, upon concatenation the subsystem’s momentum must continue to be in \( R \). Thus, the system’s momentum may change non-deterministically, but will always be in \( R \), so long as the system does not interact with its environment, and the measurement outcome is remembered. It follows that, even though the system dynamics may be non-deterministic, no violation of conservation of momentum can ever be detected.

Another well-known feature of quantum systems is non-additive probabilities: if \( A \) and \( B \) are two possible results of some experiment, and \( A \cup B \) is a possible result of a different experiment, it is often the case that \( P(A \cup B) \neq P(A) + P(B) \). Further, this inequality will hold in spite of the fact that a result’s experimental probability is independent of the experiment being performed, meaning that if two different experiments both have \( A \) as a possible result, \( A \) occurs with the same frequency in both experiments.

Experimental probabilities for positional system are also generally non-additive. To see this, it will be helpful to employ the language of compound measurements (subsection XIV C). Consider a compound measurement with results \( \langle A_z \rangle_Z \) and \( \langle B_z \rangle_Z \), s.t., for each \( z \in Z \), \( A_z \) and \( B_z \) are either equal or disjoint. Let’s assume that there is also a second compound measurement containing a result of \( \langle A_z \cup B_z \rangle_Z \). We’ll denote the outcomes for these results by \( \mathcal{O}_A \), \( \mathcal{O}_B \), and \( \mathcal{O}_{A \cup B} \). We are interested in the relationship between \( \mathcal{O}_A \) &
$O_B$, and $O_{A \cup B}$.

If recalling compound measurements is burdensome, you can instead consider the concrete case of an experiment that measures position at times $\lambda_1$, $\lambda_2$, and $\lambda_3$, with outcomes $A$ and $B$ corresponding to the same measurement results at times $\lambda_1$ and $\lambda_3$, but different results at $\lambda_2$. A second experiment also measures positions at times $\lambda_1$, $\lambda_2$, and $\lambda_3$, and contains an result, “$A \cup B$”, that agrees with $A$ and $B$ at $\lambda_1$ and $\lambda_3$, but at $\lambda_2$ corresponds to $A_{\lambda_2} \cup B_{\lambda_2}$.

Interaction with the environment experienced by the system may be slightly different in the two experiments. If we ignore those differences, in the r-set we will have $O'_{A \cup B} = O'_A \cup O'_B$. This equality will generally cease upon closure under concatenation. To see this, take any $\bar{s}_1[0, \lambda_f] \in O'_A$, $\bar{s}_2[0, \lambda_f] \in O'_B$ s.t. $\bar{s}_1(\lambda) = \bar{s}_2(\lambda)$ at some time, $\lambda$, after results $A$ and $B$ have been differentiated. (In the concrete example, $\lambda$ is between $\lambda_2$ and $\lambda_3$.) Because the outcomes have been differentiated by $\lambda$ in the first experiment, the experimental equipment must be in different states at $\lambda$ for results $A$ and outcome $B$. The paths for the overall system therefore cannot be concatenated at $\lambda$, meaning that $\bar{s}_1[0, \lambda] \circ \bar{s}_2[\lambda, \lambda_f]$ may not be a possible system path. On the other hand, for the experiment in which only $A \cup B$ is measured, the same set of environmental states can be paired with both paths at $\lambda$, so $\bar{s}_1[0, \lambda] \circ \bar{s}_2[\lambda, \lambda_f]$ must be an possible system path, and is an element of $O_{A \cup B}$. It follows that $O_{A \cup B}$ will generally be a strict superset of $O_A \cup O_B$. Under such conditions, not even traditional probability theory would not require $P(O_{A \cup B})$ to equal $P(O_A) + P(O_B)$.

It should be noted that, though it’s not required, additivity under these circumstances is still possible. In particular, experimental probabilities will not be effected by closure if, whenever a new r-set path is chosen, the probability distribution of the path’s outgoing velocity is equal to the probability distribution of the incoming velocity, and if there’s an initial time at which the incoming velocity distributions are unaffected by closure under concatenation. In all other cases, however, some form of non-additivity in experimental probabilities can be expected.

Double-slit experiments readily reveal the effect of closure under concatenation. Imagine a particle source at point $\vec{x}_0$, a barrier with 2 slits cut into it (so that particles can only pass through the slits), and a screen beyond the barrier that registers the position at which it is struck by particles generated at the source. By the final property of positional systems, a particle passing through a slit in the barrier can receive a kick from a particle in the barrier, causing it to be deflected. We will assume that the likelihood or extent of this deflection is
not affected by the existence of a second slit, in which case such deflections will not cause the non-additive effects seen in double-slit experiments. To see how closure under concatenation can cause these effects, assume that in the r-set there is a particle path that travels from \( \vec{x}_0 \) at time \( \lambda_0 \) through the first slit (where it may be deflected), through some intermediate point, \( \vec{x} \) at time \( \lambda \), striking the screen at \( \vec{x}_1 \) at \( \lambda_1 \). Another path goes from \( \vec{x}_0 \) at \( \lambda_0' \) through the second slit (where it may be deflected) through \( \vec{x} \) at \( \lambda \), striking the screen at \( \vec{x}_2 \neq \vec{x}_1 \) at time \( \lambda_1' \). Upon closure these two paths can be concatenated at \( \lambda \), resulting in a path that goes from \( \vec{x}_0 \), through the second slit, to \( \vec{x} \) and on to \( \vec{x}_1 \). That path mixes paths coming out of both slits, and won’t exist if the second slit is sealed. This is, once again, a situation for which even traditional probability theory would not require that the spatial distribution of particle hits on the screen when both slits are open will equal a weighted sum of the distributions when only the first slit is open, and the when only the second slit is open.

Now, in the classic turn, let’s say that both slits remain open, but we detect which slit the particle passes through. Naturally, this detection will add further path deflection, but let’s ignore that for the moment. What’s more important is that the detection will put the environment in a different state depending on which slit the particle passes through. This means that paths coming from the two different slits cannot be concatenated, and the non-additivity will cease.

Concatenation may also affect probabilities based on particle identity. Consider a system consisting of two particles, and a pair of paths for that system, \( \bar{p}_1 \) and \( \bar{p}_2 \), with \( \bar{p}_1(\lambda) = \{(\vec{x}_1, i_1), (\vec{x}_2, i_2)\} \) and \( \bar{p}_2(\lambda) = \{(\vec{x}_1, i_2), (\vec{x}_2, i_1)\} \), where \( i_1 \) and \( i_2 \) are the particle’s identifying characteristics. These paths can be concatenated at \( \lambda \) if and only if \( i_1 = i_2 \). This means that paths often exist for identical particles that do not exist for distinguishable particles. We can therefore expect particle identity to affect experimental probabilities. Famously, identical and distinguishable particles do display different probabilities.

Another multiparticle effect can be seen if we consider the case in which the total momentum of a collection of particles is known, but the individual particle momenta are not. Let’s say, for example, a pair of free particles is known to have a total momentum of zero, meaning that the pair’s environment is in a state that can only occur when the air’s total momentum is zero. Under concatenation, the total momentum must then remain zero. This means that if, upon concatenation, one particle’s momentum changes from \( \vec{p}_1 \) to \( \vec{p}_2 \), the other particle’s momentum must switch from \(-\vec{p}_1\) to \(-\vec{p}_2\). Thus, these two free, non-interacting particles
are entangled. If one particle’s momentum is later measured to be $\vec{p}_2$, the other particle will have a momentum of $-\vec{p}_2$, and will continue to have a momentum of $-\vec{p}_2$ following any further concatenation.

Other important, though less remarkable, aspects of quantum probability are also consistent with positional dynamics. Two worth mentioning are that the probability for given result is independent of the compound measurement as a whole, and that later measurements do not effect the probabilities of earlier results. The availability of the second property can hardly be a surprise, as it only requires that the likelihood of the closed system choosing to take a particular path now is not effected by the choices of path that will be made in the future, and that the system-environment interactions required for future measurements don’t effect the system prior to the measurement. The first property is equally unsurprising, but requires a little more motivation. First, assume a result’s probability is determined by its set of system paths (that is, assume all ideal partitions belong to the same dps). Next, note that for positional systems, the system-environment interactions due to measurement are likely dominated by interactions that are required to determine the outcome that occurred, while interactions required to determine outcomes do not occur likely have much less impact. This means that, in the r-set, a system’s paths for a given result will be very nearly the same for any experiment that the result may belong to. If two sets of system paths are nearly identical the r-set, then they will be nearly identical after closure. If these differences are too small to affect the probability, then a measurement result has the same probability regardless of context.

As indicated in Sec XIV if these two aspects of quantum probability hold, then probabilities will be additive for the last moment measurement of any sequence of measurements. This is a property of quantum probabilities, and under the circumstances just described, it will also be a property of positional systems’ experimental probabilities.

The quantum behavior discussed thus far display the elusiveness of many quantum effects, in that individual observations do not reveal anything unusual; the peculiarities only show up statistically. For positional systems, this elusiveness derives from the fact that, upon concatenation, any new path will have all the known properties of the old path. However, not all quantum effects possess this elusiveness. Two counter examples are quantum tunneling, and the discrete detection of low intensity light. These effects are not probabilistic; they can be observed in individual events. They also both involve interactions, to which we now
briefly turn our attention.

In a non-relativistic positional system, particles interact via discrete, non-deterministic, action-at-a-distance kicks that are momentum conserving in the r-set. These interactive “kicks” may alter particle paths in ways that remain evident even over long time scales. Such behavior is also characteristic of quantum systems, and is most conspicuous when forces are sharp-edged. For example, when a quantum particle encounters a thin barrier, there is generally no way to know in advance whether the particle will recoil from the barrier, or pass through. The incident particle can, for example, tunnel through a thin barrier simply because no particle happens to interact with it. Similarly, the particle may recoil from a barrier we would (classically) expect it to pass through, if it receives an anomalously strong kick. In a similar way, if the barrier has a hole in it, a particle can pass through the hole and still be deflected, because the barrier’s particle constituents can non-deterministically kick a particle passing through the hole, and a single such kick can permanently alter the particle’s path. Such interaction need not be wholly local, or particle-particle. Indeed, it appears likely that, to fully reproduce quantum effects, interactions may be dependent on the state of the system as a whole. That is, they may have characteristics similar to concatenation. This will be explored further in the next section.

Within traditional quantum mechanics, phenomenon such as tunneling and deflection when passing through a small hole are often understood in terms of “wave-like” properties of particles. This description, however, lacks something. Let’s take the case of the barrier with a small hole punched in it. Assume a quantum particle incident on the barrier/hole has a well-defined momentum; upon passing through the hole, quantum mechanics predicts that the particle will have a wide spectrum of possible momenta. If this momentum spectrum were due to diffraction, then the barrier would not have to have offsetting changes to its momentum. A wave barrier would absorb the momentum from the portion of the wave that it blocks, but it would not have to offset the momentum from the wave as it spreads out beyond the hole. In wave diffraction, momentum conservation only requires that the various elements of the diffracted wave’s momentum spectrum sum to the wave’s momentum as it exits the hole. This, however, is not what we expect for quantum systems. For quantum systems, we expect the barrier’s momentum probability distribution to change so as to precisely offset the changes to the particle’s momentum distribution, even when the particle passes through the hole. That is the only way in which momentum can be conserved. If
the particle momentum is then measured, and its momentum is seen to have changed by \( \Delta \vec{p} \), the barrier’s momentum will be seen to have changed by \(-\Delta \vec{p}\). Thus, the momentum changes as the particle passes through the hole involve momentum exchange between the particle and the barrier, which is in keeping with the positional system description, but is not expected in wave diffraction.

Positional system’s interactive kicks will also affect the precision with which measurements can be made. Measurement requires interaction between the experimental equipment and the particle being measured, and such interaction will cause the particle’s path to be deflected. They therefore make it impossible to determine a particle path to arbitrarily high precision.

Thus many of the signature behaviors of quantum systems can be motivated from a few simple assumptions. Next, we consider the effect of relativity on the model.

XVIII. RELATIVISTIC AMENDMENTS

Here we amend positional systems to make them relativistically sound. We begin with a general description of relativistic dynamic sets.

A. Relativistic dynamic sets

One of the ways in which relativistic dynamic systems differ from non-relativistic systems is in their variety of possible parametrizations. This is because relativistic system states can be described along any space-like surface. For example, given a system of particles, and any space-like surface, the positions of the particles along the surface, together with the particle’s identifying characteristics, can correspond to the system state on that surface.

Let’s call a set of space-like surfaces “complete” if every point in 4-space is on at least one of the surfaces, and “non-intersecting” if there aren’t any points on more than one surface. To parametrize a relativistic system, start by choosing any complete set of non-intersecting space-like surfaces, and then select any time-like path and any clock moving along that path. Parametrize the surfaces by assigning to each the time on the clock when the clock crosses the surface. We refer to the choice of complete, non-intersecting, space-like surfaces, together with the choice of time-reference path & clock, as the parametrization.
Each possible succession of states in a parametrization is a system path, and the set of all such paths is the parametrization’s dynamic set. Given a path for any parametrization, it ought to be possible to transform it into a path for any other parametrization.

B. Relativistic dynamic spaces

For a dynamic space to be relativistically invariant, it cannot distinguish a particular parametrization on which it is closed under concatenation. Instead, a relativistic dynamic space must be closed under concatenation along all surfaces in a set of space-like surfaces that is itself closed under translation and rotation (including boosts). Therefore, if we wish to close a dynamic set into a relativistic dynamic space, we must cut and paste along all elements of some such set of space-like surfaces.

The additional concatenations cause a mild complication to an important feature of positional systems. Let’s assume that in some positional system it’s known that 2 free particles have a total 4-momentum of \( p \). Along some surface, we cut & paste a new path on which the particles have a different pair of 4-momenta that sum to \( p \). But now, along any intersecting surface that crosses one particle path prior to the cut, and the other after, the total 4-momentum will not be \( p \). Thus, momentum will not equal known values at all times in all parametrizations.

A more detailed look shows that such deviations from known values cannot be detected. We make the relativistic assumptions that measurements are performed locally, and knowledge of their outcomes can propagate no faster than the speed of light. For simplicity, we ignore the constraints of the uncertainty principle, and allow velocities to be measured with perfect precision at a point. Let’s say that the 2 particles resulted from the decay of a particle whose 4-momentum is known at 4-space point \( x_0 \). Call the surface on which we cut at paste \( C \), and the surface on which we measure the particle momentum \( M \); both \( C \) and \( M \) are after \( x_0 \). On \( M \), call the particles’ 4-space locations \( x_1 \) and \( x_2 \), \( x_1 \) being before \( C \), and \( x_2 \) after. If particle momentum is measured at \( x_1 \), then both the total momentum and the momentum of one of the particles are known along regions of \( C \). This means that for any concatenation along \( C \), the particles’ momenta can’t change, so there is no problem.

Now assume that there is no measurement at \( x_1 \), but there is one at \( x_2 \). If, prior to the concatenation at \( C \), the particles had momentum \( p_1 \) and \( p_2 \), and after they had momentum
\(\mathbf{p}_1^{'}\) and \(\mathbf{p}_2^{'}\), then at \(x_2\) the particle momentum is measured to be \(\mathbf{p}_2^{'}\), while at \(x_1\) the particle has momentum \(\mathbf{p}_1\). However, since momentum was not measured at \(x_1\), the fact that the total momentum along \(M\) is not \(\mathbf{p}\) is unknown. If the particle at \(x_1\) has its momentum measured after \(C\), it will be \(\mathbf{p}_1^{'}\), and momentum will be seen to have been conserved. Thus, although total momentum might not equal known values along some surfaces, this discrepancy is undetectable. That is a bit of a step back from the non-relativistic case, where conserved quantities will never deviate from their known spectrum of possible values. In the relativistic case, this is weakened to: conserved will never be measured as deviating from their known spectrum of possible values. This may be disconcerting, but it quite obviously does not disagree with experiment.

Lastly, a note on locality may be in order. We are accustomed to thinking of non-relativistic systems as being non-local, due to their action at a distance forces. Relativistic systems, on the other hand, are assumed to be thoroughly local. Relativistic positional systems, however, experience non-local changes to their dynamics. This mirrors quantum systems, which display non-local behavior, but do not violate relativity.

To resolve the apparent conflict, we only need to take into account the role of determinism. While relativistic systems that are deterministic always satisfy locality, non-deterministic relativistic systems may not. The difference can be seen by considering closure under concatenation. A deterministic path can only be concatenated with itself, which means that a deterministic system will be unaffected by closure under concatenation. For non-deterministic systems, on the other hand, closure under concatenation can cause coordinated shifts across an entire closed system, while keeping relativistic invariance intact.

C. Fields

Relativistic positional systems retain nearly all the properties that were enumerated for non-relativistic positional systems. Their particles follow continuous paths through 4-space, these paths always have well defined forward and back velocities, particle momentum equals the particle’s 4-velocity times its mass, and a closed system’s dynamic space is formed by (relativistically) closing its r-set under concatenation. The relativistic r-set is, however, a little more restrictive than it is in the non-relativistic case. For all r-set paths, momentum continues to be conserved in all parametrizations, and at all times, however it is now 4-
momentum that is conserved, rather than simply spacial momentum. In addition, in a relativistic r-set, particles interact via discrete kicks along the light-like separations, rather than the instantaneous kicks of non-relativistic systems. These kicks transfer 4-momentum; when particle $P$ receives a kick, it receives 4-momentum. In response, the particle’s 4-momentum changes (in some way that keeps its mass constant), and it may kick another particle along its forward light-cone. The sum of the particle’s change in 4-momentum and the 4-momentum of the kick it gives must equal the 4-momentum of the kick it received.

Momentum conservation, together with the fact that particle interaction is not action at a distance, mean that some element of the system path must carry the kick momentum between the time the kick is given and the time it is received. The missing element will be termed “signals”, one signal for every kick. “Signal” will be used in place of “photon” because the description will not involve any specifics of electromagnetism, and out of a desire to avoid preconceptions. For momentum to be conserved at all times, the “kick” momentum must be a feature of the signal path’s moments. This means signal momentum is either an element of the signal state, or can be derived from the instantaneous change to its state. For concreteness, momentum will be part of the signal state. This is not done out of necessity, but due to a lack of readily accessible alternatives.

The above r-set description of particle interactions can now be reframed using signals. A particle emits a signal containing 4-momentum. Along the forward light cone of this event, another particle absorbs the signal, absorbing its momentum by altering its own path, and/or emitting a new signal.

(Two minor points with regard to this description may be in order. First, based on experiment, there are generally further channels for particle/signal interaction. Signals may be created when a particle, anti-particle pair is annihilated, and destroyed in the creation of a particle, anti-particle pair. These processes will not be considered, because we will not be interested in the details of any particular type of field; it will simply be assumed that such events can be incorporated into our field description. Second, for momentum to be conserved at all times, the signal momentum at either the emission point or the absorption point must be ignored. If particle momentum is taken to be its back momentum, the emission point is not counted; otherwise, the absorption point is not counted.)

In order to be able to transform between parametrizations, another necessary aspect of the signal moment are the points of emission and absorption. To know the time at which
to add a signal in any parametrization, the point of emission is required, and similarly for knowing when to remove it. This information will have to be part of the signal path’s moments. Once again, we choose to add it to the state, for lack of an obvious alternative. The point of origin will be part of the signal state at the time of its emission (but not afterward), and the point of absorption will be part of the signal state at the time of its absorption (but not before). The point of origin is not in the signal state following emission in order to allow for interference; its removal allows signals from different origins to mix upon concatenation. The mixing of elements from two different 4-space origins is always required for interference.

Other elements may be added to the signal state; for example, to help enforce the character of the interaction. Identifying characteristics can also be added, if more than one type of interactive field is being considered. However, for our purposes, signal states consisting of 4-momentum, together with the momentary inclusion of emission & absorption points, will be sufficient. Signal paths are then constant except at emission, where they begin and are momentarily stamped with their point of origin, and absorption, where they are stamped with the point of absorption, and cease.

Much like concatenation, rules governing which signals can be emitted, and which can absorbed, may depend on the state as a whole. This appears to be a feature of quantum systems. For example, a particle’s radiative spectrum is discrete if it is bound, and being bound is a function of the state of the system as a whole. Similarly, in quantum field theory, individual photon states do not contain enough information to be able to generate the characteristics of electromagnetic interactions. Even something as simple as opposite charges attract and like charges repel cannot be enforced by individual photon states. Instead, the required information is in the state as a whole.

This similarity between concatenation & signal emission/absorption is convenient, because the two operations can be combined. Indeed, for any dynamic space, concatenation and discontinuous transitions (such as signal emission/absorption) can always be combined into a single operation. To see this, we start by defining moments that are slightly coarser grained than path moments.

**Definition 75.** \([\bar{p}, \lambda] = \{ \bar{p}' \in S : \text{for some } \lambda' < \lambda, \text{ all } \lambda'' \in [\lambda', \lambda], \bar{p}'(\lambda'') = \bar{p}(\lambda'') \}\)

\((\bar{p}, \lambda] = \{ \bar{p}' \in S : \text{for some } \lambda' > \lambda, \text{ all } \lambda'' \in (\lambda, \lambda'], \bar{p}'(\lambda'') = \bar{p}(\lambda'') \}\)
It follows that if \( \bar{p}' \in [\bar{p}, \lambda) \) then \([\bar{p}', \lambda) = [\bar{p}, \lambda)\), and similarly for \((\bar{p}, \lambda]\). If paths are continuous at \( \lambda \), then \([\bar{p}, \lambda)(\lambda)\) and \((\bar{p}, \lambda)(\lambda)\) will only have one element, and if these sets only have one element, then \([\bar{p}, \lambda) = [\bar{p}, \lambda, b]\) and \((\bar{p}, \lambda] = [\bar{p}, \lambda, f]\). If these equalities don’t hold, then paths have non-deterministic, discontinuous jumps. The value of the above moments is in their ability to capture such jumps.

The following theorem establishes a useful property of jumps in dynamic spaces.

**Theorem 76.** For a dynamic space

1) If \( \bar{p}_1, \bar{p}_2 \in [\bar{p}, \lambda) \) then there exists a \( \bar{p}' \in [\bar{p}, \lambda) \) s.t. for all \( \lambda' < \lambda \), \( \bar{p}'(\lambda') = \bar{p}_1(\lambda') \), and \( \bar{p}'(\lambda) = \bar{p}_2(\lambda) \).

2) If \( \bar{p}_1, \bar{p}_2 \in (\bar{p}, \lambda] \) then there exists a \( \bar{p}' \in (\bar{p}, \lambda] \) s.t. for all \( \lambda' > \lambda \), \( \bar{p}'(\lambda') = \bar{p}_1(\lambda') \), and \( \bar{p}''(\lambda) = \bar{p}_2(\lambda) \).

*Proof.* 1) There’s \( \lambda_0 < \lambda \) s.t. for all \( \lambda' \in [\lambda_0, \lambda) \), \( \bar{p}_1(\lambda') = \bar{p}_2(\lambda') \), then \( \bar{p}' = \bar{p}[-\infty, \lambda_0] \circ \bar{p}[\lambda_0, \infty] \) satisfies the stated conditions.

The proof for 2 is similar. \( \square \)

**Definition 77.** For path \( \bar{p} \):

- \( \bar{p}[-\infty, \lambda) \) is \( \bar{p} \) restricted to the domain \([-\infty, \lambda)\)
- \( \bar{p}(\lambda, \infty] \) is \( \bar{p} \) restricted to the domain \((\lambda, \infty]\)

For paths \( \bar{p}_1, \bar{p}_2 \), define the concatenation of \( \bar{p}_1[-\infty, \lambda) \) and \( \bar{p}_2(\lambda, \infty] \) by:

\[
\bar{p} \in \bar{p}_1[-\infty, \lambda) \circ \bar{p}_2(\lambda, \infty] \text{ if for some } p \in [\bar{p}_1, \lambda)(\lambda) \cap (\bar{p}_2, \lambda](\lambda), \bar{p}(\lambda) = p, \bar{p}[-\infty, \lambda) = \bar{p}_1[-\infty, \lambda), \text{ and } \bar{p}(\lambda, \infty] = \bar{p}_2(\lambda, \infty]
\]

We will call the new operation “open concatenation”, or “o-concat” for short. If \( \bar{p}_1(\lambda) = \bar{p}_2(\lambda) \), then \( \bar{p}_1[-\infty, \lambda] \circ \bar{p}_2[\lambda, \infty] \in \bar{p}_1[-\infty, \lambda) \circ \bar{p}_2(\lambda, \infty] \), so o-concat extends concatenation. It follows from Thm 76 that dynamic spaces are closed under o-concat. This means that, like concatenation, it can be used to generate dynamic spaces.

To generate a dynamic space with the o-concat operation, it is necessary to specify “jump rules”, which allow us to derive the states in \([\bar{p}, \lambda)(\lambda)\) and \((\bar{p}, \lambda)(\lambda)\) for any \( \bar{p} \). Starting with a dynamic set and jump rules, a dynamic space can then be uniquely generated by applying the o-concat operation.

In positional models, the jump rules specify the conditions for signal absorption/emission. Starting with \((r\text{-set})\) free particle & signal paths, the full dynamic space can be generated.
by recursively applying the o-concat operation along a complete set of space-like surfaces, using the signal transition rules. Paths for closed positional systems are then composed of cells in 4-space, with the cell boundaries being space-like surfaces (for simplicity, we may assume these surfaces are flat). Within each cell, signal states and particle velocities are constant, while on the cell boundary, either or both of these can change.

If the signal transition rules are properly defined, it ought to be possible to extract a relativistic \( r \)-set from the generated dynamic space. To do so, first take the subset of all system paths on which momentum is conserved. Next, for these paths, retain the point of emission in the signal state, so that the point of emission is part of the signal state at all times. Then take just those paths s.t. all points of absorption can be assigned to signals with the necessary momentum, and whose point of emission are light-like separated from the point of absorption. Erasing the excess point of emission information yields the \( r \)-set. The dynamic space ought to be the closure of this \( r \)-set under concatenation. Whether this is the case is entirely a matter of the set of transitions. It requires that the transitions conserve momentum, and are consistent with the light cone restriction, which are the two relativistic assumptions we had started with.

D. Points of Comparison

Up to this point, positional systems properties have been compared to observed characteristics of quantum systems. We will now take a moment to briefly relate their properties to traditional quantum theory.

Positional systems may be seen in the light of quantum theory by taking the perspective that they have a preferred “physical” basis - the position basis for particles, and momentum basis for fields. In that basis, the states for positional systems are nearly identical to those in quantum theory. Particle dynamics are constrained in positional systems, and because of those constraints, particle momentum can be derived from the particle’s path. However, because the traditional quantum formalism cannot be used to describe measurements of instantaneous changes in state, this need not necessarily represent a break with traditional theory.

Positional systems are also in accord with traditional quantum theory in that many of their attributes require the mixing of histories. In quantum theory, this mixing is ac-
accomplished through overlapping amplitudes, while in positional systems, it is accomplished through concatenation. Our description of positional systems differs from quantum theory by treating underlying particle & field dynamics independently from system probabilities. In traditional quantum theory, amplitudes entwine both. This renders it unclear whether amplitudes represent the underlying physical states, or are solely a means for calculating probabilities. For quantum theory to be applied to a positional system, the latter interpretation would have to be taken. Probabilities for positional models will be discussed in greater detail in the next section.

Positional systems also mirror traditional quantum theory in their intrinsic uncertainty. For a single particle, there is no way ascertain both particle position & velocity in a single interaction. Any such measurement must therefore take place over time an extended period of time. Since the interactions affect the particle path, this means that particle position & velocity can never be determined to complete accuracy. Further, as in quantum field theory, a positional system’s field state cannot generally be precisely determined experimentally.

Finally, there is an important aspect of quantum theory that has not yet been discussed...

**E. Angular Momentum**

A great deal has been said about linear momentum, but angular momentum has yet to be mentioned. A few words may be in order to explain this discrepancy.

Two assertions were made with regard to positional systems that together have strong bearing on momentum: Particle paths can be measured, and the measured probability for particle path’s velocity corresponds to the probability distribution for the particle’s quantum linear momentum. For angular momentum, we cannot make an assertion analogous to that second statement. It cannot be asserted that the probabilities for $m \vec{x} \times \vec{v}$ obtained from measurements of particle paths correspond to the probability distribution for quantum angular momentum. As a result, no strong claims can be made about how quantum angular momentum may be related to positional system paths.

There is no question that the quantum system dynamics conserves “quantum angular momentum”, the only question is how this quantity may be realized in positional systems. Because the underlying dynamics are not Lagrangian, rotational invariance need not be associated with a conserved quantity. Probability dynamics may be Lagrangian, and so may
have an angular momentum-like conserved quantity. However, because quantum angular momentum is conserved for every measurement, it is not simply a property of the probability distributions; it must be a property of the system paths.

It is interesting to note that, if quantum angular momentum can be represented in positional systems, spin may not need to be an element of the particle state. It is possible that position is sufficient, and that all particle quantum angular momentum is of the same nature. The necessity of adding spin as a separate coordinate in traditional quantum theory could be due to the fact that wave-functions contain a limited amount of information, and that information is not sufficient to represent all quantum angular momentum values. For example, different spin values may be associated with the same overall position & momentum distributions, but may differ in how the two quantities are correlated (once again, relying on the ability to measure position and velocity simultaneously). It is therefore conceivable that paths composed of position states could be sufficient to represent all values of quantum angular momentum, without having to rely on new, internal particle coordinates.

Polarization, on the other hand, likely does need to be an element of the electromagnetic signal state. Note that in the r-set, free particles’ classical angular momentum is conserved. As things stand, however, classical angular momentum is not conserved under particle-signal interactions. If quantum angular momentum is a residue of classical angular momentum, then key to understanding it would lie in the nature of the angular momentum component of the signal state (or moment), and the manner in which it couples to particle paths.

XIX. PROBABILITIES AND PROBABILITY DYNAMICS

We start this section with a simple claim: All experimental outcomes on quantum systems can be described in terms of particle position, velocity, and identifying characteristics (such as mass and charge), together with the field energy, momentum, and possibly polarization. The basis of this claim can be seen by considering the handful of measurable quantities of greatest interest: position, velocity, momentum, energy, and angular momentum. Clearly position and velocity can be described in these terms, and the fact that momentum can be described in terms of particle mass and velocity, together with field momentum, has been a central claim of this part. For energy, the best known way of measuring the internal energy of a quantum system is to let all system energy pass into the radiation field (possibly by
applying perturbative fields), and measuring the total radiated energy. The initial system energy is equal to the radiation energy, up to a meaningless constant. Similarly, the best known method of measuring quantum angular momentum is to pass the system through a Stern-Gerlach apparatus, and measure the system’s final position. In all cases, it is the above quantities that distinguish the various possible outcomes from each other.

The claim is somewhat different from saying that all measurable quantities can be described in terms of particle position/velocity/characteristics & field 4-momentum/polarization. Quantum angular momentum, for example, may or may not be definable in terms of particle position and velocity, but when measuring quantum angular momentum using a Stern-Gerlach set-up, it is the final position that determines the outcome.

The ability to reduce experimental outcomes to just these quantities is exactly what we would expect for positional systems. In Sec X B it was shown that all experimental outcomes can be described in terms of moments, and for positional systems, moments are comprised of particle position and velocity (together with identifying characteristics), and field energy and momentum (and possibly polarization). As with quantum systems, it is not required that all physical quantities must be definable in terms of these quantities, it is only specified that all experimental outcomes can be described in terms of them.

We can extend our claim about quantum systems by saying that their experimental probabilities can be described entirely in terms of probability distributions over particle position and velocity, and field momentum, energy, and polarization. For example, to calculate the probability of measuring a system as having a certain angular momentum using a Stern-Gerlach experiment, we can integrate the final probability distribution over the region of space consistent with that angular momentum.

Note that, given any probability distribution for position and any probability distribution for velocity, there always exist joint probability distributions over position and velocity that are consistent with those individual distributions. For example, if a quantum particle has a position distribution of $\rho(x)$, and a velocity distribution of $\nu(v)$, there will always be joint probability distributions, $\eta(x,v)$, such that $\rho = \int \eta dv$ and $\nu = \int \eta dx$. (A trivial example would be $\eta(x,v) = \rho(x)\nu(v)$.) However, if the problem is further constrained - requiring more than that the joint distribution must agree with the individual distributions - then joint probability distributions may not exist. An example of this will be detailed shortly.

The ability to describe experimental probabilities entirely in terms of conditional prob-
ability distributions on particle position/velocity and field 4-momentum/polarization is a characteristic of standard dps’s on positional systems. This is because, for a standard dps, all experimental probabilities can be calculated from probability distributions on the system’s moments. And as with quantum systems, standard dps’s only require that probabilities can be calculated in this manner while the experiment is in progress. If an experiment is not in progress, probability calculations for some physical quantities (e.g., quantum angular momentum) may require other calculational methods. Because the moment probability distribution summarizes all known information about the system, we can expect any such alternative method of calculation to utilize this distribution, even if the method in not simply a matter of integrating over regions of the distribution.

We can connect these moment probability distributions to quantum wave functions by introducing q-distributions. A time-dependent probability distribution over a system’s particle position/velocity/characteristics and (possibly) field 4-momentum/polarization variables, \( \eta(\vec{x}, \vec{v}, ..., t) \), is a q-distribution if there exists a time-dependent density matrix, \( \hat{\rho}(t) \) s.t. (1) \( \hat{\rho}(t) \) satisfies the system’s quantum equation of motion, and (2) at every time, \( \hat{\rho}(t)’ \)’s (unconjoined) position, velocity, and field probabilities equal those for \( \eta(t) \). As noted above, such joint probability distributions must exist for all time dependent density matrices. Although q-distributions are a restricted set of probability distributions, the success of the quantum formalism shows that they can be used to describe systems under very general circumstances.

It is important to note, however, while these distributions are common, they do not appear to be complete. Path measurements imply joint position velocity distributions that are not q-distributions, as a particle on which such a measurement is made would be described by a distribution with limited non-zero ranges in both of position & velocity, and no q-distribution has this property. Similarly, path measurements imply distributions with limited non-zero ranges for all components of velocity, even in the presence of a magnetic field, and in the presence of a magnetic field, no q-distribution has this property either. There may, however, be q-distributions that provide good approximations.

Even if q-distributions are not universal, they are highly prevalent. There are a number of reasons why this may be the case. There may be limitations in the system dynamics that cause the available distributions to be almost exclusively q-distributions. Alternately, q-distributions may be akin to Gaussian distributions: under general conditions, they provide a reliable approximation to the actual distribution. Our working assumption will be a
combination of these. It will be assumed that, for quantum systems, q-distributions provide
the complete set of steady state distributions, and for non-steady state distributions, it will
be assumed that q-distributions generally provide a reasonable approximation.

It was mentioned earlier that if the properties of q-distributions are over specified, some
density matrices may have not have any q-distributions associated with them. In and of
itself, this is hardly surprising; what is surprising is how easy it is to over specify the problem
in this manner. To see this, we start by defining various kinds of probability currents:

**Definition.** If \( \eta(\vec{x}, \vec{v}, t) \) is a q-distribution,

1) \( \vec{j} \equiv \int \vec{v} \eta d^3v \)

2) \( \vec{j}_q \) is the quantum probability current for the density matrix whose probabilities agree
   with \( \eta \)

3) \( \vec{j}_p \) is an expression on \( \eta \) that, based on \( \eta \)'s equation of motion, satisfies \( \frac{\partial}{\partial t} \int \eta d^3v \equiv
   \frac{\partial}{\partial t} \rho = -\nabla \cdot \vec{j}_p \) (if such an expression exists). For example, if \( \eta \)'s equation of motion is of the
   form \( \left( \frac{\partial}{\partial t} + \vec{v} \cdot \nabla \right) \eta = Z \), and there exist a vector field \( \vec{i} \) s.t.
   \( \int Z d^3v = -\nabla \cdot \vec{i} \), then \( \vec{j}_p = \vec{j} + \vec{i} \).

It will be demonstrated in Appendix B that there is no set of q-distributions can satisfy
all of the following conditions:

1. For all \( \eta \), there exists a \( \vec{j}_p \) s.t. \( \frac{\partial}{\partial t} \rho = -\nabla \cdot \vec{j}_p \)

2. \( \vec{j}_p = \int \vec{v} \eta d^3v \) (that is, \( \vec{j}_p = \vec{j} \))

3. \( \vec{j}_p = \vec{j}_q \)

4. The q-distributions satisfy a linear differential equation that \( \rho \)'s first-order in time

5. There exists a q-distribution for every density matrix

The essence of this result can be seen by considering q-*pseudo*-distributions, which are
distributions that obey the same constraints as q-distributions except that, unlike q-
distributions, they are allowed to take on negative values. The best known example of
q-pseudo-distributions is the Wigner pseudo-distributions. They satisfy 1-5, but they are
not probability distributions. Appendix B shows this to be general, any set of q-pseudo-
distributions that satisfy 1-5 will not be entirely composed of probability distributions.

It is clear that condition 5 can hold for a set of q-distributions. Let's choose these
q-distributions so as to also reflect, as well as possible, the probabilities of joint position
and velocity measurements obtained by measuring particle paths. For such a set of q-
distributions, it would be interesting know which of conditions 1-4 fail. It is possible that
condition 4 fails, but suspicion also falls on the double equality \( \vec{j}_p = \vec{j}_q = \int \vec{v} \eta d^3v \). This
raises the question of how the quantum probability current, \( \vec{j}_q \), may be related to joint
position/velocity distributions. Because \( \vec{j}_q \) is closely related to quantum angular momentum,
the questions of the nature of \( \vec{j}_q \) and the nature quantum angular momentum are intertwined.

To answer such questions, it would be necessary to know what a joint position-velocity
probability distribution equation of motion may look like. Such an equation of motion need
not be restricted to q-distributions; it would presumably apply to any distribution that
describes a possible state of knowledge about a quantum particle or system. The nature of
such an equation of motion can be investigated via experiments much like the one described
in the introduction, with a low intensity particle source, a barrier with a narrow slit, and a
tracking detector on the other side of the barrier. Placing the detector at various distances
from the barrier, we can see how the joint position & velocity distribution changes with
distance. Such an experiment can be repeated with two slits, and so forth.

While such experiments can yield valuable information, they cannot by themselves
uniquely determine the equation of motion, in part because the measurements cannot be
made to arbitrarily high precision. To further specify the equation of motion, we can
also include the demands that all steady state solutions must be q-distributions, and that
every time independent density matrix corresponds to at least one steady state solution.
For multiparticle systems, this should be sufficient to ensure the exclusion principle. Such
an equation of motion would also provide a functionally complete description of quantum
systems.

Part VII

Conclusion

When developing a scientific theory that is to be expressed mathematically, it has been
proposed here that after a working phenomenological theory has been established, and before
the writing of the full scientific theory, it is necessary to ensure that a suitable mathematical
language is available. This is because the mathematical language may be essential for creating a conceptual framework from which to understand the subject matter.

Traditional quantum theory can be viewed as being a phenomenological theory. It is not holy writ, handed down from on high, which we can’t possibly hope to truly understand, but which we must none the less accept in all detail. Rather, it evolved over time by trial and error as a means of calculating results to match newly discovered experimental phenomenon. It has been quite successful in achieving that goal, however it has also historically yielded little understanding of why its calculational methods work. This lack of understanding has often led to claims that we don’t understand these matters because we can’t understand them; they lie outside the sphere of human comprehension. While we cannot state with certainty that such bold claims of necessary ignorance are false, we can say that they are scientifically unfounded, and so ought to be approached with skepticism. Here, we have attempted to explore the possibility that quantum mechanics may grow comprehensible if a suitable mathematical framework is available. With humility, it is hoped that this article has lent support to this methodology, and in doing so has shed light on some matters that have heretofore been allowed to lie in darkness.

Appendix A: An example of a nearly ideal partition that is not ideal

Here, the simplest example of a nearly ideal partition that is not an ideal partition will be described.

Assume that system time is discrete, and that at time $\lambda = 0$ the system has 3 points, $S(0) = \{A_0, B_0, C_0\}$, at time $\lambda = 1$ it has 2 points, $S(1) = \{D_1, E_1\}$, and at time $\lambda = 2$ it also has 2 points, $S(2) = \{F_2, G_2\}$. Further assume that the paths that pass through these points are $A_0 \rightarrow D_1 \rightarrow F_2$, $A_0 \rightarrow D_1 \rightarrow G_2$, $B_0 \rightarrow D_1 \rightarrow F_2$, $B_0 \rightarrow D_1 \rightarrow G_2$, $C_0 \rightarrow E_1 \rightarrow F_2$, and $C_0 \rightarrow E_1 \rightarrow G_2$.

The partition: $\{A_0 \rightarrow D_1 \rightarrow F_2, C_0 \rightarrow E_1 \rightarrow F_2\}$, $\{B_0 \rightarrow D_1 \rightarrow G_2, C_0 \rightarrow E_1 \rightarrow G_2\}$, $\{B_0 \rightarrow D_1 \rightarrow F_2\}$, $\{A_0 \rightarrow D_1 \rightarrow G_2\}$ is nearly ideal, but not ideal.

If “$\sim$” is taken to mean “the value not measured”, these outcomes may be represented as $(\sim B_0, F_2)$ (meaning the system was measured as not being at $B_0$ at $\lambda = 0$, then measured as being at $F_2$ at $\lambda = 2$), $(\sim A_0, F_2)$, $(B_0, F_2)$, $(A_0, G_2)$

This nearly ideal partition may be formed from the following 3 ideal partitions by applying
the \(-\) operation:
\[
\{A_0 \rightarrow D_1 \rightarrow F_2, C_0 \rightarrow E_1 \rightarrow F_2\}, \{B_0 \rightarrow D_1 \rightarrow F_2\}, \{A_0 \rightarrow D_1 \rightarrow G_2\}, \{B_0 \rightarrow D_1 \rightarrow G_2\},
\{C_0 \rightarrow E_1 \rightarrow G_2\}
\[
\{A_0 \rightarrow D_1 \rightarrow F_2\}, \{C_0 \rightarrow E_1 \rightarrow F_2\}, \{B_0 \rightarrow D_1 \rightarrow F_2\}, \{A_0 \rightarrow D_1 \rightarrow G_2\}, \{B_0 \rightarrow D_1 \rightarrow G_2\},
\{C_0 \rightarrow E_1 \rightarrow G_2\}
\[
\{A_0 \rightarrow D_1 \rightarrow F_2\}, \{C_0 \rightarrow E_1 \rightarrow F_2\}, \{B_0 \rightarrow D_1 \rightarrow F_2\}, \{A_0 \rightarrow D_1 \rightarrow G_2\}, \{B_0 \rightarrow D_1 \rightarrow G_2\},
\{C_0 \rightarrow E_1 \rightarrow G_2\}
\[
\{A_0 \rightarrow D_1 \rightarrow F_2\}, \{C_0 \rightarrow E_1 \rightarrow F_2\}, \{B_0 \rightarrow D_1 \rightarrow F_2\}, \{A_0 \rightarrow D_1 \rightarrow G_2\}, \{B_0 \rightarrow D_1 \rightarrow G_2\},
\{C_0 \rightarrow E_1 \rightarrow G_2\}
\]

Using the notation \(F_2^{-}\) to mean “the set of backward path moments at point \(F_2\), time \(\lambda = 2\)”, these ideal partitions can be written in terms of moment measurements as
\[
\{B_0, \sim B_0\} \times (\{F_2^{-}\} \cup G_2^{-})
\]
Either \(\{B_0, \sim B_0\} \times (F_2^{-} \cup G_2^{-})\) or \(\{A_0, \sim A_0\} \times (F_2^{-} \cup G_2^{-})\) (the 2 representations correspond the same ideal partition)
\[
\{A_0, \sim A_0\} \times (F_2^{-} \cup \{G_2\})
\]

Note that, in order to construct the nearly ideal partition using moment representations, the representation of the middle partition has to switch between \(\{B_0, \sim B_0\} \times (F_2^{-} \cup G_2^{-})\) and \(\{A_0, \sim A_0\} \times (F_2^{-} \cup G_2^{-})\).

**Appendix B: How Quantum System Probabilities Do Not Propagate**

Here we justify the claim made earlier that quantum system probabilities do not propagate according to the most straightforward set of assumptions.

Let’s start with the Madelung equations for quantum probability dynamics. If the particle’s probabilities can be described by wave function \(\Psi = \sqrt{\rho} e^{i\phi}\), then define \(\vec{j}_q \equiv \frac{i}{\hbar} \rho (\vec{h} \nabla \phi - \vec{Z})\) and \(\vec{u}_q \equiv \frac{1}{\rho} \vec{j}_q\). If the particle has mass \(m\), and is subject to classical force \(\vec{F} \equiv - \nabla V - \frac{\vec{e}}{\hbar} \vec{Z} + \vec{u}_q \times (\nabla \times \vec{Z})\), then the Schrödinger equation on \(\Psi\) is equivalent to the pair of equations, \(\frac{\hbar}{2m} \rho + \nabla \cdot \vec{j}_q = 0\) and \(m \rho (\frac{\vec{e}}{2m} \vec{u}_q + \vec{u}_q \cdot \nabla \vec{u}) = \rho \vec{F} + \frac{k^2}{4m} \nabla \cdot (\nabla \nabla \rho - \frac{1}{\rho} (\nabla \rho)(\nabla \rho))\). When particle probabilities are captured by a wave function (as opposed to a density matrix), \(\vec{u}_q\) must also satisfy the condition \(\oint_C \vec{u}_q \cdot d\vec{s} = -\frac{\mu}{m} \oint_C \vec{F} \cdot d\vec{s} + \frac{h}{m} \nu\), where \(C\) is any closed curve, \(\hbar = 2\pi \hbar\), and \(n\) is any Natural number \((0, 1, 2, ...).\)

If the particle’s probabilities are described by density matrix \(\varrho(x_1, x_2) \equiv \sum_{i} \alpha_i \Psi_i^*(x_1) \Psi_i(x_2)\), then the first Madelung equation remains \(\frac{\hbar}{2m} \rho + \nabla \cdot \vec{j}_q = 0\), while the second becomes \(m \rho (\frac{\vec{e}}{2m} \vec{u}_q + \vec{u}_q \cdot \nabla \vec{u}_q) = \rho \vec{F} + \frac{k^2}{4m} \nabla \cdot (\nabla \nabla \rho - \sum_{i} \alpha_i \frac{1}{\rho_i} (\nabla \rho_i)(\nabla \rho_i))\), where \(\rho_i(x) = |\Psi_i(x)|^2\).
It is instructive to compare the Madelung equations to their classical counterparts. If \( \eta(\vec{x}, \vec{v}, t) \) is the probability distribution for a classical particle’s position and velocity, \( \eta \) satisfies \( \frac{\partial}{\partial t} \eta = -\vec{v} \cdot \nabla \eta - \frac{1}{m} \vec{F} \cdot \nabla \eta \), where \( \nabla \vec{v} \) is the gradient on velocity. Defining \( \rho(\vec{x}, t) \equiv \int \eta(\vec{x}, \vec{v}, t) d^3v, \vec{j}(\vec{x}, t) \equiv \int \vec{v} \eta(\vec{x}, \vec{v}, t) d^3v \) and \( \vec{u} \equiv \frac{\vec{j}}{m} \), assuming \( \lim_{\vec{x}\to\infty}(\eta \vec{v}) = 0 \), and taking the force to be of the form \( \vec{F} = -\nabla V - \frac{\Phi}{\hbar} \vec{Z} + \vec{v} \times (\nabla \times \vec{Z}) \), where \( V \) and \( \vec{Z} \) may be functions of space and time, but not velocity, \( \rho \) and \( \vec{u} \) satisfy the pair of equations \( \frac{\partial}{\partial t} \rho = -\nabla \cdot \vec{j} \) and \( m \rho \left( \frac{\partial}{\partial t} \vec{u} + \vec{u} \cdot \nabla \vec{u} \right) = \rho \vec{F} - m \vec{v} \cdot \int (\vec{v} - \vec{u})(\vec{v} - \vec{u})\eta d^3v \). These are quite close to their quantum counterparts. Indeed, if \( \vec{j}_q = \vec{j} \), and \( \int (\vec{v} - \vec{u})(\vec{v} - \vec{u})\eta d^3v = \left( \frac{\hbar}{2m} \right)^2 \sum_i \alpha_i (\frac{1}{\rho_i} (\nabla \rho_i) (\nabla \rho_i) - \nabla \nabla \rho_i) \), then they are identical.

This means that the Madelung’s equations can be derived from a linear differential equation of the form \( \frac{\partial}{\partial t} \eta = -\vec{v} \cdot \nabla \eta - \frac{1}{m} \vec{F} \cdot \nabla \eta + ... \), so long as \( \vec{j}_q = \int \vec{v} \eta d^3v \), and the velocity moments of the distribution are of an acceptable form. For any wave-function, \( \Psi = \sqrt{\rho} e^{i\phi} \), \( \langle \vec{p}\vec{p} \rangle = \int \rho(\vec{u}_q, \vec{u}_q) + \left( \frac{\hbar}{2m} \right)^2 \frac{1}{\rho} \nabla \rho \nabla \rho d^3x \), meaning that if \( \eta \) is a q-distribution for a wavefunction, and \( \vec{j}_q = \vec{j} \), then \( \int (\vec{v} - \vec{u})(\vec{v} - \vec{u})\eta d^3v = \left( \frac{\hbar}{2m} \right)^2 \int \frac{1}{\rho} \nabla \rho \nabla \rho d^3x \). This gives us \( \int (\vec{v} - \vec{u})(\vec{v} - \vec{u})\eta d^3v = \left( \frac{\hbar}{2m} \right)^2 \int \frac{1}{\rho} \nabla \rho \nabla \rho d^3x + \vec{X} \) where \( \vec{X} \) is some function s.t. \( \int \vec{X} d^3x = 0 \).

The Madelung equations are then a direct consequence of any equation of motion on \( \eta \) of the form \( \frac{\partial}{\partial t} \eta = -\nabla \cdot (\vec{v}_q \eta) - \frac{1}{m} \vec{F} \cdot \nabla \eta - \left( \frac{\hbar}{2m} \right)^2 (\nabla \vec{v} \cdot \nabla)(\nabla^2 \eta) - m \nabla \cdot (\nabla \vec{v} \cdot \vec{X}) + q \), where \( q \) may be any additional terms that satisfy \( \int q d^3v = 0 \) and \( \int \vec{v} q d^3v = 0 \). As we want the equation of motion to be linear in \( \eta \), and because \( \int (\vec{v}_i - \vec{u}_i)^2 \eta d^3v \) must be non-negative, we take \( \int (\vec{v} - \vec{u})(\vec{v} - \vec{u})\eta d^3v = \left( \frac{\hbar}{2m} \right)^2 \int \frac{1}{\rho} \nabla \rho \nabla \rho d^3x \), and so \( \vec{X} = 0 \). This gives us \( \frac{\partial}{\partial t} \eta = -\nabla \cdot (\vec{v}_q \eta) - \frac{1}{m} \vec{F} \cdot \nabla \eta - \left( \frac{\hbar}{2m} \right)^2 (\nabla \vec{v} \cdot \nabla)(\nabla^2 \eta) + q \) as our seed equation of motion for \( \eta \).

Choosing a slightly different form to make things a little simpler down the road (the result will be the same either way), we choose \( \eta \)’s equation of motion to be of the form:

\[
\frac{\partial}{\partial t} \left[ \eta - \frac{\hbar^2}{8m^2} (\nabla \cdot \nabla \eta)^2 \eta \right] = - (\vec{v} \cdot \nabla) \left[ \eta - \frac{\hbar^2}{8m^2} (\nabla \cdot \nabla \eta)^2 \eta \right] - \frac{1}{m} \vec{F} \cdot \nabla \eta + q_2 \tag{B.1}
\]

where \( q_2 \) represents possible additional term(s) that satisfy \( \int q_2 d^3v = 0 \) and \( \int \vec{v} q_2 d^3v = 0 \). To preserve linearity, \( q_2 \) should be linear in \( \eta \), and to preserve the equation’s transformation properties, it should be even under parity, odd under time inversion, as well as invariant under translations, rotations, and boosts, unless the term involves external forces that don’t respect these invariances. We also must assume that \( \vec{j}_q = \int \vec{v} \eta d^3v \).

It is easy to see that if we integrate Eq. \( \text{B.1} \) over \( \vec{v} \), we get the continuity equation, and if
we multiply through by \( \vec{v} \), integrate over \( \vec{v} \), and take \( \int (\vec{v} - \vec{u})(\vec{v} - \vec{u}) \eta d^3v = (\frac{h}{2m})^2 \int \frac{1}{v} \nabla \rho \nabla \rho d^3v \), we get the second Madelung equation. More generally, if we assume that \( \int \vec{v} \vec{v} \eta d^3v = \sum \alpha_i \rho_i (\vec{u} + (\frac{h}{2m})^2 \frac{1}{v} \nabla \rho_i \nabla \rho_i) \), we get the Madelung equation for density matrices. To simplify these equations somewhat, we define \( \vec{v}_d \equiv -\frac{h}{2m} \rho \nabla \rho \). Thus, for example, we can now write \( \int \vec{v} \vec{v} \eta d^3v = \rho (\vec{u} + \vec{v}_d \vec{v}_d) \) rather than \( \int \vec{v} \vec{v} \eta d^3v = \rho (\vec{u} \vec{u} + (\frac{h}{2m})^2 \frac{1}{v} \nabla \rho \nabla \rho) \).

For a joint distribution corresponding to a wave function, the relation \( \int \vec{v} \vec{v} \eta d^3v = \rho (\vec{u} \vec{u} + \vec{v}_d \vec{v}_d) \) holds for all time. Eq. [B.1] may not ensure this for any arbitrary \( q_2 \), so we need to understand the conditions under which this relation will hold for all time. To do so, multiply Eq. [B.1] by \( \vec{v} \vec{v} \), and integrate over \( \vec{v} \). This gives us the equation for the time evolution of \( \int \vec{v} \vec{v} \eta d^3v \). If we plug in \( \int \vec{v} \vec{v} \eta d^3v = \rho (\vec{u} \vec{u} + \vec{v}_d \vec{v}_d) \), we then get the condition we’re looking for:  

\[
\frac{\partial}{\partial t} \int \vec{v} \vec{v} \eta d^3v = -\nabla \cdot \int \vec{v} \vec{v} \eta d^3v + \frac{h^2}{4m^2} \frac{1}{v} \nabla \rho \nabla \rho \]

where \( f(v) \) is defined so that, for the \( i, k \) coordinate, \( f(v) = \eta \). As before, we assume that \( \vec{F} \) is such that \( \vec{F} \cdot \nabla \eta = \nabla \cdot (\eta \vec{F}) \), and that \( \lim_{\vec{v} \to \infty} (\eta \vec{v}) = 0 \). This allows us to reduce the force term, giving us:  

\[
\frac{\partial}{\partial t} \int \vec{v} \vec{v} \eta d^3v = -\nabla \cdot \int \vec{v} \vec{v} \eta d^3v + \int \vec{v} \vec{v} \eta d^3v + \int \vec{F} \eta d^3v.
\]

As there are no linear terms on the right-hand side of this equation, and we are looking for a linear equation of motion for \( \eta \), we take \( \int \vec{v} \vec{v} \eta d^3v = 0 \). This gives us the following for the third velocity moment:

\[
\int v^3 \eta dv = \rho \left[ u^3 + 3uv_d^2 - \frac{h}{m} v_d^2 \frac{\partial}{\partial x} u \right] + 2 \left( \frac{h}{2m} \right)^2 \frac{\partial}{\partial x} \left( \rho \frac{\partial}{\partial x} u \right)
\]  \hspace{1cm} (B.2)

Eq [B.2] is consistent with the value for wave-functions: \( \langle v^3 \rangle = \int \Psi^* \nabla^3 \Psi d^3x = \int (u^3 + 3uv_d^2 - 2 \frac{h}{m} v_d \frac{d}{dx} u) d^3x \). Thus, to ensure that the expression for the second velocity moment always holds, the above expression for the third velocity moment must hold.

Let’s now define \( q_n \) in analogy with \( q_2 \), as any function such that for all \( m < n \), \( \int \vec{v}^n q_n \eta d^3v = 0 \), and that respects all the invariances listed for \( q_2 \). The fact that \( \int v^2 q_2 \eta d^3v = 0 \) then gives a slightly revised equation of motion:

\[
\frac{\partial}{\partial t} \left[ \frac{h^2}{8m^2} \frac{\partial^2}{\partial x^2} \frac{\partial^2}{\partial v^2} \eta \right] = -\nabla \cdot \left[ \frac{h^2}{8m^2} \frac{\partial^2}{\partial x^2} \frac{\partial^2}{\partial v^2} \eta \right] - \frac{1}{m} \vec{F} \cdot \frac{\partial}{\partial v} \eta + q_3
\]  \hspace{1cm} (B.3)

We have found that for a distribution to have \( \int v^2 \eta d^3v = \rho (u + v_d^2) \) hold for all time, it is necessary and sufficient for Eq [B.2] to hold for all time. We now need to understand the
conditions under which this expression for $\int v^3 \eta dv$ holds for all time. To do so, we multiply equation B.3 through by $v^3$, integrate over $v$, and use the expressions for $\int v^3 \eta dv$ and $\int v^2 \eta dv$. This gives us:

$$\frac{\partial}{\partial t} \{ \rho u^3 + 3\left(\frac{\hbar}{2mA}\right)^2 u \left(\frac{1}{\rho} \left(\frac{d}{dx} \rho\right)^2 - \frac{\partial^2}{\partial x^2} \rho\right) - \left(\frac{\hbar}{2mA}\right)^2 \rho \frac{\partial^2}{\partial x^2} u \} = -\frac{\partial}{\partial x} \int dv v^4 \eta + \int dv v^3 q_3 + \frac{\hbar}{m} F \left[ \rho u^2 + \left(\frac{\hbar}{2mA}\right)^2 \frac{1}{\rho} \left(\frac{d}{dx} \rho\right)^2 \right] + 3 \left(\frac{\hbar}{2mA}\right)^2 \frac{\partial^3}{\partial x^3} \left[ \rho u^2 + \left(\frac{\hbar}{2mA}\right)^2 \frac{1}{\rho} \left(\frac{d}{dx} \rho\right)^2 \right].$$

When we evaluate the derivative with respect to time we get:

$$\frac{\partial}{\partial x} \int v^4 \eta dv - \int v^3 q_3 dv = \frac{\partial}{\partial x} \left\{ \rho \left[ u^2 - 2 \left(\frac{\hbar}{2mA}\right)^2 \frac{1}{\rho} \frac{\partial^2}{\partial x^2} \rho - \frac{1}{2 \rho^2} \left(\frac{\partial}{\partial x} \rho\right)^2 \right] \right\} + 4 \left(\frac{\hbar}{2mA}\right)^2 \rho \left[ u \left(\frac{\partial}{\partial x} \rho\right) + \frac{\partial}{\partial x} u \right] + 4 \left(\frac{\hbar}{2mA}\right)^2 \frac{\partial^3}{\partial x^3} (\rho u^2 + \left(\frac{\hbar}{2mA}\right)^2 \frac{1}{\rho} \left(\frac{d}{dx} \rho\right)^2) + \left(\frac{\hbar}{2mA}\right)^4 \frac{\partial^5}{\partial x^5} \rho + 3 \frac{1}{m} \left(\frac{\hbar}{2mA}\right)^2 F \frac{\partial^2}{\partial x^2} \rho + \frac{1}{m} \left(\frac{\hbar}{2mA}\right)^2 \rho \frac{\partial^2}{\partial x^2} F.$$

The terms on the right-hand side need to be assigned to either $\frac{\partial}{\partial x} \int v^4 \eta dv$ or $\int v^3 q_3 dv$. However, no matter how we assign them, we cannot ensure both that $\eta$’s equation of motion is linear, and $\int v^4 \eta dv$ is non-negative. Thus, our attempt to find a linear equation of motion for $\eta$ that’s first order in time, with $\vec{j}_q = \int \vec{\eta} d^3 v$, and such that every density matrix corresponds to a $q$-distribution, has failed. By the nature of the calculation, it can be seen that there is no way to satisfy all these requirements.
