Medium-induced parton energy loss, resulting from gluon exchanges between the QCD matter and partonic projectiles, is expected to underly the strong suppression of jets and high- p_T hadron spectra observed in ultra-relativistic heavy ion collisions. Here, we present the first color-differential calculation of parton energy loss. We find that color exchange between medium and projectile enhances the invariant mass of energetic color singlet clusters in the parton shower by a parametrically large factor proportional to the square root of the projectile energy. This effect is seen in more than half of the most energetic color-singlet fragments of medium-modified parton branchings. Applying a standard cluster hadronization model, we find that it leads to a characteristic additional softening of hadronic spectra. A fair description of the nuclear modification factor measured at the LHC may then be obtained for relatively low momentum transfers from the medium.

High transverse momentum partons ($p_T \gg 10$ GeV) produced in heavy ion collisions interact with the QCD matter in the collision region while branching. This interaction is thought to cause the strong medium modification of hadronic spectra and jets measured in heavy ion collisions at the LHC and at RHIC. The modeling of this jet quenching phenomenon has focussed so far on medium-induced parton energy loss prior to hadronization [1], assuming that for sufficiently high p_T hadronization occurs time-delayed outside the medium. However, if the color flow of a parton shower is modified within the medium, then hadronization can be affected irrespective of when it occurs. Here, we analyze for the first time the medium-induced color flow in a standard parton energy loss calculation. Compared to the current modeling of parton energy loss [2–7], this will be seen to result in a characteristic softening of the ensuing hadronization. It may thus affect significantly the extraction of medium properties from the measured nuclear modification factor at the LHC [8–10].

We start by considering an elementary building block of a parton shower, the $q \rightarrow qg$ parton splitting. For a small light-cone energy k^+ of the gluon compared to the parent parton, $x \equiv k^+/p^+ \ll 1$, and for transverse gluon momentum \mathbf{k} with $\mathbf{K}_0 \equiv \mathbf{k}/k^2$, the gluon spectrum reads, to leading order in α_s ,

$$k^+ \frac{dI^{\text{vac}}}{dk^+ d\mathbf{k}} = \frac{\alpha_s C_R}{\pi^2} \mathbf{K}_0^2. \quad (1)$$

In the presence of QCD matter, interactions between projectile parton and medium result in a modified spectrum $dI^{\text{rad}} \equiv dI^{\text{vac}} + dI^{\text{med}}$ that can be written as an expansion in powers of the ratio $\zeta \equiv L^+/\lambda_{\text{el}}^+$ of in-medium path length L^+ and an elastic mean free path λ_{el}^+ (for details, see [1]). To first order in this opacity expansion, the medium-induced radiation spectrum reads

$$k^+ \frac{dI^{\text{med}}}{dk^+ d\mathbf{k}} = \zeta \frac{\alpha_s C_R}{\pi^2} \left\langle \left((\mathbf{K}_0 - \mathbf{K}_1)^2 - \mathbf{K}_0^2 + \mathbf{K}_1^2 \right) \mathcal{T}_{\mathcal{I}} \right\rangle. \quad (2)$$

FIG. 1: $N = 1$ opacity diagrams for gluon radiation from a projectile quark in the large- N_c limit. The most energetic color-singlet clusters are denoted by thicker lines and correspond to color flow between projectile components (upper diagrams, contribution $dI_{\text{low } M}^{\text{med}}$) or between projectile and target (lower diagrams, contribution $dI_{\text{high } M}^{\text{med}}$). Diagrams on the right hand side include a 3-gluon vertex.

Here, $\langle \dots \rangle$ denotes averaging over the transverse momentum transfer \mathbf{q} of a single interaction, and $\mathbf{K}_1 \equiv (\mathbf{k} - \mathbf{q})/(\mathbf{k} - \mathbf{q})^2$. Medium-induced interference effects enter via the factor

$$\mathcal{T}_{\mathcal{I}} = \left(1 - \frac{\sin(\omega_1^- L^+)}{\omega_1^- L^+} \right) = \begin{cases} 1 & \text{for } 1/\omega_1^- \ll L^+, \\ 0 & \text{for } 1/\omega_1^- \gg L^+. \end{cases} \quad (3)$$

Thus, the medium-modification dI^{med} can occur only for quanta of sufficiently small formation time $1/\omega_1^- \equiv 2k^+ / (\mathbf{k} - \mathbf{q})^2 \ll L^+$. To first order in opacity and at large N_c , we identify three contributions with distinct color flow

$$dI^{\text{med}} = dI_{\text{virt}}^{\text{med}} + dI_{\text{low } M}^{\text{med}} + dI_{\text{high } M}^{\text{med}}. \quad (4)$$

Here, $dI_{\text{virt}}^{\text{med}}$ arises from probability-conserving *virtual* corrections that do change neither color flow nor kinematic distributions in the projectile. The contributions $dI_{\text{low } M}^{\text{med}}$ and $dI_{\text{high } M}^{\text{med}}$ contain medium effects and can be characterized by the invariant mass of their leading cluster, as we discuss now.

For a projectile with (light-cone) energy much larger than that of its target scattering partner, $p^+ \gg t^+$, and for $x \ll 1$, the most energetic parton in the final state in Fig. 1 is defined unambiguously and carries energy $p_f^+ \equiv (1-x)p^+$. Distributing the energy of the gluon equally between its q and \bar{q} -legs in the large N_c -limit (our final conclusions will not depend on this assumption), the energy and invariant mass of the most energetic singlet cluster in a vacuum splitting read

$$P_{\text{C}_{\text{vac}}}^+ \simeq (1+x/2)p_f^+, \quad M_{\text{C}_{\text{vac}}}^2 \simeq \mathbf{k}^2/2x. \quad (5)$$

These relations hold for the leading color singlet clusters of the vacuum contribution (1), for the virtual correction $dI_{\text{virt}}^{\text{med}}$ in (4), and for $dI_{\text{low } M}^{\text{med}}$ (in the latter case, the distributions in x and \mathbf{k} contain information about the medium modification). In contrast, for $dI_{\text{high } M}^{\text{med}}$ color flows from the most energetic final state parton directly to a target component of momentum t , and

$$P_{\text{C}_{\text{targ}}}^+ \simeq p_f^+, \quad M_{\text{C}_{\text{targ}}}^2 = (p_f + t)^2 \simeq p^+ Q_T. \quad (6)$$

Here, $Q_T \equiv \sqrt{2}E_{\text{th}}$ and E_{th} is the typical (thermal) energy of the target component. The invariant mass in (6) is parametrically larger than in the vacuum case (5) by a factor $\sqrt{p^+}$. This motivates the choice of subscripts in $dI_{\text{low } M}^{\text{med}}$ and $dI_{\text{high } M}^{\text{med}}$.

One can determine the kinematic conditions and time scales required for $dI_{\text{high } M}^{\text{med}}$ to contribute. The color-inclusive sum (4) depends on the formation time $1/\omega_1^-$. To first order in opacity, we find that the color-differential contributions on the right hand side of (4) carry interference factors involving two formation times $1/\omega_1^-$ and $1/\omega_0^- \equiv 2k^+/\mathbf{k}^2$ (see [11] for full result). Here, we focus on the relevant limiting cases.

If parton energy loss becomes negligible ($\omega_1^- L^+ \ll 1$) and if the formation time of the final state gluon is large ($\omega_0^- L^+ \ll 1$), then

$$k^+ \frac{dI_{\text{virt}}^{\text{med}}}{dk^+ d\mathbf{k}} = -\zeta \frac{\alpha_s C_R}{2\pi^2} \langle \mathbf{K}_0^2 \rangle, \\ k^+ \frac{dI_{\text{low } M}^{\text{med}}}{dk^+ d\mathbf{k}} = \zeta \frac{\alpha_s C_R}{2\pi^2} \langle \mathbf{K}_0^2 \rangle, \quad k^+ \frac{dI_{\text{high } M}^{\text{med}}}{dk^+ d\mathbf{k}} = 0. \quad (7)$$

In this case, the color exchange between the medium and the projectile occurs predominantly at early times *before* the splitting and hence the color flow and invariant mass of the leading color singlet is vacuum-like, $dI_{\text{high } M}^{\text{med}} = 0$. In contrast, in the limit $1/\omega_0^- \ll L^+ \ll 1/\omega_1^-$, one finds that $dI_{\text{virt}}^{\text{med}} \sim -3\langle \mathbf{K}_0^2 \rangle$, $dI_{\text{low } M}^{\text{med}} \sim \langle \mathbf{K}_0^2 \rangle$, and $dI_{\text{high } M}^{\text{med}} \sim 2\langle \mathbf{K}_0^2 \rangle$. Thus, even if the color-inclusive sum (4) vanishes, there is a kinematic regime in which medium-induced color flow changes the invariant mass of the leading color singlet significantly.

If there is parton energy loss, one finds in the limit $1/\omega_1^-, 1/\omega_0^- \ll L^+$

$$k^+ \frac{dI_{\text{virt}}^{\text{med}}}{dk^+ d\mathbf{k}} = -3\zeta \frac{\alpha_s C_R}{2\pi^2} \langle \mathbf{K}_0^2 \rangle,$$

$$k^+ \frac{dI_{\text{low } M}^{\text{med}}}{dk^+ d\mathbf{k}} = \zeta \frac{\alpha_s C_R}{2\pi^2} \langle (\mathbf{K}_0 - \mathbf{K}_1)^2 + \mathbf{K}_1^2 \rangle, \\ k^+ \frac{dI_{\text{high } M}^{\text{med}}}{dk^+ d\mathbf{k}} = \zeta \frac{\alpha_s C_R}{2\pi^2} \langle (\mathbf{K}_0 - \mathbf{K}_1)^2 + \mathbf{K}_1^2 + \mathbf{K}_0^2 \rangle. \quad (8)$$

In summary, whenever the color-averaged contribution (4) to radiative energy loss is significant, the resulting medium modification of color flow changes the kinematic properties of the most energetic color singlet in more than 50% of all cases, $dI_{\text{high } M}^{\text{med}} > 0.5 dI^{\text{med}}$.

For a gluonic projectile, one finds [11] to first order in opacity, and in the large N_c limit a similar fraction of clusters $\mathcal{C}_{\text{targ}}$ of parametrically large invariant mass (6). To higher orders in opacity, multiple interactions between projectile and target enhance the fraction of color singlet clusters $\mathcal{C}_{\text{targ}}$ [11]. Therefore, the calculation above illustrates generic features of medium-modified color flow in models of parton energy loss.

Since color is conserved in QCD and since hadrons are color singlets, a dynamically consistent hadronization prescription must relate hadrons to color singlet fragments of the parton shower. We therefore expect on general kinematic grounds that the medium-modified distribution (8) of leading color singlets has consequences for the dynamics of hadronization. We now illustrate this point in a cluster hadronization model that encodes essential features of the prescription implemented in the MC event generator HERWIG [12]; the parton shower is evolved perturbatively to a hadronic scale ($Q_0 \simeq 600$ MeV in Ref. [12]) at which the entire shower is decomposed into its color singlet components ('clusters'). Clusters \mathcal{C} of low invariant mass ($\mathcal{M}_{\mathcal{C}} < \mathcal{M}_{\text{cr}} = 4$ GeV) are then decayed directly into pairs of hadrons, while clusters of larger invariant mass are decayed first into pairs of daughter clusters, $\mathcal{C} \rightarrow XY$, till the invariant mass of the daughters satisfies the condition for decay into hadrons. In parton showers evolved in the vacuum, far more than 90% of all clusters are found to have a small invariant mass, $\mathcal{M}_{\mathcal{C}} < 4$ GeV [12]. We therefore take in the following $\mathcal{M}_{\text{C}_{\text{vac}}} < 4$ GeV. We want to adapt this cluster hadronization model to a medium-modified parton shower, for which at the final scale Q_0 the most energetic parton carries energy p_f^+ . In more than 50% of these showers, color will flow from this parton directly to the target, and one finds for the most energetic cluster $\mathcal{C}_{\text{targ}}$ an invariant mass $\mathcal{M}_{\text{C}_{\text{targ}}} > 4$ GeV within the range $p_f^+ > p_{\text{cr}}^+ = \mathcal{M}_{\text{cr}}^2/Q_T$. Estimating the thermal energies of target scatterers by their ideal gas value $E_{\text{th}} \simeq 2.7T$, we find for $T = 200$ (500) MeV a value of $Q_T \simeq 760$ (1900) MeV corresponding to $p_{\text{cr}}^+ = 21.0(8.4)$ GeV. Therefore, for a wide, phenomenologically relevant range of parton energies $p_f^+ > p_{\text{cr}}^+$, hadronization of $\mathcal{C}_{\text{targ}}$ involves an additional step $\mathcal{C}_{\text{targ}} \rightarrow XY$ that is absent in the fragmentation of cluster \mathcal{C}_{vac} , and that leads to a most energetic

daughter cluster X of energy [12]

$$P_X^+ = \left(1 - \frac{Q_0}{\mathcal{M}_{\mathcal{C}_{\text{targ}}}}\right) p_f^+ + \frac{Q_0}{\mathcal{M}_{\mathcal{C}_{\text{targ}}}} t^+. \quad (9)$$

Therefore, amongst the distribution of *final* clusters \mathcal{C}_f , defined as those that decay directly into hadrons, the daughters of $\mathcal{C}_{\text{targ}}$ are significantly softer ($\mathcal{C}_f = X$, $P_X^+ < p_f^+$) than \mathcal{C}_{vac} ($\mathcal{C}_f = \mathcal{C}_{\text{vac}}$, $P_{\mathcal{C}_{\text{vac}}}^+ \geq p_f^+$), see (5).

To illustrate how the softening of the cluster distribution due to color flow may affect transverse momentum spectra, we consider a sample of hadronic collisions with final state parton showers evolved to scale Q_0 . We parametrize the resulting transverse partonic spectrum by a power-law (within the geometry of a heavy ion collision, the large momentum component of a hard process points transverse to the beam direction)

$$\frac{dN}{dp_f^+} = \frac{c}{p_f^{+n}}. \quad (10)$$

A fraction f_t of the partons in (10) are endpoints of clusters $\mathcal{C}_{\text{targ}}$ with color flowing directly to the target. The distribution of final clusters \mathcal{C}_f resulting from $\mathcal{C}_{\text{targ}}$ reads

$$\begin{aligned} \frac{dN^{\mathcal{C}_f}}{dP^+} &= f_t \int_0^{P_{\text{cr}}^+} dp_f^+ \delta(P^+ - p_f^+) \frac{dN}{dp_f^+} \\ &+ f_t \int_{P_{\text{cr}}^+}^{\infty} dp_f^+ \delta\left(P^+ - p_f^+ \left(1 - \frac{Q_0}{\sqrt{p_f^+ Q_T}}\right)\right) \frac{dN}{dp_f^+} \\ &= f_t \frac{c}{P^{+n}} F(P^+), \end{aligned} \quad (11)$$

$$F(P^+) = \Theta(P_{\text{cr}}^+ - P^+)$$

$$+ \Theta(P^+ - (P_{\text{cr}}^+ - \Delta)) \frac{2 \left(1 + \frac{Q_0}{\sqrt{P^+ Q_T}}\right)^{1-n}}{\left(2 + \frac{Q_0}{\sqrt{P^+ Q_T}}\right)}. \quad (12)$$

Here, $\Delta \equiv Q_0 \sqrt{P_{\text{cr}}^+ / Q_T}$, and the last factor in (12) comes from transforming (10) from p_f^+ to P_X^+ with the help of (9). The first term in (12) comes from clusters $\mathcal{C}_{\text{targ}}$ of small energy $P^+ < P_{\text{cr}}^+$ and small invariant mass, that decay directly into hadrons, $\mathcal{C}_f = \mathcal{C}_{\text{targ}}$. The second term comes from clusters $\mathcal{C}_{\text{targ}}$ of large invariant mass that undergo a cluster decay, $\mathcal{C}_f = X$. Both mechanisms contribute in an intermediate range $P_{\text{cr}}^+ - \Delta < P^+ < P_{\text{cr}}^+$ where one finds an enhancement $F(P^+) > 1$. A more realistic treatment, including corrections to the limit $p_f^+ \gg t^+$, may be expected to smoothen the Θ -functions in (12). Here, we steer clear of these model-dependent uncertainties by focussing on the high-energy region $P^+ > P_{\text{cr}}^+$ where an additional cluster decay results in a suppression, $F(P^+) < 1$. For phenomenologically motivated parameter choices, namely a power-law spectrum (10) with $n = 6$, values $Q_0 = 600$ MeV

FIG. 2: The color-induced suppression factor $F(P^+)$ of (12) plotted for sufficiently large cluster energies $P^+ > P_{\text{cr}}$ where additional color-flow induced cluster decays occur.

and $\mathcal{M}_{\text{cr}} = 4$ GeV typical of hadronization models, and a range of expected thermal energies, the color-induced suppression persists up to cluster energies well above 100 GeV, see Fig. 2.

Medium-effects in single inclusive hadron spectra are typically expressed in terms of the nuclear modification factor $R_{\text{AA}}(p_T) \equiv (dN^{\text{AA}}/dp_T) / (n_{\text{coll}} dN^{\text{pp}}/dp_T)$. Let us denote by $R_{\text{AA}}^{\text{fact}}$ the nuclear modification factor calculated in a standard implementation of parton energy loss in which the quenching dynamics is factorized from hadronization and the latter is treated as in the vacuum [1]. In this case, the energy degradation due to (4) is accounted for in $R_{\text{AA}}^{\text{fact}}$, whereas effects of medium-induced color flow are not. The latter effects may be included by subjecting a fraction f_t of the hadronic yield to a further suppression (12) at the cluster level. We do this by relating the energy of the final clusters \mathcal{C}_f to the hadronic transverse momentum, $P^+ = \sqrt{2} \frac{p_T}{z}$, and approximating the momentum fraction z carried by the hadron by the average of a boosted, isotropic two-body decay, $\langle z \rangle \sim 3/4$,

$$\begin{aligned} R_{\text{AA}}(p_T) &\simeq (1 - f_t) R_{\text{AA}}^{\text{fact}}(p_T) \\ &+ f_t F\left(\sqrt{2} \frac{4}{3} p_T\right) R_{\text{AA}}^{\text{fact}}(p_T). \end{aligned} \quad (13)$$

The resulting R_{AA} is plotted in Fig. 3 starting from a standard implementation of parton energy loss for central Pb-Pb collisions at the LHC (curve for $R_{\text{AA}}^{\text{fact}}$ taken from Fig. 5 of Ref. [13]). We chose this baseline since - in contrast with many results in the recent literature - it refers to a relatively small density of the medium (characterized by the quenching parameter $\hat{q} = 1$ GeV²/fm), and therefore significantly overpredicts the R_{AA} measured at the LHC. Supplementing this model with a color-flow induced suppression F in $f_t = 50\%$ (100%) of all fragmentation patterns according to (13), we find that R_{AA} is reduced significantly by ~ 0.1 (~ 0.2) compared to

FIG. 3: The nuclear modification factor $R_{AA}(p_T)$. The baseline calculation of kinematic effects (solid black curve) is supplemented with the effect of color-flow modified hadronization according to (13).

R_{AA}^{fact} . For $f_t = 100\%$, this brings the model into reasonable agreement [16] with preliminary results of ALICE and CMS at the LHC.

Recent measurements of the nuclear modification factor R_{AA} in central Pb-Pb collisions at the LHC have established unambiguously that $R_{AA}(p_T)$ increases notably at intermediate transverse momentum $p_T \in [5; 20]$ GeV, and they provided first information about the continuing slow rise of $R_{AA}(p_T)$ in the range $p_T \in [20; 100]$ GeV. This has been used in several recent studies [2–7] to constrain medium properties entering the modeling of parton energy loss. It is a common feature of all these models to assume gluon exchanges between the projectile parton and the medium, while neglecting in their dynamical implementation the ensuing changes in the color structure of the parton shower. Although heuristic models of medium-modified hadronization have been discussed previously [14, 15], we assessed here for the first time the color-differential information that is implicitly contained in standard implementations of parton energy loss. From Figs. 2 and 3 we learn that medium-modified color flow may affect single inclusive hadron spectra significantly up to the highest transverse momenta ($p_T > 100$ GeV, say). Also, remarkably, in contrast with the temperature dependence of the baseline R_{AA}^{fact} , the smaller the thermal energy in (12), the larger the color-flow induced contribution to the suppression of R_{AA} . As a consequence, a significantly smaller density of the medium may then be sufficient to account for the observed suppression of R_{AA} .

Medium-modified color flow is an inevitable consequence of models of parton energy loss. However, its numerical manifestation in R_{AA} may depend sensitively on the microscopic implementation of parton energy loss,

including e.g. the spatio-temporal embedding of the parton shower in the QCD matter and the probability that the produced partons escape the medium without gluon exchange. As illustrated in Fig. 3, the effect of medium-induced color flow is potentially large and thus needs to be constrained in phenomenological applications. It is thus important to include the effect of medium-modified color flow in full microscopic simulations of parton energy loss, where also refined or different hadronization prescriptions can be explored. Such further studies could give insight into the existence or absence of changes in the hadrochemistry and in the fragmentation pattern of jets in heavy ion collision. They could also help to understand any possible difference between the R_{AA} of reconstructed jets and leading hadrons.

We thank G. Corcella and K. Zapp for helpful discussions. JGM acknowledges the support of Fundação para a Ciência e a Tecnologia (Portugal) under project CERN/FP/116379/2010.
