Searches For the Standard Model Higgs boson in final states with τ leptons in $p\bar{p}$ collision at $\sqrt{s} = 1.96$ TeV

E. Pianori

Department of Physics and Astronomy, University of Pennsylvania, Philadelphia, PA, USA

We present the status of the Standard Model Higgs boson searches in final states containing τ leptons using data collected from $p\bar{p}$ collisions at Fermilab Tevatron collider at $\sqrt{s} = 1.96$ TeV. A summary of the latest results from CDF and D0 collaborations is reported in this paper.

1. Introduction

The Higgs mechanism, proposed in the 1960 by P. Higgs to explain the origin of the electroweak symmetry breaking and particle masses [1], predicts the presence of a yet to be discovered neutral scalar particle, called the Higgs boson. Since the Higgs boson couplings to the Standard Model particles are fixed by the particle masses, the only free parameter of the theory is the Higgs boson mass. Indirect constraints from precision electroweak measurements prefer a Higgs boson with mass $m_H = 92^{+34}_{-26} \text{ GeV}/c^2$ at 68% confidence level, with a 95% upper limit of 158 GeV/ c^2 [2]. Direct limits set at LEP excluded $m_H < 114.4 \text{ GeV}/c^2$ at 95% C.L. level [3].

In the last few years CDF and D0 have steadily increased the sensitivity of the Higgs boson searches: as of July 2011, the combined results from both the Tevatron experiments excluded at 95% C.L. a Higgs boson in the range $100 \le m_H \le 108 \text{ GeV}/c^2$ and $156 \le m_H \le 177 \text{ GeV}/c^2$ [4].

A constant effort has been made to improve analysis of the most sensitive channels, and an effort have been started to include analysis of channels with lower expected sensitivity. The searches that include τ leptons in the final state fall into this last category, and will be discussed in this paper.

There are two classes of analyses that include τ leptons that will be explored: searches that target $H \to \tau \tau$ final states, and searches where the W boson presents in the final state decays as $W \to \tau \nu$.

The former ones are important at low mass, where the BR $(H \to \tau \tau)$ is ~ 7.4% for $m_H = 115 \text{ GeV}/c^2$: not only they contribute to improve the low mass sensitivity, but also, in case the Higgs boson exists, will allow to measure some of its properties. The latter one can be considered an addition to the main analyses, such as $WH \to l\nu b\bar{b}$ and $H \to WW$, that target final states where the W decays into e and μ .

2. Experimental Apparatus

The CDF and D0 detectors, already described in details in [6] and [5] are used to perform the searches presented in this paper. The Tevatron, that ceased its operation on September 30th 2011, provided $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. Since the beginning or Run II, over 12 fb^{-1} of data were delivered at the two collision points, and almost $10fb^{-1}$ of data were made available for the analysis to each experiment. The results discussed here were performed using data corresponding to $5.5 < \int L < 8.2 \ fb^{-1}$.

3. Object reconstruction

Tau leptons are short-lived particles which can be detected only through their visible decay products. Hadronic decays, denoted as τ_h , are of the form $\tau \to X_h \nu_{\tau}$, where X_h is a system of hadrons, mainly composed of charged and neutral pions: the corresponding B.R. is about 65%. The remaining channels are represented by the leptonic decays into muons (τ_{μ}) or electrons (τ_e), through the process $\tau \to l\nu_l\nu_{\tau}$. Since it is not possible to distinguish leptonically decaying τ 's from e and μ produced in the primary interaction, when talking about τ 's throughout the paper we will mean hadronically decaying ones. The best quantity to describe the energy of the decay products of the τ is the visible four-momentum, defined as the sum of the track momenta and the neutral pions. Because of its signature in the detector as a narrow calorimeter clusters matched to low multiplicity reconstructed tracks, a τ can be easily mimicked by a jet. Since τ 's from W, Z and H decays are isolated and boosted, it is possible to exploit isolation-related observables to improve the purity of the τ identification algorithm.

The $H \to \tau \tau \tau$ +jets analysis of CDF and all the D0 analyses discussed here use Multivariate Technique based

algorithm to identify the τ leptons. The NN used by D0 is trained for three different decay modes of the τ separately: $\tau \to \pi^{\pm} \nu$ (type-I), $\tau \to \pi^{\pm} \pi^{0} \nu$ (type-II) and $\tau \to \pi^{\pm} \pi^{\pm} \pi^{\mp} (\pi 0) \nu$ (type-III). The CDF Boosted Decision Tree [7] was developed independently for 1-prong and 3-prong τ candidates. More details can be found in [8], [9]. All the other CDF analyses use cut based identification algorithms, optimized to the particular final state and trigger in use.

Jets are reconstructed as clustered energy depositions in the calorimeter towers using a cone algorithm, with cone size $R = \sqrt{(\Delta \Phi)^2 + (\Delta \eta)^2} = 0.4(0.5)$ for CDF(D0).

The missing transverse energy $E_{\rm T}$, calculated as the vector sum of all the calorimeter tower energy depositions projected to the transverse plane, is used to determine the presence of neutrinos in the event.

4. Searches for $H \rightarrow \tau \tau$ final states

For Higgs boson masses $m_H \leq 135 \text{ GeV}/c^2$, the branching ratio BR $(H \to \tau \tau)$ is in the range of 4 - 8%. Depending on the production mechanism, other objects other than the τ candidates will be present in the events: the analyses discussed in this review include extra jets or extra leptons in the final state.

In case the Higgs boson exists, it will be crucial to measure its couplings to different particles. The $\tau - \tau$ final states can be used to measure both the BR $(H \rightarrow \tau \tau)$ and the Higgs particle couplings to gauge bosons. A significant deviation of one of these quantities from its expected value could be evidence of new physics at play, since the branching ratios and production cross sections differ in Standard Model and Beyond the Standard Model scenarios.

4.1. $H \rightarrow \tau \tau + jets$

Both CDF and D0 search for $H \to \tau_h \tau_l$, where $l = e, \mu$: the choice of the "leptonic+hadronic" decay final state represents the best compromise between the high B.R. of the hadronic tau decay and the large background suppression provided by the request of an electron or a muon. Both the analysis use a multivariate technique to identify the hadronically decaying τ 's, and distinguish them from jets (see section 3 for more details). Although BR $(H \to \tau \tau)$ is small, < 10%, sensitivity is recovered by including four different production mechanisms: vector boson fusion $(qHq' \to q\tau\tau q')$, that corresponds to 5% of the total cross section; associated production with a gauge boson $(WH(\to \tau \tau), ZH(\to \tau \tau))$ that contributes for 18% of the total cross section; gluon fusion $(gg \to H \to \tau \tau)$, the main production mechanism, corresponding to 77% of the total cross section.

The $\tau - \tau$ signature alone is not useful to reject the dominant Drell-Yan $Z/\gamma * \to \tau \tau$ background. Due to the presence of at least 3 neutrinos per event and limited energy resolution, the $\tau - \tau$ invariant mass has a very broad distribution, and it is not very powerful in separating background from signal, as Figure 1a shows.

Both CDF and D0 analyses require the presence of calorimeter jets in the events (one or two jets at CDF, only

Figure 1: a) $\tau - \tau$ invariant mass for the CDF analysis. b) Final discriminant in the 2-jets channel at CDF c) Final discriminant in the $e - \tau$ channel at D0.

2 jets at D0): this reduces the size of the signal, and affects the relative contributions of the signal processes. Events where the Higgs boson is produced through vector boson fusion and in association with a guage boson exhibit kinematical properties different from the background events. Requiring the presence of jets in the events increases the contribution of these two processes over gluon fusion, improving the overall sensitivity of the search. A multivariate technique, based on a set of Boosted Decision Trees, is used to maximally exploit the kinematical differences between the $H \rightarrow \tau \tau$ signal and the backgrounds. We do not see evidence for a Higgs

boson signal and therefore we set a 95% confidence limit (C.L.) upper limit on the Higgs boson production cross section times $BR(H \to \tau \tau)$ relative to the Standard Model (S.M.) prediction. Figure 2b/c show the results for a Higgs boson mass varying from $m_H = 100 \text{ GeV}/c^2$ to $m_H = 150 \text{ GeV}/c^2$ for the CDF analysis and up to $m_H = 200 \text{ GeV}/c^2$ for D0. The analysis performed at D0 is sensitive to a wider range of masses, since it also considers signal events from $H \to W^+W^-$.

CDF observes a 95% C.L. limit of 14.7 times S.M. prediction ($m_H = 115 \text{ GeV}/c^2$), while expecting $15.2^{+6.5}_{-4.4}$. For the same test mass, D0 analysis observes a limit of 32.8 times S.M., while expecting 12.8. More details can be found in [8] and [10].

Figure 2: 95% C.L. limit on Higgs boson production rate times branching ratio over the Standard Model expection as a function of the Higgs boson mass for the $H \rightarrow \tau \tau \tau$ +jets analysis at CDF(a) and D0(b).

4.2. Higgs Associated production with W/Z

A Supplement Vector Machines (SVM) is used to separate signal from backgrounds in candidate events. A SVM [11] is a supervised training binary classifier, effective when trained on low statistic samples. The idea of an SVM is to determine the hyperplane in the space of the training variables that separates maximally two classes of events. Depending on the channel, different SVMs are trained to separate the signal from each of the backgrounds, and their individual output scores are multiplied together: this defines the final discriminant in Figure 3a.

All the tri-leptons channels containing at least one τ_h have very similar sensitivity: the $ll\tau_h$ channel, for example, is sensitive to a Higgs boson ($m_H = 115 \text{ GeV}/c^2$) production rate of 38.2 times the S.M. expected one, see 3b. The best sensitivity is achieved combining all the channels, as shown in Figure 3c: at $m_H = 115 \text{ GeV}/c^2$, the observed limit divided by the the Standard Model prediction is 18.5, while the expected one is $17.3^{+7.4}_{-3.9}$. [10].

5. Including τ leptons into main searches

With Tevatron data-taking coming to an end, both CDF and D0 collaborations, in a effort to maximize their sensitivity to the Higgs boson, are pursuing more challenging channels. The main analyses, $WH \rightarrow l\nu b\bar{b}$ at low mass, and $H \rightarrow WW \rightarrow l\nu l\nu$ at high mass, target events with e and μ . Adding final states with hadronically decaying τ 's is a natural step. The higher amount of backgrounds typical of τ final states, though, limits the sensitivity of these analyses.

Figure 3: a) Comparison between the background model of the final discriminant and the data distribution, in the $ll\tau_h$ channel. b)95% C.L. upper limit on the Higgs boson production rate divided by the standard model expectation as a function of the Higgs boson mass in the $ll\tau_h$ channel. c) 95% C.L. upper limit on the Higgs boson production rate divided by the standard model expectation as a function of the Higgs boson mass, for all the channels combined.

5.1. $H \rightarrow WW$ with τ leptons in final state

We present here the search for $gg \to H \to WW \to l\nu\tau\nu$, where the τ decays hadronically. Final states where the τ decays leptonically are already included in the main $H \to WW$ analysis with e and μ . The CDF collaboration considers events triggered on the presence of either a central e or a μ : this sets the lower bound on the lepton $p_{\rm T}$ ($p_{\rm T} \geq 20$ GeV). The τ signal cone of aperture $\alpha = min(0.17, 5/E^{clu}[{\rm GeV}])$ rad is built around a track with $p_{\rm T} \geq 10$ GeV/c (seed track), where E^{clu} is the calorimeter energy of the τ -candidate. To be identified, the τ must exhibit $E_T^{Vis} \geq 15$ (20) GeV for 1-prong(3-prong) candidates, be central ($|\eta| \leq 1$, and be isolated.

The D0 collaboration, instead, selects only events in the "muon+tau" final state, using a mixture of single and dilepton triggers requiring both lepton and jet signatures. The μ 's are identified down to a $p_{\rm T} \geq 15$ GeV/c, and must have pseudorapidity $|\eta| \leq 1.6$. The hadronically decaying τ , built around a a seed track with $p_{\rm T} \geq 7/5/7$ GeV/c, must have have a transverse momentum, as measured in the calorimeter, $p_{\rm T} \geq 12.5/12.5/15$ GeV/c for type-I/II/III, and $|\eta| \leq 2.0$. The τ -candidate, not to be rejected, mush exhibit a neural network score $NN_{\tau} \geq 0.9/0.9/0.95$. This selection corresponds to an overall efficiency of ~ 55% in signal events for a fake rate of ~ 2% in multijet events.

The sample where the two leptons are required to have opposite charge is dominated by Drell-Yen $Z/\gamma * \to \tau \tau$ events, with contribution from W+jets and multijet production. The Drell-Yen and multijet backgrounds can be easily suppressed: D0 requires transverse mass $m_T(l, \not\!\!E_T) = \sqrt{2|p_T^l||\not\!\!E_T|(1 - \cos\Delta\Phi(l, \not\!\!E_T))} \geq 25 \text{GeV}/c^2$ (see Figure 4a), while CDF cuts on different kinematical variables, such as the $\not\!\!E_T$, the angle between the dilepton system and the $\not\!\!\!E_T$. More details are described in [13].

The dominant background after these selections is the W production when the gauge boson decays into e or μ , and an additional jet is identified as a τ candidate. Monte Carlo simulated events are used to describe it. Both the collaboration developed corrections to the τ mis-identification rate, that is not properly modeled in simulated events.

There is no single variable able to distinguish the W+jets background from the signal, so both the collaborations use multivariate techniques to maximize the separation between the two processes. One of the most powerful variable is the angular correlation of the leptons, due to the spin of the Higgs particle.

CDF adds τ -related observables, as the energy deposited in the isolation annulus, to the kinematical variables used as inputs to the Boosted Decision Tree. More details can be found in [13].

Figure 4b shows the final Neural Network discriminant in the D0 analysis for the different classes of τ 's separately, and for all of them combined. Details on the input variables to the NN discriminant can be found in [14].

Figure 4c shows the 95% C.L. limit of the Higgs boson production rate time BR($H \rightarrow WW$) as a function of its mass. For $m_H = 160 \text{ GeV}/c^2$, the observed(expected) limit is 7.2(6.5) time the S.M. expectation.

Figures 5a and 5b show, for the CDF analysis, the final Boosted Decision output for the $e - \tau$ and $\mu - \tau$ final states, and the combined 95% C.L. limit, fig 5c. For $m_H = 160 \text{ GeV}/c^2$, the observed(expected) limit is 23.3(15.6). Among the two CDF channels, the $e - \tau$ one has the best sensitivity (with an expected limit of 20.5 time the S.M. expectation for $m_H = 160 \text{ GeV}/c^2$): the $\mu - \tau$ events have a sensitivity ~ 20% worst than that.

Figure 4: D0 analysis. a) Transverse mass distribution in $\mu - \tau$ events. The Drell-Yen and multijet backgrounds, where $\not\!\!E_{\rm T}$ arise from the energy mis-measurement of one of the object in the event, pile up at lower values of $m_{\rm T}$. 5.2. WH associated production with τ 's

The events analyzed are recorded using a trigger that selects events with jets and \not{E}_{T} at D0, and one that selects events with a τ candidate and \not{E}_{T} at CDF. The choice of trigger affects the event selection: in the D0 analysis, the type-I and type-II τ candidates must exhibit $p_{T}^{seed} \geq 7/5$ GeV/c, and transverse momentum, measured using calorimeter information only, $p_{T}^{Clu} \geq 12/10$ GeV/c. A Neural Network algorithm is used to reduce the contamination of jets mimicking the τ signature ($NN_{\tau} \geq 0.9$), retaining 65% of the hadronically decaying τ 's. Since the trigger used in the CDF analysis requires the presence of a τ candidate, the offline cuts used to identify the τ must be at least as tight as the ones used online. The τ candidate, reconstructed with a fixed-size cone with aperture $\alpha = 10^{\circ}$, must satisfy $p_{T}^{seed} \geq 10$ GeV/c and $p_{T}^{Clu} \geq 20$ GeV/c, and must be isolated. The efficiency for this selection is ~ 35%: most of the inefficiency is due to the tight energy requirements. More details can be found in [16] and [15].

The main backgrounds arise from (W/Z)bb, from (W/Z)+(non-b jets) due to flavor mis-identification (mistagging), from top quark production, diboson production, and from multijet events with fake $\not\!\!E_{\rm T}$ resulting from fluctuations in jet energy measurements. Except for the multijet background, which is model using a multijet enriched data sample, all the other backgrounds are described using Monte Carlo simulated events. The multijet-enriched sample used in the D0 analysis is defined by the NN_{τ} output value: $0.3 \leq NN_{\tau} \leq 0.7$. CDF uses events where the identified τ has exactly two tracks in the 10 ° signal cone, while τ 's candidate in the signal sample have either one or three tracks in the signal cone.

reduce the multijet background. Figure 7a shows the distribution of $\not\!\!\!E_{\mathrm{T}}^{Perp}$ before any b-tagging requirement is applied.

Figure 7: a) CDF analysis: \mathcal{B}_{T}^{perp} distribution for events with an identified τ and exactly two jets, before requiring *b*-tagging. The dash histograms represent the sum of the background contributions. b)Di-jet invariant distribution for events in signal sample with exactly one *b*-tagged jets. The yellow line represents the Higgs boson signal ($m_H = 115 \text{ GeV}/c^2$) time 50. c) 95% C.L. limit on the Higgs boson productions in factors away from the S.M. prediction. The limits set in events with exactly one *b*-tagged jet and two *b*-tagged jets are combined to give the final result.

Since the low mass Higgs boson $(m_H \leq 135 \text{ GeV}/c^2)$ decays mostly into $b\bar{b}$ pairs ($\text{BR}(H \to b\bar{b}) \sim 72\%$ for $m_H = 115 \text{ GeV}/c^2$), requiring that at least one of the jet is consistent with originating from a *b*-quark improves the S/\sqrt{B} by a factor of 2.

D0 cuts on the outputs of a Neural Network algorithm to identify *b*-quark jets (for more details, see [17]). Two classes of events are selected: either both the two jets are tagged with a lower efficiency by higher purity ("loose tag"), or only one of the jet is tagged with a lower efficiency but higher purity ("very tight tag").

CDF definition of a b-tagged jet relies on a secondary vertex tagging algorithm called SecVtx (see [18]). The algorithm reconstructs a secondary vertex inside a jet using tracks with large impact parameter. A jet is b-tagged if the significance of the displacement of the secondary vertex from the primary one is greater than 3. Events must contain at least one b-tagged jet.

In the low mass Higgs boson searches, the invariant mass of the two jets corresponds to the Higgs boson mass, and it is the most powerful observable to discriminate the signal from the backgrounds.

CDF uses a binned likelihood fit of the di-jet invariant mass distribution to test for a potential Higgs boson

signal, and, in its absence, set the 95% C.L. limit. Events are classified in two statistically independent channels: events with exactly one *b*-tagged jet, and events with two *b*-tagged jets. The two channels have similar sensitivity, since the \mathcal{I}_{T}^{perp} cut value was optimized for the best sensitivity separately in the two samples.

D0 combines the information carried by the di-jet invariant mass with other kinematical observable, such as the energy and pseudorapidity of the individual jets, of the τ candidate, and the $\not\!\!E_T$, in a boosted decision tree (BDT), to achieve the best separation between signal and backgrounds. The BDT is trained for type-I and type-II τ 's, for events with two or three jets and one or two *b*-tagged jets, separately, for a total of 8 independent channels.

Figures 6c and 7c shows the 95% C.L. upper limit on the Higgs boson production rate time BR $(H \rightarrow b\bar{b})$ as a function of the Higgs boson mass for D0 and CDF respectively. The D0 analysis results with a observed(expected) limit for $m_H = 115 \text{ GeV}/c^2$ of 14.1(22.4) time the S.M. expectation. CDF analysis sets an upper limit of 28.7(46.6) for the same mass hypothesis.

6. Conclusion

We presented here the most recent results for the Higgs boson searches at the Tevatron, performed in final states that include τ leptons. The main challenge, in these analysis, is due to the necessary compromise between retaining as much Higgs boson signal as possible and minimizing the contribution of the multijet background, that is difficult to model.

Although these channels set limits on the Higgs boson production cross section 10 time greater than the Standard Model expectation, in the current effort to extend the potential sensitivity at the Tevatron, their contribution is important.
