Abstract

The status of light $I = 0$, $J^{PC} = 2^{++}$ and 0^{++} mesons is discussed, particularly the separation of $n\bar{n}$ and $s\bar{s}$ states. They fall into a simple scheme except for $f_2(1810)$. A case is made that this has been confused with the $f_0(1790)$. It should be possible to check this with existing or forthcoming data.

PACS numbers: 14.40.Be, 14.40.Df, 13.75.-n

1 Introduction

The objective of this paper is a critical review of the identification of light mesons with $J^{PC} = 2^{++}$ and 0^{++} , particularly the separation of 2^{++} states into $\bar{n}n$ and $s\bar{s}$. That detail is important in its own right. It will also be vital input information into the search for the 2^{++} glueball in radiative J/ψ decays. It is unrealistic that those data will be extensive enough to sort out the complex spectroscopy of $q\bar{q}$ states as well as glueballs.

Section 2 reviews 2^{++} states. They fall into a regular scheme except for $f_2(1810)$, whose identification is presently weak. Section 3 reviews 0^{++} states and makes the case that $f_2(1810)$ may have been confused with $f_0(1790)$. Without an f_0 in that mass range, the 0^{++} spectrum is obviously incomplete, but $f_0(1790)$ fits in naturally. Section 4 draws conclusions and comments on improvements needed in present partial wave analyses to resolve this question; these are straightforward and can be done with existing data and/or forthcoming BES III data.

2 $J^P = 2^{++}$ states

There are extensive data from Crystal Barrel on $\bar{p}p$ scattering in flight to 17 final states. These concern purely neutral final states which can be classified into four families with isospin $I = 0$ and 1, and charge conjugation $C = +1$ and -1 . We shall concentrate here on $I = 0$, $C = +1$ where the data are most complete. This is a formation experiment of the type $\bar{p}p \rightarrow \text{resonance} \rightarrow A + B$. These data are listed by the PDG under ‘Further States’, requiring confirmation [1]. That is not possible for most states because other data come from production reactions of the form $\pi p \rightarrow X + p$ (or n), where the exchanged meson is uncertain, leading to ambiguities in partial wave analysis; also they have no polarisation data.

A combined analysis has been published [2] of 8 sets of data with $I = 0$, $C = +1$ on $\bar{p}p \rightarrow \pi^0\pi^0$, $\eta\eta$, $\eta\eta'$, and $\eta\pi^0\pi^0$ from Crystal Barrel at 9 beam momenta, plus measurements of differential cross sections and polarisation from the PS172 experiment [3] and an earlier experiment of Eisenhandler et al. at the CERN PS [4]. The first set of $\pi^+\pi^-$ data covers the momentum range 0.36–1.55 GeV/c and the second covers 1–2.5 GeV/c. They agree accurately where they overlap. The data of PS172 are particularly valuable because they extend down to a beam momentum

of 360 MeV/c (a mass of 1910 MeV) in quite small steps of momentum (30–100 MeV/c) and therefore cover in detail the lower side of the cluster of resonances around 2000 MeV; they also used a beam going through the detector and therefore cover centre of mass scattering angles to $\cos\theta > 0.999$. Two further analyses were reported of Crystal Barrel data for $\bar{p}p \rightarrow \eta'\pi^0\pi^0$ [5] and 3η [6]. They find masses and widths consistent within errors with the combined analysis.

The polarisation data are very important. Because 3P_2 and 3F_2 have orthogonal Clebsch-Gordan coefficients, they separate those partial waves accurately. Differential cross sections contain real parts of interferences within singlet and triplet sets of amplitudes; polarisation data measure the imaginary part of interferences within the triplet set. Formulae are given in Ref. [7]. Column 5 of Table 1 gives the ratio $r_J = g_{L=J+1}/g_{L=J-1}$ of amplitudes, where g_L are coupling constants for $\bar{p}p$ orbital angular momentum L ; intensities depend on r_J^2 . The phase sensitivity of the polarisation data improves greatly the accuracy of masses and widths. The only singlet states with $I = 0$, $C = +1$ are 1S_0 , 1D_2 and 1G_4 and these states are separated by their angular dependence.

The analysis relies on fitting with analytic functions of s and assumes two towers of states in mass ranges 1910–2100 and 2200–2370 MeV; it includes Blatt-Weisskopf centrifugal barrier factors with a radius which optimises at 0.83 ± 0.021 fm. The tails of $\eta_2(1870)$ and $f_6(2465)$ are included using masses and widths determined elsewhere. It is fortunate that 3F_4 states near 2050 and 2300 MeV are strong and accurately determined by their rapid angular dependence, and act as powerful interferometers to determine lower partial waves. Starting from these partial waves and adding lower J^P , the analysis finds a unique set of amplitudes; only in two low partial waves with little or no angular dependence are there sizable errors in fitted masses and widths. Recently, as a convenience, we have installed the relevant publications on the arXiv system, and give references in the bibliography. Further details and figures of data are given in a full length review [8]. There is a total of > 10 million fully reconstructed events. The data and Monte Carlo sets are publicly available from the authors of this paper, subject to a joint publication of results. A complete set of data is also available on $\bar{p}p$ annihilation at rest in liquid hydrogen and deuterium and in gas for both. This makes one of the largest data sets available in meson spectroscopy.

Table 1 lists $I = 0$, $J^{PC} = 2^{++}$ states. The top half of the table lists states which are dominantly $n\bar{n}$ and the lower half $s\bar{s}$ states. Masses and widths are from Crystal Barrel where available.

There is also evidence for a broad f_2 listed by the PDG as $f_2(1950)$; in Crystal Barrel data it appears in the $\eta\eta$ channel with a mass of 2010 ± 25 MeV and a width of 495 ± 35 MeV. It is observed by other groups in $\pi\pi$, $\eta\eta$, 4π , KK and $KK\pi\pi$. It is a candidate for the 2^+ glueball. Another possibility is that it is a dynamically generated state related to the opening of the strong 4π and $KK\pi\pi$ thresholds.

2.1 Separation of $n\bar{n}$ and $s\bar{s}$ states

There is a publication concerning Crystal Barrel data in flight which determines the mixing angle between $n\bar{n}$ and $s\bar{s}$ using data on $\bar{p}p \rightarrow \pi^0\pi^0$, $\eta\eta$ and $\eta\eta'$ [7]. To our knowledge, these are the only data making a clean identification of $n\bar{n}$ and $s\bar{s}$ and their mixing. Resonances R are linear combinations:

State	Mass (MeV/c^2)	Width (MeV/c^2)	$s\bar{s}$ Mixing Angle (deg)	$r_J =$ $\frac{g(L=J+1)}{g(L=J-1)}$	Observed Channels
$f_2(1270)$ [9]	1270 ± 8	194 ± 36	0	0	$\pi\pi, 4\pi$
$f_2(1565)$ [9]	1560 ± 15	280 ± 40	0	0	$\pi\pi, \eta\eta, \omega\omega$
$f_2(1910)$ [2,7]	1934 ± 20	271 ± 25	1.1	0.0 ± 0.08	$\pi\pi, \eta\eta, f_2\eta, a_2\pi$
$f_2(2000)$ [2,7]	2001 ± 10	312 ± 32	7.9	5.0 ± 0.5	$\pi\pi, \eta\eta, \eta\eta', f_2\eta$
$f_2(2240)$ [2,7]	2240 ± 15	241 ± 30	7.5	0.46 ± 0.09	$\pi\pi, \eta\eta, \eta\eta', f_2\eta$
$f_2(2295)$ [2,7]	2293 ± 13	216 ± 37	-14.8	-2.2 ± 0.6	$\pi\pi, \eta\eta, \eta\eta', f_2\eta, a_2\pi$
$f_2(1525)$ [10]	1513 ± 4	76 ± 6			K^+K^-
$f_2(1525)$ [11]	1508 ± 9	79 ± 8			$\eta\eta$
$f_2(1755)$ [12]	1755 ± 10	67 ± 12			K^+K^-
$f_2(2150)$ [1]	2157 ± 12	152 ± 30			$\eta\eta, K_S^0\bar{K}_S^0$
$f_2(2300)$ [13]	2297 ± 28	149 ± 41			$K\bar{K}, \phi\phi$
$f_2(2340)$ [13]	2339 ± 55	319^{+81}_{-69}			$\eta\eta, \phi\phi$

Table 1: $I = 0$ $J^{PC} = 2^{++}$ Resonances primarily discussed here, $n\bar{n}$ in the top half of the table, $s\bar{s}$ in the bottom half.

$$R = \cos \Phi (|u\bar{u} \rangle + |d\bar{d} \rangle) / \sqrt{2} + \sin \Phi |s\bar{s} \rangle. \quad (1)$$

The quark content of η and η' may be written in terms of the pseudoscalar mixing angle Θ as

$$|n\bar{n} \rangle = \cos \Theta |\eta \rangle + \sin \Theta |\eta' \rangle, \quad (2)$$

$$|s\bar{s} \rangle = -\sin \Theta |\eta \rangle + \cos \Theta |\eta' \rangle. \quad (3)$$

Amplitudes for decays of R are given by

$$f(\pi^0\pi^0) = \cos \Phi / \sqrt{2}, \quad (4)$$

$$f(\eta\eta) = \cos \Phi (\cos^2 \Theta + \sqrt{2}\lambda \sin^2 \Theta \tan \Phi) / \sqrt{2}, \quad (5)$$

$$f(\eta\eta') = \cos \Phi \cos \Theta \sin \Theta (1 - \sqrt{2}\lambda \tan \Phi) \sqrt{2}. \quad (6)$$

where $\sin \Theta$ was taken as 0.6 and λ as 0.85. Values of the $s\bar{s}$ mixing angle Φ are listed in column 4 of Table 1. Errors are not listed in the original publication, but are quoted as typically $\pm 5^\circ$. Each mixing angle of Table 1 is consistent with zero within three standard deviations, though from the overall χ^2 there is a definite indication that some small mixing with $s\bar{s}$ occurs; that is to be expected from $\bar{s}s$ states across the mass range. The conclusion is that none of the states listed in the first half of the table is dominantly $s\bar{s}$. Amongst recognised or possible $s\bar{s}$ states, a small signal from $f_2(1525)$ can be detected in Crystal Barrel data for $K\bar{K}$ and $\eta\eta$ via its interference with $f_0(1500)$ [11], [14]. The $f_0(980)$ appears as a dip in the Dalitz plot for $\bar{p}p \rightarrow 3\pi^0$, but with a much smaller branching ratio compared with the σ amplitude than in $\pi\pi$ elastic scattering, see Figs 2 and 4(a) of Ref. [15].

Otherwise, recognised $s\bar{s}$ states are conspicuous by their absence in $\bar{p}p$ annihilation. The $f_2(2300)$ and $f_2(2340)$ are observed by Etkin et al. in $K\bar{K}$ and $\phi\phi$ [13]. The initial state for

those data is $\pi\pi$, but no $\pi\pi$ decays are observed, showing that any $\pi\pi$ coupling in these states, hence $n\bar{n}$ component, must be small. Presently, the PDG lists $f_2(2240)$ under $f_2(2300)$. That is clearly inconsistent with the mixing angles of Table 1 and needs to be corrected in PDG tables. The $f_2(2295)$ is missing from the tables and needs to be included, since it is observed in five channels of data: $\pi\pi$, $\eta\eta$, $\eta\eta'$, $f_2(1270)\eta$ and $a_2(1320)\eta$; dropping it from the $\pi\pi$ channel alone increases χ^2 by 2879, which is highly significant. Figures 9(n) and 9(o) of that paper illustrate the effects of dropping them from the analysis and re-optimising all other components; the changes near $\cos\theta = 1$ are very large, leaving no doubt of their significance.

Visual evidence for $f_2(2240)$ and $f_2(2295)$ are also displayed in the first analysis of $\bar{p}p \rightarrow \eta\pi^0\pi^0$ data in Ref. [16]. Fig. 16 of that paper displays the requirement for $f_2(2240) \rightarrow [f_2(1270)\eta]_{L=1}$, where L is the angular momentum in the decay. In the final combined analysis of Ref. [2], log likelihood is worse by 468 if $f_2(2240)$ is omitted in the $\eta\pi^0\pi^0$ channel and by 1557 if $f_2(2295)$ is omitted; here log likelihood is defined so that it increases by 0.5 for a one standard deviation change in each coupling constant.

There is no convincing evidence in Crystal Barrel data for $f_2(2150)$, which is observed by other groups only in $\eta\eta$ and $K\bar{K}$. The $f_2(2150)$ may be interpreted as the $s\bar{s}$ 3P_2 partner of $f_2(1910)$. Their mass difference is similar to that between $f_2(1270)$ and $f_2(1525)$. The $f_2(2300)$ and $f_2(2340)$ are observed by Etkin et al. in $K\bar{K}$ and $\phi\phi$ S and D-waves. Both $f_2(2300)$ and $f_2(2340)$ may be interpreted as the partner of the 3F_2 $n\bar{n}$ state at 2001 MeV, with decays to $\phi\phi$ S and D-waves; the $L=2$ dependence makes the D-wave peak higher. However, the 150 MeV mass gap between $f_2(2150)$ and $f_2(2300)$ is a little surprising compared with the 90 MeV gap between $f_2(1910)$ and $f_2(2000)$.

Under $f_2(2150)$, the PDG lists Anisovich 99K data on $\bar{p}p \rightarrow \eta\eta\pi^0$ [14] as presenting evidence that there is a state at 2105 ± 10 MeV consistent with the $f_2(2150)$. In fact, the paper presented a careful study of both the angular distribution, which is flat, and the energy dependence of production (which is different for production of $J = 2$ and 0); the conclusion from both sources is that the signal is due to $f_0(2105)$, which is observed in many sets of data and unambiguously has $J^P = 0^+$. It is the only state observed in Crystal Barrel data with a large mixing angle $(68 - 71.6)^\circ$ to $s\bar{s}$. It makes up $(4.6 \pm 1.5)\%$ of the $\pi^0\pi^0$ intensity and $(38 \pm 5)\%$ of $\eta\eta$. The branching ratio to $\eta\eta'$ is not well determined because of low statistics in this channel. The best estimate of amplitude ratios is

$$\pi^0\pi^0 : \eta\eta : \eta\eta' = 0.71 \pm 0.17 : 1 : -0.85 \pm 0.45. \quad (7)$$

For an unmixed $q\bar{q}$ state, the ratio expected between $\pi^0\pi^0$ and $\eta\eta$ is $0.8^{-4} = 2.44$. A possible interpretation is that it is an $s\bar{s}$ state mixed with $f_0(2020)$. An alternative is that it is the second 0^+ glueball predicted by Morningstar and Peardon in this general mass range [17]. A pointer in this direction is that it was first identified in Mark III data for $J/\psi \rightarrow \gamma(4\pi)$ [18]. A pure glueball would have a mixing angle of $+37^\circ$. Its strong coupling to $\bar{p}p$ is clearly anomalous.

We are able to check the partial wave analyses of $\bar{p}p \rightarrow \pi^+\pi^-$ done by Hasan et al. [19] and Oakden and Pennington [20]. Because their analyses were limited to this channel alone, errors on mass and width are larger than from the full analysis by a factor ≥ 5 . This explains why their results have larger errors and fluctuations. Our experience is that, as a rule of thumb, each data set with large statistics reduces errors by a factor 2 because different sets of data have different sensitivity to details. The PDG attributes the $f_2(2226)$ reported by Hasan [19] as $f_2(2150)$. That is a mistake. It should be attributed to $f_2(2240)$.

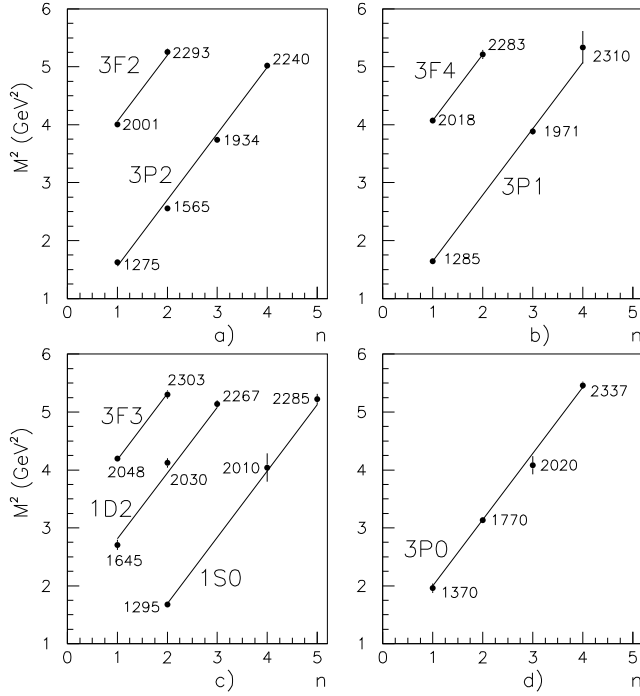

Figure 1: Trajectories of light mesons with $I = 0$, $C = +1$ observed in Crystal Barrel data in flight, plotted against radial excitation number n ; masses are marked in MeV.

The outcome of this analysis is that states observed in the Crystal Barrel analysis for the four sets of quantum numbers $I = 0$, $C = \pm 1$ and $I = 1$, $C = -1$ fall on to parallel trajectories displayed in Figs. 1 and 3 of Ref. [8]. Those with $I = 0$, $C = +1$ are shown here in Fig. 1. They are particularly well identified because of the availability of the polarisation data. Some states are significantly displaced from straight line trajectories by thresholds. A striking example is $f_2(1565)$ which coincides with the $\omega\omega$ threshold and is displaced downwards from its isospin partner $a_2(1700)$ by ~ 135 MeV. The origin of this shift is a narrow cusp in the real part of the amplitude at the opening of any sharp threshold, as explained in Ref. [21].

The experimental data separate $\bar{p}p$ 3F_2 and 3P_2 states. These can be interpreted as 3F_2 and 3P_2 $q\bar{q}$ configurations for the following reasons. A feature of the data is that F -states decay strongly to channels with high orbital angular momentum. The origin of this effect is clearly a good overlap between initial and final state wave functions. Llanes-Estrada et al. point out a formal analogy with the Frank-Condon principle of molecular physics consistent with this observation [22]. In essence, this analogy provides a mechanism via which $n\bar{n}$ 3F_2 states couple preferentially to $\bar{p}p$ 3F_2 states and likewise 3P_2 $n\bar{n}$ states couple preferentially to $\bar{p}p$ 3P_2 states.

It is observed that 3F_2 states lie systematically higher in mass than 3P_2 by ~ 60 MeV, see Fig. 1. For $I = 1$, $C = -1$, D-states lie roughly midway in mass. These observations are consistent with stronger centrifugal barriers in F -states delaying the appearance of F -wave resonances to higher masses. The spin-splitting between F -states is consistent within errors with tensor splitting, which is predicted to be dominantly from one-gluon exchange between $q\bar{q}$ [23]. The 3F_4 states have some admixtures of 3H_4 ; the 3H_6 state does not appear until 2465 ± 60 MeV [1]. The overall picture is the first appearance of the lowest-lying F -states at ~ 2030 MeV. This is

what is to be expected from Regge trajectories for $n\bar{n}$ states.

2.2 Discussion of other $J^{PC} = 2^{++}$ listings of the PDG.

There are other candidates for 2^{++} states listed by the PDG. Firstly, the $f_2(1640)$ has a simple explanation. It is the $\omega\omega$ decay mode of $f_2(1565)$ [24]. The latter state sits precisely at the $\omega\omega$ threshold. The $f_2(1640)$ has a line-shape which is well fitted by folding $\omega\omega$ S-wave phase space with the line-shape of $f_2(1565)$. It is fitted like that by Baker et al., including the dispersive term which originates from the opening of the $\omega\omega$ threshold. The square of the coupling constant to $\rho\rho$ is 3 times that for $\omega\omega$ by SU(2) symmetry. The result is that $\rho\rho$ decays of $f_2(1565)$ also peak at ~ 1640 MeV, but the peak is broader than for $\omega\omega$ when the widths of the two ρ are folded in, see Fig. 5(b) of Ref. [24].

The $f_2(1430)$ listed by the PDG has an explanation, illustrated in Fig. 10 of Ref. [25]. Below the $\omega\omega$ threshold, the Breit-Wigner denominator of $f_2(1565)$ needs to include an analytic continuation of the phase space factors below both $\rho\rho$ and $\omega\omega$ thresholds. The analytic continuation causes a phase variation in $\pi\pi$ and leads to an interference between the $f_2(1565)$ and $f_2(1270)$. This interference is very clear for the $\pi\pi$ D-wave in Crystal Barrel data for $\bar{p}p$ at rest $\rightarrow 3\pi^0$. The effect is maximal at a mass of 1420 MeV. Similar interferences in other channels listed under $f_2(1430)$ may be explained this way. It was a good observation by the experimental groups before the existence of the $f_2(1565)$ was well known.

The $f_2(2010)$ listed by the PDG has a simple explanation. The peak observed in the data of Etkin et al. [13] is at 2150 MeV and agrees with the $f_2(2150)$. It is not necessary to have two separate f_2 states at 2010 and 2150 MeV. The partial wave analysis of Etkin et al. used the K-matrix approach. It is possible to have a K-matrix pole at the $\phi\phi$ threshold, significantly displaced from the T-matrix pole at 2150 MeV.

3 Discussion of $f_2(1810)$ and $J^P = 0^+$ states

This leaves the $f_2(1810)$. It does not fit well on to the 2^+ trajectories shown in Fig. 1; it appears to be an ‘extra’ state. Dudek [27] has recently presented a lattice QCD calculation of hybrid masses and light mesons. He predicts a lowest group of hybrids with $J^{PC} = 1^{-+}, 0^{-+}, 1^{--}$ and 2^{-+} . His mass scale needs to be normalised against the well known $f_4(2050)$ and the $\rho(1700)$ 3D_1 states. It then agrees quite well with the exotic $\pi_1(1600)$ (actually at 1660 MeV), the $\pi(1800)$ and the two ‘extra’ 2^{-+} states $\eta_2(1870)$ and $\pi_2(1880)$, which do not fit into the 1D_2 trajectory of Fig. 1(c) above. No 2^{++} hybrid is predicted in this mass range.

This prompts a careful re-examination of the data on which $f_2(1810)$ is based. The $f_2(1810)$ is not well established. Also there is clear evidence for an $n\bar{n}$ $J^{PC} = 0^{++}$ state $f_0(1790)$ very close to this mass, distinct from $f_0(1710)$. We shall consider possible confusion between $J = 0$ and 2 for this state.

The primary data for $f_2(1810)$ come from the GAMS collaboration [26]. These are mostly on $\pi^-p \rightarrow 4\pi^0 n$. In these data, the separation between $J^P = 2^+$ and 0^+ rests on the number of events observed below and above $\cos\theta = 0.4$, where θ is defined in their paper. In practice this is a rather fine distinction. The argument is that f_2 events are enhanced at small $\cos\theta$ and f_0 events are enhanced at large $\cos\theta$. That is counter-intuitive and must depend strongly on the

Monte Carlo of acceptance which is quoted but not shown. It would be valuable if the Compass collaboration could check these results in $\pi^+\pi^-\pi^+\pi^0$ and in $4\pi^0$ if that is possible.

Data of Costa et al. [28] are also quoted, but these refer to $\pi^-p \rightarrow K^+K^-n$. There are eight alternative solutions, which mostly contain some mild peaking near 1800 MeV. These could be explained by the $f_2(1755)$ of the L3 collaboration. The PDG quotes also an $f_2(1857^{+18}_{-71})$ fitted by Longacre to data available in 1986 [29]. At that time, $f_2(1910)$ had not been discovered. If it had been known at the time, there would undoubtedly have been some perturbation to Longacre's analysis. Finally, the observation of a structure at 1799 MeV in $\pi^+p \rightarrow \Delta^{++}\pi^0\pi^0$ by Cason et al. was not confirmed by Prokoshkin et al [30]. Cason et al. argue that their charge exchange data choose a unique solution from four ambiguous solutions to $\pi^+\pi^-$ elastic scattering. It is however somewhat puzzling that their solution does not contain any significant signal for $f_0(1500)$, which ought to be conspicuous. Neither do they observe the $f_2(1565)$ which is conspicuous in the $\pi\pi$ channel; indeed, that is where it was first observed by the Asterix collaboration [31].

The alternative assignment for the 1810 MeV state is $J^P = 0^{++}$. Here, important data come from BES II for J/ψ decays. There are six relevant sets of data. The first two are for $J/\psi \rightarrow \omega K^+K^-$ [32] and $\omega\pi^+\pi^-$ [33]. A large $f_0(1710)$ signal is observed in ωK^+K^- . In contrast, high statistics data on $\omega\pi^+\pi^-$ show no structure in $\pi^+\pi^-$ at this mass. Those data set an upper limit of 11% on the branching ratio $\pi\pi/K\bar{K}$ of $f_0(1710)$ with 95% confidence.

The third and fourth sets of data are for $J/\psi \rightarrow \phi\pi^+\pi^-$ and ϕK^+K^- [34]. In the $\phi\pi^+\pi^-$ data there is a definite $J^{PC} = 0^{++}$ $\pi\pi$ peak, but at 1790^{+40}_{-30} MeV, visibly distinct from the mass of $f_0(1710)$. There is no definite evidence for a decay to $K\bar{K}$, though a small amount can be fitted. There is a factor 22–25 discrepancy between the branching ratio $\pi\pi/K\bar{K}$ for these data and the data for $J/\psi \rightarrow \omega\pi\pi$ and ωKK , so this peak cannot be due to $f_0(1710)$. The discrepancy points strongly to the existence of a second $\bar{n}n$ state distinct from $f_0(1790)$.

Figure 2: Angular distribution for BES II data on $J/\psi \rightarrow \phi\pi^+\pi^-$ (points with errors); the full histogram shows the fit with $f_0(1790)$ and the dotted line the acceptance.

A question is whether these data can alternatively be fitted by $f_2(1810)$. The observed decay

angular distribution, shown here in Fig. 2, is flat within experimental errors in the region where the acceptance of the BES II detector (dotted histogram) is uniform. However, the acceptance falls rapidly at $|\cos\theta| \simeq 0.6$. The BES publication comments that the $f_2(1810)$ can be produced with orbital angular momentum $\ell = 0, 2$ or 4 in the production step. The $\ell = 0$ component is likely to be dominant and gives a decay angular distribution proportional to the Legendre polynomial $P_2(\alpha) = 3\cos^2\alpha - 1$, where α is the decay angle of the π^+ from $f_J(1790)$ in the resonance rest frame. On resonance, the ϕ and $f_J(1790)$ are produced with momenta of 630 MeV/c in the lab frame, and the centrifugal barrier reduces $\ell = 2$ amplitudes by a factor ~ 2 and the $\ell = 4$ amplitude by a factor ~ 30 , so the $\ell = 4$ amplitude may safely be neglected. For $\ell = 2$, there are three combinations of $\ell = 2$ with spin $j = 2$ of the $f_2(1790)$, making total spins $S = 0, 1$ and 2. Of these, spin 1 makes two amplitudes proportional to $\sin^2\alpha$ and $\sin\alpha\cos\alpha$, but no amplitude proportional to P_2 . The $S = 0$ amplitude is proportional to $P_2(\alpha)$. The $S = 2$ amplitude is formed from $S = 2$ and the spin 2 of $f_2(1790)$ and contains a P_2 term. The publication says: ‘Our experience elsewhere is that using four helicity amplitudes instead of two adds considerable flexibility to the fit. We conclude that the state is most likely spin zero.’

Entry	Amplitudes	Change in log likelihood
A	$\ell = 0$	-216
	$\ell = 2, S = 0$	-467

Table 2: Changes in log likelihood with a variety of $f_2(1790)$ amplitudes fitted to BES II data on $J/\psi \rightarrow \phi\pi\pi$ and ϕKK .

It is now worth amplifying this comment with numbers in Table 2 from the analysis; these may be understood in terms of the acceptance. Each amplitude is fitted freely in magnitude and phase. Angular correlations with the decay of the ϕ are included. The fit to $f_0(1790)$ produced with both $\ell = 0$ and 2 amplitudes is taken as a benchmark. Further entries in the table show changes in log likelihood (defined so that a change of +1 is better by one standard deviation for two degrees of freedom). The $\ell = 2$ amplitude changes sign at $|\cos\alpha| \simeq 0.577$. In entry A, changes in log likelihood are shown for four single f_2 amplitudes. Entry B shows the best three pairs of f_2 amplitudes and Entry C the best combination of 3.

In A, the best fit with $\ell = 0$ is considerably worse than the benchmark, but uses the $P_2(\alpha)$ dependence to produce a fit peaking at $\cos\alpha = 0$ and dropping sharply at $|\cos\alpha| = 0.6$, though it gives a false peak near $|\cos\alpha| = 1$. The fit with $S = 0$ requires strong correlations between the production angle and decay angle and is considerably worse. The fit with $S = 1$ is bad because two of the contributions go to zero in the middle of the angular distribution.

In B, the best fit is a combination of $L = 0$ and $L = 2$ with $S = 1$. The second of these helps produce the box-shaped distribution of data on Fig. 2 and is able to compensate P_2 to some

extent near $|\cos \alpha| = 1$. In C, three amplitudes can produce nearly as good a fit as $f_0(1790)$. There is considerably flexibility using three fitted phase angles; random phases give much worse fits.

It is of course possible that $f_2(1810)$ is produced with a set of amplitudes which happen to agree with $f_0(1790)$. Further BES III data with considerably improved acceptance and higher statistics have a high chance of resolving the situation.

3.1 X(1812)

The BES II collaboration also present data on $J/\psi \rightarrow \gamma(\omega\phi)$ [35]. There is a clear peak in $\omega\phi$ at $1812_{-26}^{+19} \pm 18$ MeV. Quantum numbers $J^{PC} = 0^{++}$ are favoured quite significantly over 2^{++} and 0^{-+} . The $\omega\phi$ channel opens at 1802 MeV. The present data may be fitted within the sizable errors by folding the line shape of $f_0(1790)$ with $\omega\phi$ phase space, using a reasonable form factor $\exp(-2k^2)$, where k is the momentum in the $\omega\phi$ channel in GeV/c. The PDG lists this state under $X(1835)$, observed in $J/\psi \rightarrow \gamma(\eta'\pi^+\pi^-)$ [36] [37]. However, as the PDG remarks, $J^P = 0^+$ is not allowed for this final state. The angular distribution of the photon for those data is consistent with $J^P = 0^-$, but might be accomodated with 1^{++} if the helicity ratio of the two possible 1^{++} amplitudes is just right. But neither of these possibilities is consistent with the observed peak presently attributed to $f_0(1790)$.

The $X(1812)$ decays to $\phi\omega$. There is an important simplification that in radiative production of $X(1812)$ there are only three $J^P = 2^+$ helicity amplitudes instead of five because helicity 0 is forbidden for the photon. An analysis of the spin correlation between these two would identify J^P of $X(1812)$. The spin of the ϕ is measured by $(p_1 - p_2)$, where p_1 and p_2 are momenta of the kaons from its decay in its rest frame; the spin of the ω is normal to the decay plane of the ω in its rest frame. For spin 0, the angular distribution of ϕ and ω decays is given by the dot product of these two vectors. This is a delicate test of the spin of the $X(1812)$. Formulae for other J^P are given by Zou and Bugg [38].

The decay to $\phi\omega$ is surprising (Okubo-Zweig-Iizuka violating). It could arise from a glueball component mixed into $X(1812)$. Two gluons couple to $(u\bar{u} + d\bar{d} + s\bar{s})(u\bar{u} + d\bar{d} + s\bar{s})$. The cross-terms between $u\bar{u} + d\bar{d}$ and $s\bar{s}$ can generate $\omega\phi$.

The $f_0(1790/1812)$ would fit naturally on to the 0^{++} trajectory of Fig. 1. It would not be surprising that there are two 0^+ states close in mass; a similar pair is $f_2(1525)$ and $f_2(1560)$. There is earlier independent evidence for an $f_0(1750)$ in Mark III data for $J/\psi \rightarrow \gamma 4\pi$ [18]. There is a further observation of a well defined 0^{++} signal in $\eta\eta$ in Crystal Barrel data in flight at 1770 ± 12 MeV with width 220 ± 40 MeV [39]. The mass is 4 standard deviations above $f_0(1710)$ and the width is 2 standard deviations higher. This signal could come from a superposition of $f_0(1790)$ with $f_0(1710)$, which clearly has a large $s\bar{s}$ component (and/or glueball).

4 Conclusions

We have made a case that existing light mesons with $J^P = 2^+$ fall into a regular pattern of $n\bar{n}$ 3P_2 and 3F_2 states except for $f_2(1810)$. There is the possibility that it has been confused with $f_0(1790)$; if not, there is a missing 0^+ state on the trajectory of Fig. 1 at a similar mass. The pattern of $f_0(1710)$ and $f_0(1790)$ is like that of $f_2(1525)$ and $f_2(1565)$.

We remark that the search for the 2^{++} glueball will require full use of existing identifications of $q\bar{q}$ and $s\bar{s}$ components with these quantum numbers. We have pointed out some corrections to PDG Tables.

We also remark that, in the long term, it would be possible to do further polarisation measurements in $\bar{p}p$ scattering in the beam momentum range from ~ 360 to 1940 MeV/c at the forthcoming FAIR facility [40]. This was part of the proposed program at LEAR, but was cut short by the closure of that machine. Measurements of polarisation in $\bar{p}p \rightarrow \eta\pi^0\pi^0$ and $\eta'\pi^0\pi^0$ are realistic and would give information on interferences between singlet and triplet partial waves. For $I = 1$, $C = +1$ and $I = 0$, $C = -1$, there are presently no polarisation data. Such data would improve vastly the identification of states with these quantum numbers.
