Abstract

Particle accelerators are invaluable tools for research in the basic and applied sciences, in fields such as materials science, chemistry, the biosciences, particle physics, nuclear physics and medicine. The design, commissioning, and operation of accelerator facilities is a non-trivial task, due to the large number of control parameters and the complex interplay of several conflicting design goals. We propose to tackle this problem by means of multi-objective optimization algorithms which also facilitate a parallel deployment. In order to compute solutions in a meaningful time frame a fast and scalable software framework is required. In this paper, we present the implementation of such a general-purpose framework for simulation-based multi-objective optimization methods that allows the automatic investigation of optimal sets of machine parameters. The implementation is based on a master/slave paradigm, employing several masters that govern a set of slaves executing simulations and performing optimization tasks. Using evolutionary algorithms as the optimizer and OPAL as the forward solver, validation experiments and results of multi-objective optimization problems in the domain of beam dynamics are presented. The high charge beam line at the Argonne Wakefield Accelerator Facility was used as the beam dynamics model. The 3D beam size, transverse momentum, and energy spread were optimized.

I. INTRODUCTION

Particle accelerators play a significant role in many aspects of science and technology. Fields, such as material science, chemistry, the biosciences, particle physics, nuclear physics and medicine depend on reliable and effective particle accelerators, both as research but as well as practical tools. Achieving the required performance in the design, commissioning, and operation of accelerator facilities is a complex and versatile problem. Today, tuning machine parameters, e.g. bunch charge, emission time and various parameters of beamline elements, is most commonly done manually by running simulation codes to scan the parameter space. This approach is tedious, time consuming and can be error prone. In order to be able to reliably identify optimal configurations of accelerators we propose to solve large multi-objective design optimization problems to automate the investigation for an optimal set of tuning parameters. Observe that multiple and conflicting optimality criteria call for a multi-objective approach.

A modular multi-objective software framework was developed (see Fig. 1) where the core functionality of the optimizer is decoupled from the “beam dynamics” but fully integrated in the OPAL framework. To that end, we use a master/slave mechanism where a master process governs a set of slave processes given some computational tasks (beam dynamics simulation) to complete. This separation allows easy interchange of optimization algorithms, forward solvers and optimization problems. A “pilot” coordinates all efforts between the

FIG. 1. Multi-objective framework: the pilot (master) solves the optimization problem specified in the input file by coordinating optimizer algorithms and workers running forward solves.
optimization algorithm and the beam dynamics task. In the sequel we will also use the notion of “forward solver” to indicate the beam dynamics task. This forms a robust and general framework for massively parallel multi-objective optimization. Currently the framework offers one concrete optimization algorithm, an evolutionary algorithm employing a NSGA-II selector [2]. Normally, simulation based approaches are plagued by the trade-off between level of detail and time to solution. This problem is addressed later in Section (V B 1) by using forward solvers with different time and resolution complexity.

The framework discussed here, incorporates the following three contributions:

1. Implementation of a scalable optimization algorithm capable of approximating Pareto fronts in high dimensional spaces,

2. design and implementation of a modular framework that is simple to use and deploy on large scale computational resources, and

3. demonstrating the usefulness of the proposed framework on a real world application in the domain of particle accelerators, with the optimization problem set as the high charge photoinjector at the Argonne Wakefield Accelerator (AWA).

The next section introduces the notation of multi-objective optimization theory and describes the first implemented optimizer. In Section [III] the implementation of the framework is discussed. We introduce the employed forward-solver in Section [IV] A validation and a proof of concept application in the two beam dynamics problems mentioned above is discussed in Section [V]

II. MULTI-OBJECTIVE OPTIMIZATION

Optimization problems deal with finding one or more feasible solutions corresponding to extreme values of objectives. If more than one objective is present in the optimization problem this is called a multi-objective optimization problem (MOOP). A MOOP is defined as

\[
\begin{align*}
\text{min} & \quad f_m(x), & m = 1, \ldots, M, \\
\text{s.t.} & \quad g_j(x) \geq 0, & j = 0, \ldots, J, \\
& \quad x_i^L \leq x_i \leq x_i^U, & i = 0, \ldots, n,
\end{align*}
\]
FIG. 2. Two competing objectives cannot be optimal at the same time. Red dots represent Pareto optimal points, while the green square $x_4$ is dominated (exhibits a worse price per performance ratio than e.g. $x_2^*$) by all points on the blue curve (Pareto front).

where $\mathbf{f}$ denotes the objectives (1), $\mathbf{g}$ the constraints (2), and $\mathbf{x}$ the design variables (3).

Often, conflicting objectives are encountered, and this complicates the concept of optimality. To illustrate this, let us consider the problem of buying a car. Naturally, we try to bargain the lowest price for the best performance, e.g. maximal horsepower or minimal fuel consumption. This can be formulated as MOOP (4).

$$\begin{align*}
\min & \quad [\text{price}, -\text{performance}]^T \\
\text{s.t.} & \quad \text{low}_{\text{pr}} \leq \text{price} \leq \text{high}_{\text{pr}} \\
& \quad \text{low}_{\text{pe}} \leq \text{performance} \leq \text{high}_{\text{pe}}
\end{align*}$$

(4)

In general, it is not possible to get the maximal performance for the lowest price and a trade-off decision between performance and price has to be reached (see Fig. 2). Since not every choice is equally profitable for the buyer (for example, car $x_4$ costs as much as $x_2^*$ but offers less performance), we pick trade-offs (red points) that are essentially “equally optimal” in both conflicting objectives, meaning, we cannot improve one point without hurting at least one other solution. This is known as Pareto optimality. The set of Pareto optimal points (blue curve) forms the Pareto front or surface. All points on this surface are considered to be Pareto optimal.

Once the shape of the Pareto front has been determined, the buyer can specify preference,
balancing the features by observing the effect on the optimality criteria, converging to the preferred solution. This is called a posteriori preference specification since a solution is selected after all possible trade-offs have been presented to us. An alternative is to specify preference a priori, e.g. by weighting (specifying preference before solving the problem) and combining all objectives into one and applying a single-objective method to solve the problem (yielding only one solution). In many situations preference is not known a priori and an a posteriori preference specification helps conveying a deeper understanding of the solution space. The Pareto front can be explored and the impact of a trade-off decision then becomes visible.

Sampling Pareto fronts is far from trivial. A number of approaches have been proposed, e.g. evolutionary algorithms [11], simulated annealing [23], swarm methods [22], and many more [10, 13, 21, 26]. In the next section, we briefly introduce the theory of evolutionary algorithms used in the present work.

### A. Evolutionary Algorithms

Evolutionary algorithms are loosely based on nature’s evolutionary principles to guide a population of individuals towards an improved solution by honoring the “survival of the fittest” principle. This “simulated” evolutionary process preserves entropy (or diversity in biological terms) by applying genetic operators, such as mutation and crossover, to remix the fittest individuals in a population. Maintaining diversity is a crucial feature for the success of all evolutionary algorithms.

In general, a generic evolutionary algorithm consists of the following components:

- **Genes**: traits defining an individual,
- **Fitness**: a mapping from genes to a fitness value for each individual,
- **Selector**: selecting the $k$ fittest individuals of a population based on some sort of ordering,
- **Variator**: recombination (mutations and crossover) operators for offspring generation.

Applied to multi-objective optimization problems, genes correspond to design variables. The fitness of an individual is loosely related to the value of the objective functions for
FIG. 3. Schematic view of interplay between selector and variator. The selector ranks all individuals in the population according to fitness and subsequently the variator uses the fittest individuals to produce new offspring. Finally, the new children are reintroduced in the population.

Since there already exist plenty of implementations of evolutionary algorithms, it was decided to incorporate the PISA library [2] into our framework. One of the advantages of PISA is that it separates variator from selector, rendering the library expandable and configurable. Implementing a variator was enough to use PISA in our framework and retain access to all available PISA selectors. As shown in Fig. 3, the selector is in charge of ordering a set of $d$-dimensional vectors and selecting the $k$ fittest individuals currently in the population. The performance of a selector depends on the number of objectives and the surface of the search space. So far, the NSGA-II selector [12] has been used and exhibits satisfactory convergence performance.
The task of the variator is to generate offspring and ensure diversity in the population. The variator can start generating offspring once the fitness of every individual of the population has been evaluated. This explicit synchronization point defines an obvious bottleneck for parallel implementations of evolutionary algorithms. In the worst case some MPI processes are taking a long time to compute the fitness of the last individual in the pool of individuals to evaluate. During this time all other resources are idle and wait for the result of this one individual in order to continue to generate and evaluate offspring. To counteract this effect, the selector is already called when two individuals have finished evaluating their fitness, lifting the boundaries between generations and evaluating the performance of individuals. New offspring will be generated and MPI processes can immediately return to work on the next fitness evaluation. By calling the selector more frequently (already after two offspring individuals have been evaluated) results in better populations since bad solutions are rejected earlier. On the other hand, calling the selector more often is computationally more expensive.

Our variator implementation uses the master/slave architecture, presented in the next section, to run as many function evaluations as possible in parallel. Additionally, various crossover and mutation policies are available for tuning the algorithm to the optimization problem.

III. THE FRAMEWORK

Simulation based multi-objective optimization problems are omnipresent in research and industry. The simulation and optimization problems arising in such problems are in general very big and computationally demanding. This motivated us to design a massively parallel general purpose framework. The key traits of such a design can be summarized as:

- support any multi-objective optimization method,
- support any function evaluator: simulation code or measurements,
- offer a general description/specification of objectives, constraints and design variables,
- run efficiently in parallel on current large-scale high-end clusters and supercomputers.
A. Related Work

Several similar frameworks, e.g. [14, 15, 24, 25], have been proposed. Commonly these frameworks are tightly coupled to an optimization algorithm, e.g. only providing evolutionary algorithms as optimizers. Users can merely specify optimization problems, but cannot change the optimization algorithm. Our framework follows a more general approach, providing a user-friendly way to introduce new or choose from existing built-in multi-objective optimization algorithms. Tailoring the optimization algorithm to the optimization problem at hand is an important feature due to the many different characteristics of optimization problems that should be handled by such a general framework. As an example, it is shown how PISA [2], an existing evolutionary algorithm library, was integrated with ease. Similarly, other multi-objective algorithms could be incorporated and used to solve optimization problems.

The framework presented in [24] resembles our implementation the most, aside from their tight coupling with an evolutionary algorithm optimization strategy. The authors propose a plug-in based framework employing an island parallelization model, where multiple populations are evaluated concurrently and independently up to a point where some number of individuals of the population are exchanged. This is especially useful to prevent the search algorithm to get stuck in a local minimum. A set of default plug-ins for genetic operators, selectors and other components of the algorithms are provided by their framework. User-based plug-ins can be incorporated into the framework by implementing a simple set of functions.

Additionally, as with simulation based multi-objective optimization, we can exploit the fact that both the optimizer and simulation part of the process use a certain amount of resources. The ratio of work between optimizer and simulation costs can be reflected in the ratio of number of processors assigned to each task. This not only provides users with great flexibility in using any simulation or optimizer, but renders influencing the role assignment easy as well.
FIG. 4. Schematic view of messages passed within the network between the three roles. The dashed cyan path describes a request (job $j_1$) sent from $O_i$ to the Pilot being handled by $W_j$. Subsequently the result $r_k$ is returned to the requesting Optimizer ($O_i$). The work $W_j$ are beam dynamics simulation within OPAL.

B. Components

The basic assumption in simulation-based optimization is that a call to an expensive simulation software component present in the constraints or objectives is needed. The framework is divided in three exchangeable components, as shown in Fig. 4, to encapsulate the major behavioral patterns of the framework.

The Pilot component acts as a bridge between the optimizer and forward solvers, providing the necessary functionality to handle passing requests and results between the Optimizer and the Simulation modules. The framework was implemented in C++, utilizing features like template parameters to specify the composition of the framework (shown in Listing 1).

**Code Listing 1: Assembling the optimizer**

```cpp
typedef InputFileParser Input_t;
typedef PisaVariator Opt_t;
typedef OpalSimulation Sim_t;
typedef Pilot< Input_t, Opt_t, Sim_t > Pilot_t;
```

The framework provides “default” implementations that can be controlled via command line options. Due to its modular design, all components can be completely customized.
Every available MPI process will take up one of the three available roles (see Fig. 1): one process acts as Pilot, the remaining processes are divided amongst Worker and Optimizer roles. Both, the Worker and the Optimizer can consist of multiple MPI processes to exploit parallelism. As shown in Fig. 4 the Pilot is used to coordinate all “information requests” between the Optimizer and the Worker. An information request is a job that consists of a set of design variables (e.g. the genes of an individual) and a type of information it requests (e.g. function evaluation or derivative). The Pilot keeps checking for idle Worker and assigns jobs in the queue to any free Worker. Once the Worker has computed and evaluated the request its results are returned to the Optimizer that originally requested the information.

After a process gets appointed a role it starts a polling loop asynchronously checking for appropriate incoming requests. To that end a Poller interface helper class has been introduced. The Poller interface consists of an infinite loop that checks periodically for new MPI messages. Upon reception a new message is immediately forwarded to the appropriate handler: the onMessage() method. The method is called with the MPI_Status of the received message and a size_t value specifying different values depending on the value of the MPI_Tag. The Poller interface allows the implementation of special methods (denoted hooks) determining the behavior of the polling process, e.g. for actions that need to be taken after a message has been handled. Every Poller terminates the loop upon receiving a special MPI tag.

C. Implementing an Optimizer

All Optimizer implementations have to respect the API shown in Listing 2.

Code Listing 2: Optimizer API

```cpp
virtual void initialize() = 0;

// Poller hooks
virtual void setupPoll() = 0;
virtual void prePoll() = 0;
virtual void postPoll() = 0;
virtual void onStop() = 0;
virtual bool onMessage(MPI_Status status,
size_t length) = 0;
```
All processors running an Optimizer component call the initialize entry point after role assignment in the Pilot. The implementation of initialize must set up and start the poller and the optimization code. Since an optimizer derives from the Poller interface, predefined hooks can be used to determine the polling procedure. Hooks can be implemented as empty methods, but the onMessage implementation should reflect the optimization part of the protocol for handling events from the Pilot. A special set of communicator groups serves as communication channels to the Pilot and its job queue and if existing to processes supporting the Optimizer component.

D. Implementing a Forward Solver

In most cases forward solver implementations are simple wrappers to run an existing “external” simulation code using a set of design variables as input. In case of the OPAL integration, basically the main function is playing the role of the “forward solver”. Underlying the general nature of our approach, in a similar project, the described methods are used for cavity shape optimisation based on [6]. As for the Optimizer component there exists a base class, labeled Simulation as common basis for all Simulation implementations. In addition, this component also inherits from the Worker class, already implementing the polling protocol for default worker types. As shown in the API in Listing 3, the Worker class expects an implementation to provide implementations for those three methods.

Code Listing 3: Simulation API

```cpp
virtual void run() = 0;
virtual void collectResults() = 0;
virtual reqVarContainer_t getResults() = 0;
```

First, upon receiving a new job, the Worker will call the run method on the Simulation implementation. This expects the Simulation implementation to run the simulation in a blocking fashion, meaning the method call blocks and does not return until the simulation has terminated. Subsequently, the Worker calls collectResults, where the Simulation prepares the result data, e.g. parsing output files, and stores the requested information in a reqVarContainer_t data structure. Finally, the results obtained with getResults are sent to the Pilot. As before, the serialized data is exchanged using MPI point-to-point communication using a specific set of communicators.
E. Specifying the Optimization Problem

We aimed at an easy and expressive way for users to specify multi-objective optimization problems. Following the principle of keeping metadata (optimization and simulation input data) together, we decided to embed the optimization problem specification in the simulation input file by prefixing it with special characters, e.g. as annotations prefixed with a special character. In some cases it might not be possible to annotate the simulation input file. By providing an extra input file parser, optimization problems can be read from stand-alone files.

To allow arbitrary constraints and objective expressions, such as

```plaintext
name: OBJECTIVE,
EXPR="5 * average(42.0, "measurement.dat") + ENERGY";
```

An expression parser using Boost Spirit \[1\] was implemented. In addition to the parser, we need an evaluator able to evaluate an expression, given a parse tree and variable assignments to an actual value. Expressions arising in multi-objective optimization problems usually evaluate to booleans or floating point values. The parse tree, also denoted abstract syntax tree (AST), is constructed recursively while an expression is parsed. Upon evaluation, all unknown variables are replaced with values, either obtained from simulation results or provided by other subtrees in the AST. In this stage, the AST can be evaluated bottom-up and the desired result is returned after processing the root of the tree.

To improve the expressive power of objectives and constraints, a simple mechanism to define and call custom functions in expressions was introduced. Using simple functors, e.g. as the one shown in Listing 4 to compute an average over a set of data points, enriches expressions with custom functions. Custom function implementations overload the () parenthesis operator. The function arguments specified in the corresponding expression are stored in a `std::vector` of Boost variants \[3\] that can be booleans, strings or floating point values.

**Code Listing 4: Simple Average Functor**

```c++
struct avg {

  double operator()(
    client::function::arguments_t args) const {

    double limit = boost::get<double>(args[0]);
    std::string filename =
```
boost::get<std::string>(args[1]);

double sum = 0.0;
for(int i = 0; i < limit; i++)
    sum += getDataFromFile(filename, i);

return sum / limit;
};
}

All custom functions are registered with expression objects. This is necessary to ensure that expressions know how they can resolve function calls in their AST. As shown in Listing 5 this is done by creating a collection of Boost functions \[18\] corresponding to the available custom functions in expressions and passing this to the **PILOT**.

**Code Listing 5: Creating function pointer for registering functor**

```cpp
functionDictionary_t funcs;
client::function::type ff;
ff = average();
funcs.insert(std::pair<std::string, client::function::type>("my_average_name", ff));
```

A set of default operators, corresponding to a mapping to C math functions, is included in the dictionary by default. This enables an out of source description of optimization problems containing only simple math primitives.

### F. Parallelization

The parallelization is defined by a mapping of the roles introduced above to available cores. Command-line options allow the user to steer the number of processors used in worker and optimizer groups. Here, we mainly use the command-line options to steer the number of processors running a forward solver.

One major disadvantage of the master/slave implementation model is the fast saturation of the network links surrounding the master node. In authors observe an exponential increase in hot-spot latency with increasing number of workers that are attached to one master process. Clearly, the limiting factor is the number of outgoing links of a node in the network topology and already for a few workers the links surrounding a master process are
subject to congestions. This effect is amplified further by large message sizes.

To that end we implemented a solution propagation based on rumor networks (see [7, 9]) using only one-sided communication. This limits the number of messages sent over the already heavily used links surrounding the master node and at the same time helps to prevent the use of global communication. Using information about the interconnection network topology and the application communication graph the task of assigning roles helps to further improve the parallel performance.

IV. FORWARD SOLVER

The framework contains a wrapper implementing the API mentioned in Listing 3 for using OPAL [4] as the forward solver. OPAL provides different trackers for cyclotrons and linear accelerators with satisfactory parallel performance [5].

With access to the OPAL forward solver the framework is able to tackle a multitude of optimization problems arising in the domain of particle accelerators. The framework is also integrated into OPAL so that users can define optimization problems within an input file, requiring no additional knowledge or installation of the API to use it.

If the objectives and constraints are simple arithmetical expressions, the FunctionEvaluator simulator can be used. Using functors and the default expression primitives already powerful multi-objective optimization problems can be specified, i.e. the benchmark problem presented in [19]:

\[
\begin{align*}
\min & \quad 1 - \exp \left( -1 \left( \left( x_1 - \frac{1}{\sqrt{3}} \right)^2 + \left( x_2 - \frac{1}{\sqrt{3}} \right)^2 + \left( x_3 - \frac{1}{\sqrt{3}} \right)^2 \right) \right), \\
1 - \exp & \left( -1 \left( \left( x_1 + \frac{1}{\sqrt{3}} \right)^2 + \left( x_2 + \frac{1}{\sqrt{3}} \right)^2 + \left( x_3 + \frac{1}{\sqrt{3}} \right)^2 \right) \right) \\
\text{s.t.} & \quad -1 \leq x_i \leq 1, \quad i = 1, 2, 3.
\end{align*}
\]

Using the default expression primitives this can be stated in an input file as:

d1: DVAR, VARIABLE="x1", LOWERBOUND="-1.0", UPPERBOUND="1.0";
d2: DVAR, VARIABLE="x2", LOWERBOUND="-1.0", UPPERBOUND="1.0";
FIG. 5. The hypervolume for a two-objective optimization problem corresponds to the shaded area formed by the dashed rectangles spanned by all points on the Pareto front and an arbitrary selected origin $p_o$.

\[
d3: \text{DVAR, VARIABLE="x3", LOWERBOUND="-1.0", UPPERBOUND="1.0";}
\]

\[
\begin{align*}
\text{obj1: OBJECTIVE,} \\
\text{EXPR=}&\,1-\exp(-1 \ast (\text{sq}(x1 - 1/\sqrt{3}) \\
&+ \text{sq}(x2 - 1/\sqrt{3}) + \text{sq}(x3 - 1/\sqrt{3}))))"; \\
\text{obj2: OBJECTIVE,} \\
\text{EXPR=}&\,1-\exp(-1 \ast (\text{sq}(x1 + 1/\sqrt{3}) \\
&+ \text{sq}(x2 + 1/\sqrt{3}) + \text{sq}(x3 + 1/\sqrt{3}))))";
\end{align*}
\]

\[
\begin{align*}
\text{objs: OBJECTIVES = (obj1, obj2);} \\
\text{dvars: DVARS = (d1, d2, d3);} \\
\text{constrs: CONSTRAINTS = ()}; \\
\text{opt: OPTIMIZE, OBJECTIVES=objs, DVARS=dvars, CONSTRAINTS=constrs;}
\end{align*}
\]

V. EXPERIMENTS

In this section a numerical results of the validation benchmark and optimization of a photoinjector operated in the space charge dominated regime is presented.

A. Optimizer Validation

To ensure that the optimizer works correctly the benchmark problem (5) was solved. To that end, we use a metric for comparing the quality of a Pareto front. Given a point in the Pareto set, we compute the $m$ dimensional volume (for $m$ objectives) of the dominated space, relative to a chosen origin. This is visualized for 2 objectives in Fig. 5. For further
information and details of the implementation see [27]. Figure 6 and the corresponding hypervolume values in Table I show expected convergence. The reference Pareto front is clearly very well approximated. It took a total of 1100 function evaluations to perform this computation. The hypervolume of the reference solution (0.6575) for our benchmark was computed by sampling the solution provided in [19]. Table I shows satisfactory convergence to the sampled reference Pareto front after 1000 (plus the additional 100 evaluations for the initial population) function evaluations.

B. AWA Photoinjector Optimization

Next the optimization framework is applied to a high charge beam line at the Argonne Wakefield Accelerator (AWA) facility. The goal of this optimization is to produce beams of electrons that meet design specifications; this includes number of particles (charge), energy, and particle distribution (characterized by beam sizes and energy spread). As shown in Fig. 7 the installed portion of the beam line consists of an rf photocathode gun, two solenoids, and six linear accelerating cavities followed by four quadrupoles and a stripline

FIG. 7. Side view of the high charge linac at the AWA. All hardware in this drawing is currently installed. Note locations $s_1$ and $s_2$, before and after the kicker. The charge of interest, 40 nC, is needed for Two Beam Acceleration (TBA) experiments performed at the AWA [16, 20], which the AWA Ali-Baba group is currently conducting. Prior experimental results were limited by beam size when the beam passed through small aperture wakefield structures located downstream. In an attempt to maximize charge transmission in upcoming experiments, magnet strengths of the solenoids and quadrupoles leading into the TBA section of the beam line were optimized, shown in Fig. 8. The simulation model includes from the gun to the septum. The optimization location is chosen as the entrance to the first quadrupole on the dog leg ($s_3$), see Fig. 8. Minimizing beam sizes here will enable capture and further focusing before space charge effects dominate the beam. This will also enable cleaner transport through downstream elements.

In addition to addressing the challenge of producing an optimized beam, this model was chosen to demonstrate the ability of the framework to tackle large problems. Six design variables and objectives were used, along with three constraints. The objectives include transverse and longitudinal beam sizes, transverse momentum, and longitudinal energy spread. The design variables include the two gun solenoids and the first four quadrupoles strengths.
This problem encompasses high dimensionality and nonlinear effects such as space charge. There is no existing information that accurately predicts optimized parameters for this beam line. This work is meaningful in that it will guide future operations at the AWA.

1. Time Step Scan

Before running a full scale optimization of the problem described in Subsection [V.B] a study on time step and number of particles in the simulation model was done to reduce the time of the simulation while maintaining the physics of interest. The grid size $16 \times 16 \times 32$ was chosen, and parallelized in the x and y directions. After comparing several options (1,000, 10,000, 20,000, 50,000, 100,000) with a small time step, the number of particles was fixed at 10,000. Next several time steps were explored, see Table II. The largest steps were too big to resolve the beam parameters accurately. See low fidelity plot in Fig. 9 for $dT = 5 \times 10^{-11}$ results.

In the drifts and linac tanks, $dT = 1 \times 10^{-11}$ was sufficient. However, it was not acceptable near the quadrupoles. For all models, the longitudinal parameters (rms$_s$ and energy) are calculated correctly, but discrepancies are seen in the transverse (rms$_x$ and $\epsilon_x$) for low fidelity results. This discrepancy is what led to the decision to adjust the time steps w.r.t. beam line elements. In the linac and drift sections $dT = 1 \times 10^{-11}$ was used. Near sensitive elements such as the quadrupoles, kicker, and septum, a time step of $dT = 1 \times 10^{-12}$ was used. The resulting simulations are low fidelity in most places, but closely approximate the
mid fidelity simulations for metrics of interest, as shown in Fig. 9. Mid fidelity simulations used steps of $dT = 1 \times 10^{-12}$ everywhere. The average run time of each simulation with the adjusted time steps was 1.6 minutes. In comparison, the mid fidelity simulation ran for 18 minutes. Note, a smaller time step, $1 \times 10^{-13}$, is always used in the gun where the beam has low energy and changing rapidly.

2. **Hyper parameter Scan**

While the optimization problem and goals were well defined (Subsection V B), it was not clear what the best hyper parameters for the genetic algorithm would be. These parameters include gene mutation probability, mutation probability, recombination probability, number of individuals, and number of generations to complete. Given the beam line in Fig. 7, four small optimization experiments were done with various hyper parameters. Similar to the time step scan, the goal of this exercise was to determine which set of optimization parameters strongly influence the results, and whether there was a time to solution difference. From here on, we will reference each experiment as ex-1, ex-2, ex-3, and ex-4 as shown in Table III.

The maximum number of individuals per generation was fixed at 80. This number was chosen based on the node architecture, and the to prevent a prohibitive computational cost. Each experiment was allowed to run for twenty four hours, with a maximum generation limit
of 100. We reduced the six objectives to four, and shortened the simulation time by moving the objectives further upstream to \( s_1 \) and \( s_2 \), the locations before and after the kicker, see Fig. 8.

The objectives include: \( \varepsilon_x (s = s_1) \), \( \varepsilon_x (s = s_2) \), \( \text{rms}_s (s = s_1) \), and \( \text{rms}_s (s = s_2) \). The OPAL input file for ex-3 is given as an example to show how optimization and design variables are defined:

```
OPTION, ECHO=FALSE;

After collection of the data for all four experiments, several metrics were compared, including number of generations completed in twenty four hours and Pareto fronts at \( s_1 \) and \( s_2 \), see Fig. 7. From Table III, we clearly see ex-3 is significantly slower, as it evaluated only 53 generations compared to the experiment with the maximum number, ex-1 at 96 generations. Perhaps this trade off would be acceptable if the Pareto front was significantly improved, but from Fig. 10, but this is not the case. Similar arguments can be made for ex-2, which evaluated about 15 less generations. The Pareto fronts at \( s_2 \), are nearly identical. It is expected this trend would continue given more time. When looking at the Pareto front at \( s_1 \), only ex-4 has a slightly larger range compared to the others. With ex-2 and ex-3 eliminated due to evaluation time, and a slightly better Pareto front at \( s_1 \) for ex-4, the hyper parameters in ex-4 were chosen as the default values for subsequent runs.

3. TBA Optimization Problem

With computational and hyper parameters set, the full optimization problem of interest is explored. The objectives (beam sizes and energy spread) are calculated at \( s_3 = 19.4 \text{ m} \),
located downstream of the septum, see Fig. 8. Given the longitudinal location of $s_3$ (unless otherwise noted), we define the objectives and input parameters as:

$$\text{min } \text{rms}_x, \text{rms}_y,$$

$$\text{rms}_{px}, \text{rms}_{py},$$

$$\text{rms}_s, \text{dE} \quad (6)$$

$$\text{constraints } \text{rms}_x < 0.1 (m)|_{s=s_1} \quad (9)$$

$$\text{rms}_y < 0.1 (m)|_{s=s_1} \quad (10)$$

$$|\text{rms}_y - \text{rms}_x| < 0.005 (m)|_{s=s_1} \quad (11)$$

subject to $$q = 40 (nC) \quad (12)$$

$$\text{Volt}_{\text{Gun}} = 64 \text{ (MV/m)} \quad (13)$$

$$\text{Volt}_{\text{Linac}} = 24 \text{ or } 25 \text{ (MV/m)} \quad (14)$$

$$R_x = R_y = 9 \text{ (mm)} \quad (15)$$

$$\phi_{\text{gun}} = -20^{\circ} \quad (16)$$

$$\phi_{\text{linac}} = -20^{\circ} \quad (17)$$

The first four objectives, parameters (6) to (7), minimize the transverse ($\text{rms}_{x,y}$) beam size and transverse momentum ($\text{rms}_{px,py}$) at the location of interest in the beam line ($s_3$, see Fig. 8). Minimizing the beam size at this location is essential to preventing loss of particles by scraping; which ensures better transmission through the wakefield structures downstream. Less divergence in the beam (lower transverse momentum spread) reduces growth of transverse beam size after the focal point (location of min beam size). This reduces halo by ensuring the beam is not over focused through a hard waist. The momentum spread is also critical to preventing large growth during transport. All of these factors help with transmission downstream.

The next two objectives in parameter (8) minimize the longitudinal beam size ($\text{rms}_s$), and energy spread ($\text{dE}$) at location $s_3$. This helps reduce the transverse beam size growth in bending elements. A small bunch length ($\text{rms}_s$) is also critical to the goals of TBA experiments. The power generated in the wakefield structures designed for TBA is related to the bunch length [17, 20].

Eqs. 9 to 11 define three constraints used to guide the algorithm. However, it is important to not over-constrain the problem, which would prevent the algorithm from converging.
The difference constraint, Eq. 11, is used to favor nearly round beams. This prevents one dimension from becoming disproportionately large compared to the other. At the AWA, there is some room in the beam pipe to allow the y dimension to grow, but round beams are preferred.

Equations 12 to 17 define the charge, gun voltage, linac voltages, laser radius, gun phase, and linac cavity phases (in that order). These are parameters in the simulation that must be defined, but do not vary during the optimization. The AWA design variables, objectives, and constraints in the OPAL input file as shown in the following code:

Design variables include the currents in two gun solenoids (IBF and IM), and four quadrupole strengths (KQ1-KQ4). The objectives include beam size (transverse and longitudinal), transverse momentum, and energy spread as defined in Eqs. (6) to (8). The location at the entrance of the kicker is $s_1 = 16.45$ meters, and the objectives are optimized at location $s_3 = 19.4$ meters. This is the entrance to the fifth quad in the beam line. This location is where the beam should be captured and focused through subsequent elements.

4. **AWA Optimization Results**

All simulations for this experiment were carried out on Bebop a high performance computing (HPC) cluster provided by the Laboratory Computing Resource Center (LCRC) at Argonne National Laboratory (ANL). Intel Knights Landing (KNL) processors at 1.3 GHz with 128 GB of memory and 64 cores per node were used for all runs. There are 352 compute nodes available on Bebop, with a total of 22,528 cores. All jobs were run and compared on 8 cores each, which allowed 8 jobs per node on the KNLs. This in combination with the number of nodes available allows for very large optimization jobs, like the AWA case. Typical runs for this paper used 41 nodes, which corresponds to 2624 KNL cores and a generation size of 328 individuals.

With the time steps and hyper parameters set by the work in Section V.B, the full optimization problem described in V.B was run for 200 generations. The initial number of individuals was fixed at 656, and the minimum number individuals in later generations was fixed at 328. These numbers were in part based on the architecture of the KNL’s. Since each simulation takes 8 cores, and there are 64 cores per KNL node, a large population size that would fit evenly on these resources was chosen. Again, the location of optimization is $s_3 = 19.4$ [m].

As expected, the x dimension is impacted by the bending elements, and unable to reach
FIG. 11. Pareto front comparing transverse beam sizes ($\sigma_{x,y}$) and transverse momentum ($\sigma_{px,py}$).

The yellow star indicates the point plotted in Fig. 12

the small beam sizes seen in the y dimension. This suggest suggests objectives in the x dimension will drive design variable choices used during operations. However, it is still necessary to include the y dimension in the optimization. Early optimization tests showed the y dimension can easily grow out of control if it is not included in the objectives. Those results are not shown here due to the unfeasible nature of the solutions (i.e. $rms_y$ larger than the beam pipe). In the case of bunch length, there are not many options to choose from.

With these observations in mind, several beam parameters corresponding to options on the Pareto Front in Fig. 11 were plotted and compared. A select result is shown in Fig. 12. The maximum beam sizes are well below the beam pipe aperture limits as shown in Fig. 12. The solution is nearly round, which will increase changes of keeping the beam nearly round as it travels to the last triplet in Fig. 8. Overall this solution is satisfactory, and meets all requirements at the AWA.

VI. CONCLUSIONS

A general-purpose framework for solving multi-objective optimization problems was presented. Its modular design simplifies the application to simulation-based optimization problems for a wide range of problems and allows to exchange the optimization algorithm. The
FIG. 12. Optimized beam sizes along high charge beam line. The gun is located at $s = 0$, both $x$ and $y$ beam sizes are shown. The black line represents the relevant beam line aperture, while the green line indicates the location of the optimization.

flexibility of being able to adapt both ends of the optimization process, the forward solver and the optimization algorithm simultaneously not only leads to broad applicability but it facilitates the ability to tailor the optimization strategy to the optimization problem as well.

The framework was integrated into OPAL, and used to study a beam dynamics problem at the AWA. A scan of time step and hyper parameters was done to determine computational settings. Then a full scale physics optimization was performed. Optimization of the 3D beam size and energy spread was accomplished. The TBA beam line presented is currently
being installed at the AWA. Once installation is complete, the results shown here will guide future experiments at the AWA.

In contrast to approaches that are tightly coupled to the optimization algorithm, the range of possible applications is much wider. Even in cases where the mathematical model of the forward solver is not known exactly, fixed or on the real time measurements can be used to guide the search for the Pareto optimal solutions. Finally, combining the presented multi-objective optimization framework with a physicist long standing experience in the field provides a solid basis for better understanding and improving the decision making process in the design and operation of particle accelerators.

VII. ACKNOWLEDGMENT

The authors thank the AWA team for contributing to the formulation of optimization problems. We gratefully acknowledge the computing resources provided on Bebop, a HPC cluster operated by the LCRC at ANL. Thanks to Scott Doran for providing CAD drawings of the AWA beam lines. This work was partly supported by the U.S. Department of Energy, Office of Science, under contract number DE-AC02-06CH11357 and grant number de-sc0015479.
