Abstract. We consider quantum computation efficiency from a new perspective. The efficiency is reduced to its classical counterpart by imposing the semi-classical limit. We show that this reduction is caused by the fact that any elementary quantum logic operation (gate) suffers information loss during transition to its classical analogue. Amount of the information lost is estimated for any gate from the complete set. The largest loss is obtained for non-commuting gates that allows to consider them as quantum computational speed-up resource. Our method allows to quantify advantages of quantum computation as compared to the classical one by direct analysis of the basic logic involved. The obtained results are illustrated by application to quantum discrete Fourier transform and Grover search algorithms.

Keywords: quantum logic, quantum algorithms, complexity
1. Introduction

The construction of a quantum computer is an important open problem in modern physics. The interest in this endeavour is mainly due to high efficiency of quantum algorithms, such as (but not only) the Grover search and Shor’s factoring, and the fact that their classical analogues are much less efficient. But why are quantum calculations much more efficient than the classical analogues? The common answer to this question is: the speed-up is based on the quantum parallelism and, probably, on entanglement. However this is only the qualitative explanation, and it is reasonable to try to explain the gap in efficiency from the basic principles of quantum and classical computation. Every computation, either it is quantum or classical, can be decomposed into a set of elementary operations. We impose the semiclassical limit and study how the complete set of quantum gates is reduced to the classical counterpart. We base our analysis on the formal rules of the quantum and classical logics, which were first formulated by G. Birkhoff and J. von Neumann in their seminal paper [1].

To date much progress has been done in the area; for the reviews see [2, 3]. Some possible quantum computational structures are presented in [4, 5]. [5] is devoted to investigations in the algebraic structure of logic within the framework of non-commutative geometry. In [6] the so-called measurement algebras, the formalism of which is weaker than that of Hilbert spaces, were explored. Description of the orthomodular lattices via the Sasaki projection is presented in [7]. [8, 9] are devoted to the analysis of contexts, i.e. the maximal sets of commuting logic statements. Different approaches in formal representation and formalism initiation for quantum logic (QL) have been explored. Investigations in categorical QL are presented in [10, 11]. On the measurement-based QL and computation, which are strongly connected to projective operators logic representation [12], we refer to [13, 14], where the first one is devoted to the “reversible measurement” – a hypothetical operation allowing to “look inside” the quantum computation, and the second one describes measurement-based computation on graph states. Theory of finite automata based on QL one may find in [15]. QL may be interpreted as a language of “pragmatically” decidable assertive formulas, thus formalizing statements about physical quantum systems [16]. [17] is devoted to QL representation based on the alternative set of logic operations. In [18] author expands the λ-calculus on quantum computation. For some extensions of QL we refer to [19, 20, 21, 22]. Computational complexity in quantum and classical logic (CL) calculus are explored in [23] or others, such as [24, 25, 26, 27]. Attempts in bridging semantic space and QL are considered in [28]. Quantum language investigation was made in [29].

Thus we conclude that investigations in logic (especially quantum) are rather actual and are tightly interconnected spanning different areas of research.

It is legitimate to conclude that the QL is much more efficient than the CL. Such a conclusion is confirmed by the fact that the algebraic structure of QL is constructed with the help of weaker conditions than that of CL, thus allowing a wider class of operations to be processed. Here we interpret efficiency in the computational complexity sense, i.e.
as the number of elementary logical operations necessary to execute some algorithm.

This paper aims to ascertain reasons for the QL being much more efficient than
the CL in terms of a quantitative, rather than the qualitative (which is mentioned
above) explanation of its superiority. The main motivation of our research is that the
existing approaches and techniques can not completely explain the efficiency gap. Till
now there is no complete theory of the classical and quantum complexity classes and of
interrelations between them. We hope that the approach presented in the manuscript
will be helpful in this challenging problem.

In our research we study how the set of elementary QL operations reduce to the
classical counterpart under taking the semi-classical limit \( h \to 0 \) (for brevity in the
following we use the term ‘dequantization’ to denote the semiclassical limit). We apply
the projective operator representation of QL, see [12]. One may argue that the projector
sets are not as wide-spread in quantum information research as the other sets of gates
(such as one-qubit gates and Toffoli gate or Controlled-NOT for example). We use
the projectors since we are going to investigate the formal rules of both quantum and
classical logics. It is much more easier to do that on the similar formal sets of logic gates
such as conjunction, implication and negation than to try to find a classical analog
for Walsh-Hadamard gate for example. In addition, as it follows from the algorithm
complexity theory, the choice of language is not essential.

After that we estimate the amount of information loss during dequantization
process, thus shedding light on the loss of logic efficiency and on the efficiency gap
problem itself. To quantify our approach, we use the von Neumann and Shannon
entropies for the quantum and dequantized logic gates respectively.

Estimation of the information difference in QL and CL can be made by means of the
well-known Kolmogorov complexity or quantum complexities [23, 24, 25]. Some common
properties of them and their possible applications were studied in [26]. Alternatively,
algorithmic entropies can be applied [27].

Our method, having much in common with the Kolmogorov complexity, is however
different. We estimate the information loss of every elementary logic operation during
reduction of QL to CL, and then generalize to an arbitrary calculation. Such an
approach allows to estimate the contribution to the quantum (classical) calculation
of any subspace (domain) of Hilbert (phase) spaces correspondingly.

[30, 31] extend QL proposed in [1]. We build upon these studies by providing
dequantization of the complete set of logic operations. To do this, we use path integral
formalism together with the von Neumann and Shannon entropy definitions. It allows
to estimate the information loss of any quantum algorithm in the semiclassical limit.
Compared to [32], we go further and formalize the approach for any logic gate.

The interrelation between abelian QL subalgebras and CL algebra has been
explored in [33]. In [34] some aspects of dequantization of measurement and of
entanglement, which is noted as lifting, were considered with the help of logic
entropy. Instead, we consider dequantization of any QL statement using the von
Neumann and Shannon entropy definitions. We demonstrate that the non-commuting
propositions play significant role in QL efficiency. Compared to the results of Gottesman-Knill theorem, we exactly demonstrate the significant efficiency contribution of non-commuting statements, which may be outside the Clifford group, while making the transition from QL to CL.

The method we propose estimates the amount of information loss (IL) for every elementary logical operation after its processing through the semiclassical limit, but not in the register itself. Efficiency in its common interpretation is invariant under dequantization, since the amount of elementary logical operations does not change in the limit $\hbar \to 0$.

In this paper we develop the general scheme of IL estimation for any QL proposition. Finally, we exemplify the obtained results with the dequantization and IL estimation of quantum discrete fast Fourier transform ($\text{FFT}_Q$) and Grover search ($\text{Gr}_Q$) algorithms. It was demonstrated [35, 36] that $\text{FFT}_Q$ transforms into the Legendre transform under the dequantization. It indicates that the dequantized algorithm might change the task it solves.

We stress that our method does not allow to compare the quantum and classical algorithms directly: under dequantization the initial task that the algorithm has been designed for may change. The approach calculates amount of information being lost with any quantum logic proposition under dequantization only, i.e. it is useful in analysis of how much computational efficiency is being lost under the semi-classical transition. Application for complexity classification requires reverse engineering of the approach: one should be able to estimate the gain in efficiency for any classical algorithm while transiting it to the quantum one; such a task is highly non-trivial to date, see Section 8 for details.

In Sections 2 and 3 we introduce the CL and QL formalisms correspondingly; for details see [1, 12]. Dequantization of QL operations one can find in Section 4. Estimation of the information loss during the transition from QL to CL is presented in Section 5. We formulate and prove theorem, which is necessary for the application of the technique to any quantum algorithm, in Section 6. Examples of how the scheme works on $\text{FFT}_Q$ and $\text{Gr}_Q$ are given in Section 7. Discussion of the obtained results, their relation to other approaches and open questions one may find in Section 8.

2. Classical Logic

Let $\Gamma_S$ be the phase space describing a physical system $S$ in some state $\lambda$. We assume that this state corresponds to some domain in $\Gamma_S$ and it is characterized by a characteristic function $\chi_\lambda$ which is defined on $\Gamma_S$. The statement “$S$ possesses physical property $\lambda$” or “$S$ is in the state $\lambda$” will be true or false for those domains in $\Gamma_S$ where $\chi_\lambda = 1$ or $\chi_\lambda = 0$ respectively.

Such characteristic functions may be used to define formal rules and elementary operations of CL on $\Gamma_S$. For example, they can describe conjunction, implication and negation in terms of the phase space subsets [1].
Conjunction $\land$ is defined as
\[ \chi \land = \chi \land \chi \mu = \chi \lambda \chi \mu \]  
and describes the intersection subset.

Implication $\leq$ is defined as
\[ \chi \lambda \leq \chi \mu; \chi \lambda \land \chi \mu = \chi \lambda \]  
and corresponds to rules of the subset inclusion; this operation initiates statement ordering.

Negation $\neg$
\[ \chi \neg \lambda = 1 - \chi \lambda \]  
is equivalent to transition to the complementing subset.

Also the operation of disjunction $\lor$ may be introduced. However, as $\lor$ can be expressed in terms of preliminary operations
\[ \chi \lor = \chi \lambda + \chi \mu - \chi \lambda \chi \mu, \]  
it is not important for us in the following.

3. Quantum Logic

Let $H_S$ be the Hilbert space of a physical system $S$. Let $S$ be in a state $|\zeta\rangle$. Then for any statement about some property $\lambda$ of $S$ there exists a projective operator $P_\lambda$ projecting its state onto the corresponding subspace of $H_S$. In other words, the statement "$S$ possesses physical property $\lambda$" will be true if $P_\lambda |\zeta\rangle \neq 0$, and false if $P_\lambda |\zeta\rangle = 0$.

The projective operators on $H_S$ have much in common with the classical characteristic functions on $\Gamma_S$. However, there are some significant differences: $P_\lambda$ defines some subspace in $H_S$, while $\chi_\lambda$ defines some domain in $\Gamma_S$; two projective operators do not commute in general, but any two characteristic functions do.

To start with, let us define quantum logical operations for commuting projectors.

Conjunction $\land$ is defined as
\[ P_\lambda |\zeta\rangle = (P_\lambda \land P_\mu) |\zeta\rangle = P_\lambda P_\mu |\zeta\rangle = P_\mu P_\lambda |\zeta\rangle. \]  
It describes the intersection of subspaces of commuting operators.

Implication $\leq$ is defined as
\[ P_\lambda \leq P_\mu; (P_\lambda \land P_\mu) |\zeta\rangle = P_\lambda |\zeta\rangle \ \ \ \ \forall |\zeta\rangle. \]  
It corresponds to the subspace inclusion. It initiates the statement ordering similarly to its classical analog. The same definition will also hold true for non-commuting projectors.

Negation $\neg$ (complementation) is defined as
\[ P_{\neg \lambda} |\zeta\rangle = (I - P_\lambda) |\zeta\rangle, \]  
where $I$ is the unit operator. This operation is equivalent to transition to the orthogonal subspace.
We define conjunction for non-commuting operators as (see [8], table IV)

\[ P_\lambda |\zeta\rangle = (P_\lambda \wedge P_\mu)|\zeta\rangle = \lim_{n \to \infty} (P_\lambda P_\mu)^n |\zeta\rangle. \] (8)

Such a definition is necessary since conjunction leaves the statement belonging to both subspaces only, which are determined by \( P_\lambda \) and \( P_\mu \) (see [8] for details). One can easily verify that such a definition ensures that conjunction is a projective operator, i.e. \( P_\lambda^2 = P_\lambda \). Obviously, if \( P_\lambda P_\mu = P_\mu P_\lambda \), then (8) transforms into (5).

Similarly to the CL case, disjunction may be expressed in terms of the previously defined operations

\[ P_\vee |\zeta\rangle = (P_\lambda + P_\mu - P_\lambda \wedge P_\mu)|\zeta\rangle \] (9)

and thus is not needed in the following.

4. Quantum Logic Dequantization

Let \( |\zeta\rangle \) be any state in the Hilbert space \( H_S \) of the physical system \( S \). Projective operator \( P_\lambda \) projects the state onto some subspace in \( H_S \). Within the path integral formalism it can be written as

\[ P_\lambda |\zeta\rangle = |\lambda\rangle \langle \lambda|\zeta\rangle = \int Dxe^{iS_\lambda[x]/\hbar} \int Dy e^{iS_{\lambda \rightarrow \zeta}[y]/\hbar}, \] (10)

where integration is made over all phase space trajectories possible. Here \( S_\lambda[x] \) is the action describing transition to the state \( |\lambda\rangle \) (that is underlined with the subscript \( \lambda \)) along some fixed trajectory \( x \) in phase space with \( x = \{x_1, x_2, x_3, p_{x_1}, p_{x_2}, p_{x_3}\} \). Action \( S_{\lambda \rightarrow \zeta}[y] \) describes transition amplitude \( \langle \lambda|\zeta\rangle \) (that is underlined with a subscript \( \lambda \rightarrow \zeta \)) along some fixed phase trajectory \( y \) with \( y = \{y_1, y_2, y_3, p_{y_1}, p_{y_2}, p_{y_3}\} \).

Result of projection \( P_\lambda |\zeta\rangle \) may be interpreted as state \( |\lambda\rangle \) multiplied by the corresponding transition amplitude \( \langle \lambda|\zeta\rangle \). In terms of path integration over the phase space this process may be represented as consisting of two stages: integration over the phase space resulting in the state \( |\lambda\rangle \) (stage 1, the 1st path integral) multiplied by integration over the phase space resulting in \( \langle \lambda|\zeta\rangle \) (stage 2, the 2nd path integral).

Such a representation of projective operator has much in common with symbol of operator. It interconnects \( P_\lambda \) (operator) defined in Hilbert space to the action (symbol of operator) defined in phase space.

Taking the limit \( \hbar \to 0 \) results in classical action. Path integrals extinct when taking the limit because of fast oscillating exponents, and only trajectories for which action has the extremum survive. It gives

\[ \lim_{\hbar \to 0} \frac{\hbar}{i} \ln \int Dxe^{iS_\lambda[x]/\hbar} \int Dy e^{iS_{\lambda \rightarrow \zeta}[y]/\hbar} \]

\[ = \begin{cases} S_\lambda[x] + S_{\lambda \rightarrow \zeta}[y] & \text{for } \delta S_\lambda[x] = \delta S_{\lambda \rightarrow \zeta}[y] = 0 \\ 0 & \text{for } \delta S_\lambda[x] \neq 0 \text{ or } \delta S_{\lambda \rightarrow \zeta}[y] \neq 0 \end{cases}, \]

where \( \delta \) is variation. So one obtains that

\[ \lim_{\hbar \to 0} \frac{\hbar}{i} \ln P_\lambda |\zeta\rangle = (S_\lambda[x] + S_{\lambda \rightarrow \zeta}[y]) \chi_\lambda, \]
where

\[ \chi_\lambda = \begin{cases} 1 & \text{for } \delta S_\lambda[x] = \delta S_{\lambda \rightarrow \zeta}[y] = 0 \\ 0 & \text{for } \delta S_\lambda[x] \neq 0 \text{ or } \delta S_{\lambda \rightarrow \zeta}[y] \neq 0 \end{cases} \]

or in the compact form

\[ P_\lambda|\zeta\rangle \xrightarrow{\hbar \rightarrow 0} \chi_\lambda. \]  

Expression (11) defines the transition from the projective operator \( P_\lambda \) to some characteristic function \( \chi_\lambda \). The notation \( \chi_\lambda \) is used because \( |\zeta\rangle \) is any vector from \( H_S \) and so there is no need in the subscript \( \zeta \). This function defines the classical action that describes transition of \( S \) from the state with some physical property \( \lambda \) to the state with the property \( \zeta \). As one can see, \( \chi_\lambda \) vanishes only for those regions in the phase space where \( \delta (S_\lambda[x] + S_{\lambda \rightarrow \zeta}[y]) \neq 0 \).

Expression (11) encodes the transition of the system’s description from the quantum mechanical to the classical one. At the beginning one has the Hilbert space with projectors and wavefunctions, see (10), and at the end one obtains the phase space with some classical trajectories fixed by the extremum of the action. The transition (we call it quantization for brevity) is similar to a well-known semiclassical approximation, when the wavefunction is being expanded into series by \( \hbar \) up to the zeroth order.

At first we consider QL operations for commuting projectors.

Conjunction of two commuting operators

\[ (P_\lambda \wedge P_\mu) |\zeta\rangle = |\lambda\rangle \langle \lambda| |\mu\rangle \langle \mu| |\zeta\rangle \]

after taking the limit \( \hbar \rightarrow 0 \) (11) transforms as

\[ (P_\lambda \wedge P_\mu) |\zeta\rangle \xrightarrow{\hbar \rightarrow 0} \chi_\lambda \chi_\mu, \]  

that corresponds to the classical conjunction (1).

Negation (7) can be written as

\[ P_\neg \lambda |\zeta\rangle = (I - P_\lambda) |\zeta\rangle = \left( \int_{-\infty}^{+\infty} |\mu\rangle \langle \mu| d\mu - |\lambda\rangle \langle \lambda| \right) |\zeta\rangle, \]

thus giving the equivalent classical expression, see (3),

\[ P_\neg \lambda |\zeta\rangle \xrightarrow{\hbar \rightarrow 0} 1 - \chi_\lambda. \]  

Now we consider conjunction of non-commuting operators. This case is more complicated because of appearance of the commutator in expressions. Dequantization will consist of two steps: at first any power of product of two non-commuting projective operators will be considered, and only then their conjunction will be dequantized.

Let \( P_\lambda, P_\mu \) be two non-commuting projective operators such that

\[ P_\lambda P_\mu - P_\mu P_\lambda = i\hbar \Pi, \]  

where \( \Pi \) is hermitian. One may argue that (14) can not describe the general case, since one may use the commutator not proportional to \( \hbar \). But according to algorithm complexity theory the choice of language consisting of the complete set of operations
plays no significant role: it can not change the complexity class of the algorithm; see [5] for details. Using

$$\forall k > 0 \quad P^k_\lambda = P_\lambda, \quad P^k_\mu = P_\mu,$$

we obtain $\forall n > 0$

$$(P_\lambda P_\mu)^n = (P_\lambda P_\mu)^{n-1} (P_\mu P_\lambda + i h \Pi) = (P_\lambda P_\mu)^{n-1} (P_\lambda + i h \Pi)$$

$$\quad = \cdots = P_\lambda P_\mu (P_\lambda + i h \Pi)^{n-1},$$

where $n$ is integer. From the following

$$\forall k \geq 0 \begin{cases}
P_\lambda (i h \Pi)^{2k} = (i h \Pi)^{2k} P_\lambda \\
(P_\lambda (i h \Pi)^{2k} + 1) = (i h \Pi)^{2k+1} (I - P_\lambda)
\end{cases}$$

we obtain then

$$\forall k \geq 0 \quad (P_\lambda + i h \Pi)^{2k} = \left[ P_\lambda + (i h \Pi)^2 + i h \Pi \right]^k$$

$$\quad = \sum_{s=0}^{k} \frac{k!}{(k-s)!s!} [P_\lambda + (i h \Pi)^2]^{s} (i h \Pi)^{k-s}$$

$$\quad = \sum_{s=0}^{k} \frac{k!}{(k-s)!s!} [P_\lambda \sum_{l=0}^{s} \frac{s!}{(s-l)!l!} (i h \Pi)^{2(s-l)}}$$

$$+ (I - P_\lambda) (i h \Pi)^{2s}] (i h \Pi)^{k-s}$$

$$\quad = P_\lambda [I + (i h \Pi)^2 + i h \Pi]^k + (I - P_\lambda) (i h \Pi)^k (I + i h \Pi)^k$$

$$\quad = P_\lambda (I + \alpha)^k + (I - P_\lambda) \alpha^k,$$

where $\alpha = i h \Pi (I + i h \Pi)$, and finally results in

$$\forall n > 0 \quad (P_\lambda P_\mu)^n = \begin{cases}
\beta (I + \alpha)^k + P_\lambda i h \Pi \alpha^k & \text{for } n = 2k + 1 \\
\beta ((I + \alpha)^k + i h \Pi \alpha^k) + \gamma_k & \text{for } n = 2(k + 1)
\end{cases},$$

where $\beta = P_\mu P_\lambda + (I - P_\lambda) i h \Pi$ and $\gamma_k = P_\lambda (i h \Pi)^2 (I + \alpha)^k$. It gives

$$\forall n > 0 \quad \lim_{h \to 0} (P_\lambda P_\mu)^n = \lim_{h \to 0} P_\mu P_\lambda.$$

Using (12) and (13) one gets

$$\lim_{h \to 0} \frac{h}{i} \ln (P_\lambda \land P_\mu) |\zeta\rangle = \lim_{h \to 0} \frac{h}{i} \ln (P_\mu P_\lambda) |\zeta\rangle = S_\mu + S_{\mu \to \lambda} + S_{\lambda \to \zeta}$$

$$\quad = S_\lambda + S_{\lambda \to \mu} + S_{\mu \to \zeta},$$

for which the following variations are true:

$$\delta S_\mu = \delta S_{\mu \to \lambda} = \delta S_{\lambda \to \zeta} = 0, \quad \delta S_\lambda = \delta S_{\lambda \to \mu} = \delta S_{\mu \to \zeta} = 0.$$

Expression (17) determines conjunction dequantization for the non-commuting projectors.

Implication (6) by virtue of the previous result also transforms into the classical one (2):

$$P_\lambda \leq P_\mu \xrightarrow{h \to 0} \chi_\lambda \leq \chi_\mu.$$
5. Dequantization Information Loss Estimation

Suppose that $S$ is in the pure quantum state $|\zeta\rangle$. Von Neumann entropy $H_N$ of the state

$$H_N (|\zeta\rangle) = -\text{Tr} \rho \ln \rho = 0. \hspace{1cm} (19)$$

Here $\rho = |\zeta\rangle\langle \zeta|$ is the density matrix of the system.

After dequantization the system $S$ can be described by the corresponding characteristic function $\chi_\lambda$, see (11), that splits the phase space $\Gamma_S$ into two domains. As a result, $S$ can be characterized with Shannon entropy $H_{\text{Sh}}$

$$H_{\text{Sh}} (\chi_\lambda) = -\phi_\lambda \ln \phi_\lambda - (1 - \phi_\lambda) \ln (1 - \phi_\lambda), \hspace{1cm} \phi_\lambda = \frac{\int \mathcal{D}x \chi_\lambda}{\int \mathcal{D}x} \hspace{1cm} (20)$$

In the following the argument of $H_{\text{Sh}}$ may be denoted with the characteristic function or the corresponding projectors with no change in the expression meaning.

Thus after dequantization entropy depends on how $\chi_\lambda$ splits $\Gamma_S$. It is nonzero except when $\phi_\lambda = 0$ or $\phi_\lambda = 1$. One may notice that the entropy is upper bounded, i.e.

$$\forall \lambda \hspace{0.2cm} H_{\text{Sh}} (\chi_\lambda) \leq \ln 2. \hspace{1cm} (21)$$

The existence of the upper bound means that some quantum states after the dequantization lose all quantum correlations causing the maximal information loss possible.

Any logic statement consisting of commuting projectors is equivalent to some projector. Consequently, any pure quantum state under the statement transforms to another pure state leaving the von Neumann entropy $H_N$ unchanged. However, after statement dequantization the entropy will change because of re-splitting $\Gamma_S$. To show this, the entropy of dequantized logic operations should be explored.

Conjunction entropy of commuting projectors after taking the limit $\hbar \to 0$, see (12), is defined as

$$H_{\text{Sh}} (\chi_\wedge) = -\phi_\wedge \ln \phi_\wedge - (1 - \phi_\wedge) \ln (1 - \phi_\wedge) \leq \ln 2, \hspace{1cm} \phi_\wedge = \frac{\int \mathcal{D}x \chi_\wedge}{\int \mathcal{D}x} \hspace{1cm} (22)$$

where $\chi_\wedge = \chi_\lambda \chi_\mu$. Since $\chi_\wedge$ is nothing more but some characteristic function, we used expression (21) to define the upper bound on $H_{\text{Sh}} (\chi_\wedge)$.

For the quantum negation entropy after dequantization (13) we obtain

$$H_{\text{Sh}} (\chi_\neg_\lambda) = H_{\text{Sh}} (1 - \chi_\lambda) = H_{\text{Sh}} (\chi_\lambda). \hspace{1cm} (23)$$

Expression (23) means that because of the symmetry of (20) negation does not change entropy in statement even after the dequantization.

For the implication of commuting projectors one gets that, according to (2) and (6), after the logic conversion (18) entropy will have the following property:

$$P_\lambda \leq P_\mu \hspace{1cm} \Rightarrow \hspace{1cm} H_{\text{Sh}} (\chi_\wedge) = H_{\text{Sh}} (\chi_\lambda), \hspace{1cm} (24)$$

where $\chi_\wedge = \chi_\lambda \chi_\mu$.

As before, in case of non-commuting projectors it is enough to consider entropy of the corresponding conjunction (8) after the logic conversion (17).
Let $P_\lambda, P_\mu$ be two non-commuting projectors satisfying (14). The initial state $|\zeta\rangle$ of the system can be expanded into series by the eigenstates of commutator $\Pi$:

$$|\zeta\rangle = \sum_\pi \zeta_\pi |\pi\rangle, \quad \Pi|\pi\rangle = \pi|\pi\rangle.$$  

Terms containing nonzero powers of $\Pi$ will vanish in accordance with (15) while taking the limit $\hbar \to 0$ in conjunction (8). Thus density matrix $\rho$ should be traced over the eigenstates of $\Pi$. Under this averaging pure state transforms into the mixture for which the von Neumann entropy is nonzero:

$$H_N(|\zeta\rangle) \to H_N(\rho_\Pi) = -\text{Tr} \rho_\Pi \ln \rho_\Pi = -\sum_\pi |\zeta_\pi|^2 \ln |\zeta_\pi|^2 \leq \ln \dim \Pi. \quad (25)$$

Here $\rho_\Pi = \text{Tr}_\Pi |\zeta\rangle\langle \zeta|$.

In addition, the contribution of every eigenstate $|\pi\rangle$ from the mixture $\rho_\Pi$ to the whole entropy should be included. Any such term is expressed similarly to (20)

$$H_{\text{Sh}}(\chi_{\lambda|\pi}) = -\phi_{\lambda|\pi} \ln \phi_{\lambda|\pi} - (1 - \phi_{\lambda|\pi}) \ln (1 - \phi_{\lambda|\pi}), \quad (26)$$

where $\chi_{\lambda|\Pi}$ is the characteristic function corresponding to the conjunction of our projectors and

$$\phi_{\lambda|\pi} = \frac{\int Dx|\pi\rangle \chi_\lambda \chi_\mu}{\int Dx|\pi\rangle}.$$  

Here and in the following subscript $|\pi\rangle$ means that the transition starting from the state $|\lambda\rangle$ or $|\mu\rangle$ results in the corresponding state $|\pi\rangle$ but not in $|\zeta\rangle$ as before, see (10).

Summarizing, the whole entropy for the dequantized conjunction of two non-commuting projectors is

$$H(\chi_{\lambda|\Pi}) = H_N(\rho_\Pi) + \sum_\pi |\zeta_\pi|^2 H_{\text{Sh}}(\chi_{\lambda|\pi}). \quad (27)$$

There is no subscript $\text{sh}$ nor $N$ on the lhs of (27) since it is a sum of both the von Neumann and Shannon entropies. As one can see, (22) is easily obtained via formal setting $\dim \Pi = 1$ in (27). The upper bound of $H(\chi_{\lambda|\Pi})$, see (21) and (25), is

$$H(\chi_{\lambda|\Pi}) \leq \ln \dim \Pi + \ln 2. \quad (28)$$

Now we can consider the case of the commutators not proportional to $\hbar$ in details, see (14) and the text right after it. To do it one can replace $\hbar \Pi$ in (14) by some hermitian operator $C$. Such an operator can be diagonalized, i.e. represented in the form $C = \sum_i^{\dim C} cP_i$, where $P_i$ is the projector on the eigenstate of $C$ with eigenvalue $c$. Now, following the dequantization procedure for such an operator (see (11)) one will result in re-definition of coefficients $\alpha, \beta, \gamma$ in (15) without any change in (16) and in (27). In other words, one again will meet with the information loss while taking the semiclassical limit $\hbar \to 0$ without any change at the end and hence with no additional entropy except the estimated one.
Implication of the non-commuting operators is similar to analysis of the commuting ones, see (24). The only difference is that the non-commuting conjunction entropy (27) should be used, i.e.

$$P\lambda \leq P\mu \Rightarrow H(\chi_{\land\Pi}) = H_{Sh}(\chi_{\lambda}),$$

(29)

where projectors satisfy (14). However, this is the generalization of (24); the latter is obtained by setting dim\Pi = 1 in (29) as we did it before.

The obtained results define the entropy increase for any elementary logical statements under the logic conversion. Such elementary statements are atomic, and thus are equivalent to the one-qubit register. But for the complete analysis of the information gap registers of arbitrary length should be observed.

Let $|\zeta\rangle^{\otimes N_1}$ be an $N_1$-qubit register. Any calculation with it is equivalent to construction of some logical expression $E_1$ from the elementary logical operations defined on projectors. Suppose that $E_1$ has no implications inside (that’s underlined with index 1) and consists of $n_1$ negations $\neg$ and $c_1$ conjunctions $\land$. The following expression

$$N_1 \leq n_1 + c_1$$

must be true since else such a coding can be applied where $N_1 - n_1 - c_1$ qubits will be obsolete.

Conjunctions $c_1$ are defined on the non-commuting projectors in general. Thus one has to include all commutator (14) contributions while estimating the entropy. After neglecting the first such commutator all subsequent elementary statements will operate on the mixture but not on the pure state. However, as negation does not influence the entropy, the conjunctions operating on the mixture should be observed only.

Suppose that the expression $E_{1,\Pi_2\Pi_1}$ consists of two conjunctions characterized with commutators $\Pi_1$ (corresponds to the first calculated conjunction) and $\Pi_2$ (the second one). After dequantization entropy of the expression will be

$$H(E_{1,\Pi_2\Pi_1}|\zeta\rangle) = H(\chi_{\land\Pi_1} + \sum_{\pi_1} |\zeta_{\pi_1}|^2 H_{Sh}(\chi_{\land\Pi_2|\pi_1}).$$

In general, for $E_1$ on the register $|\zeta\rangle^{\otimes N_1}$ the whole entropy will be estimated by recurrent formula

$$H(E_1|\zeta\rangle^{\otimes N_1}) = \sum_{i=1}^{q_1} H_{Sh}(\chi_{\lambda_i}) + H(\chi_{\land\Pi_1}) + \sum_{\pi_1} |\zeta_{\pi_1}|^2 H_{Sh}(\chi_{\land\Pi_2|\pi_1}).$$

(30)

Here $q_1$ is the number of qubits equipped in no conjunction. Using (21) and (28), one may obtain the upper bound for the entropy:

$$H(E_1|\zeta\rangle^{\otimes N_1}) \leq (q_1 + c_1) \ln 2 + \sum_{k=1}^{c_1} \ln \dim\Pi_k.$$

(31)

To estimate the entropy of some general expression $E$ one must count over all implications made during the calculation. It means that for $E$ containing subexpressions $\{E_i\}_1$ on the register $|\zeta\rangle^{\otimes N}$ total entropy $H(E|\zeta\rangle^{\otimes N})$ must consist of contributions from all the subexpressions, each of which is defined by (31).
6. Conjunction Theorem

Now we are almost ready to verify our approach on real algorithms. However, any quantum algorithm, to be the computable one in finite time, should not contain the conjunction of non-commuting projectors since it requires an infinite time for its construction, see (8). The algorithm should use the finite products of non-commuting projectors instead. So there is a need in setting an interrelation between the non-commuting conjunction and the finite product of the non-commuting projectors. We provide this with the help of the following theorem.

**Theorem.** Let $P_\lambda, P_\mu$ be any two projective operators such that $[P_\lambda, P_\mu] = i\hbar \Pi$, $P_\lambda = P_\lambda \wedge P_\mu$. Then

$$\forall k > 0, \quad H((P_\lambda P_\mu)^k) = H(P_\wedge) .$$

(32)

**Proof.** From (8) we can write

$$(P_\lambda P_\mu)^k P_\wedge = P_\wedge (P_\lambda P_\mu)^k = P_\wedge . \quad (33)$$

As it follows from (8), $P_\wedge^2 = P_\wedge$, i.e. it is a projective operator. This is not true for the product $(P_\lambda P_\mu)^k$, since $P_\lambda$ and $P_\mu$ do not commute. But, such the product defines some Hilbert subspace, and therefore (33) is the common implication for commuting operators, see (6). Then, using (24) finally we result in (32) completing the proof. $\square$

Now we can generalize expressions (30) and (31). Due to (6) any conjunction gives the same IL as the product of the projectors involved in it. In such a case, the implication (commuting or non-commuting) IL can be estimated directly: due to definition it contains the conjunction or the projector replacing the conjunction itself. All we need to do is just to remove the subscript $1$ in (30) and (31). So, finally we obtain

$$H(\mathbb{E}|\zeta\rangle \otimes^N) = \sum_{i=1}^q H_{\text{Sh}}(\chi_{\lambda_i}) + H(\chi_{\wedge \Pi_1}) + \sum_{\pi_1} |\zeta_{\pi_1}|^2 H_{\text{Sh}}(\chi_{\wedge \Pi_2 | \pi_1}) \quad (34)$$

and

$$H(\mathbb{E}|\zeta\rangle \otimes^N) \leq (q + c) \ln 2 + \sum_{k=1}^c \ln \dim \Pi_k , \quad (35)$$

where $\mathbb{E}$ is the expression being processed on the $N$-qubit register, $q$ is the number of qubits equipped in no conjunction, and $c$ is the number of conjunctions; any product of non-commuting operators should be considered as conjunction due to (6).

7. Examples

Let us introduce some notations before we proceed. At first we define the following projectors:

$$P_\lambda = |q\rangle \langle q|, \quad P_{-q} = I - P_q, \quad |q\rangle : \sigma_q |q\rangle = |q\rangle ,$$

where $I$ is the unit operator, $q = \{x, y, z\}$ and $\sigma_q$ is the corresponding Pauli matrix. It is easy to check that $P_q P_{q'} \neq P_{q'} P_q$ if $q \neq q'$.
Since \( \{ I, P_x, P_y, P_z \} \) are linearly independent, we can encode any qubit operator as some linear combination of these matrices. To proceed we need the following operators:

\[
W_k = \frac{1}{\sqrt{2}} (P_{zk} - P_{\neg zk} + P_{zk} - P_{\neg zk}) = \sqrt{2} (P_{zk} - P_{\neg zk}),
\]

\[
C_{k,s} = (1 - e^{i\phi_{k,s}}) (P_{zs}P_{\neg zk} + I_sP_{zk}) + e^{i\phi_{k,s}}I_sI_k,
\]

where \( W_k \) is the Walsh-Hadamard gate on the \( k \)-th qubit, and \( C_{k,s} \) is the controlled-phase gate on the \( k \)-th and \( s \)-th qubits with phase shift \( \phi_{k,s} = \pi/2^{s-k} \). Here and in the following the operator’s subscripts \( k, s \) denote the qubits these operators act on.

We emphasize that using another basis matrices (and consequently the projectors) will not influence the result, since may be provided by simple unitary rotation of the one presented. This is simple consequence of the fact that changing the language (but except the unary languages consisting of one symbol only) can not significantly influence the algorithm complexity.

Now we can use (35) for estimation of the IL of any quantum algorithm \( \mathbb{E} \). Processing the estimation we should keep in mind that the number of conjunctions \( c \) equals to the number of projector’s intersections from the viewpoint of the IL (see (6)).

Below we estimate IL for two different quantum algorithms: quantum discrete Fourier transform FFT\( Q \) and Grover search algorithm Gr\( Q \). Those who are interested in the details of the algorithms we refer to [37]. These algorithms provide essential speed-up compared to their classical analogs, which are exponentially complex, and one expects that to be reflected by IL in some way.

7.1. FFT\( Q \) dequantization

As it is known, FFT\( Q \) on the \( N \)-qubit register may be written as the following operator:

\[
\text{FFT}_Q = \Phi_0 \cdots \Phi_{N-1}, \quad \Phi_k = W_kC_{k,N-1}C_{k,N-2} \cdots C_{k,k+1}.
\]

One can notice that every \( C_{k,s} \) contains 2 non-reducing terms with \( P_{zk} \) which do no commute with the corresponding \( P_{zk} \) of \( W_k \). Then the number of non-commuting projector products is \( c_k = 2^{N-k-1} \) for any \( \Phi_k \) and

\[
c = \sum_{k=0}^{N-1} c_k = \sum_{k=0}^{N-1} 2^{N-k-1} = 2^N - 1.
\]

Any \( \Phi_k \) contains \( N - k - 1 \) commuting projector products (commuting conjunctions); summing over \( k \) gives \( N(N-1)/2 \) commuting conjunctions in general. Substituting this, (37) and \( \dim \Pi_k = 2^N \) in (35), we obtain then

\[
H(\text{FFT}_Q) \leq \left[ q + \frac{N(N-1)}{2} + (N + 1)(2^N - 1) \right] \ln 2 = O(N 2^N),
\]

thus meeting an exponential IL of the dequantized FFT\( Q \). As it is known, its classical analog FFT\( C \) needs \( O(N 2^N) \) amount of resources.
7.2. Grover dequantization

Gr_Q, which is operating on the database containing $2^N$ elements, can be represented with the following operator

$$Gr_Q = \left\{ \left[ 2 (WP_z W)^{\otimes N} - I^{\otimes N} \right] \otimes (P_{\neg z} - P_z) \right\}^{\pi 2^{N/2}} U_\Gamma,$$

$$U_\Gamma : |x\rangle|0\rangle \rightarrow |x\rangle|\Gamma(x)\rangle,$$

where $\Gamma$ is the tested statement (i.e. Gr_Q determines the elements on which $\Gamma$ is true). The operator $U_\Gamma$ requires a number of gates depending on particular expression for $\Gamma$, and thus will not be considered in the following.

As for the component $(P_{\neg z} - P_z)$ acting on the ancillary qubit, it includes $c_{k|\Gamma} = 1$ intersections for the complementary (and hence commuting) projectors only, for which one can put formally $\dim \Pi_{k|\Gamma} = 1$ while estimating IL. The number of these ancillary intersections is

$$c_{|\Gamma} = \sum_{k=1}^{\pi 2^{N/2}} c_{k|\Gamma} = \frac{\pi}{4} 2^{N/2}.$$  \hspace{1cm} (40)

For operator in the square brackets we obtain that

$$WP_z W = 2 (P_x - P_{\neg z}) P_z (P_x - P_{\neg z}) = 2P_x P_z P_x,$$

thus giving one intersection of non-commuting projectors. The number of such intersections in the square brackets is $c_{k|[\ ]} = N$ (one for every qubit in the register). Since iteration should be applied $\frac{\pi}{4} 2^{N/2}$ times, then

$$c_{|[\ ]} = \sum_{k=1}^{\pi 2^{N/2}} c_{k|[\ ]} = \sum_{k=1}^{\pi 2^{N/2}} N = \frac{\pi}{4} N 2^{N/2}.$$  \hspace{1cm} (41)

As $\dim \Pi_{k|[\ ]} = 2^N$, we obtain after substituting (40) and (41) into (35)

$$H(Gr_Q) \leq (q + c_{|\Gamma}) \ln 2 + c_{|[\ ]}(1 + N) \ln 2$$

$$= \left[ q + \frac{\pi}{4} (N^2 + N + 1) 2^{N/2} \right] \ln 2 = O\left(N^2 2^{N/2}\right).$$  \hspace{1cm} (42)

As it is known, classical search algorithm requires $O\left(2^N\right)$ number of resources, while Gr_Q needs $O\left(2^{N/2}\right)$. Thus, as we see, we obtain non-polynomial IL in this case. It may be an example of the “not complete” algorithm reduction, i.e. when the algorithm under the dequantization reduces to the rather complicated one.

As the search algorithm belongs to the NP complexity class, the example demonstrates that at least some quantum algorithms being NP (here this is Gr_Q) do not meet complete IL (i.e. IL for them does not necessarily equal in the number of resources required with their classical analogs) under dequantization: here we obtained $O\left(N^2 2^{N/2}\right)$ instead of $O\left(2^N\right)$ IL. The reason for such a difference is the transformation of the algorithm which is discussed in the next section.

One may argue that the obtained results may be explained by the Gottesman-Knill theorem (see [37] for the formulation and proof): (36) includes the gates outside the
Clifford group, while (39) employs the gates from the Clifford group only. And this is what we obtained by expressions (38) and (42). However, compared to the Gottesman-Knill theorem, we exactly show how the computational efficiency is being reduced and give concrete recipe for the loss estimation, see (34) and (35).

8. Discussion

In the manuscript we dequantized the complete set of elementary quantum logic operations including the non-commuting conjunction. We calculated the IL and its upper bound for the operations after taking the semiclassical limit. We derived the general expression estimating the IL for any dequantized quantum algorithm, see (34) and (35). We formulated and proved theorem (see Section 6), which is necessary for estimation of conjunction of non-commuting projectors. Finally, the obtained results were applied for IL estimation for FFT$_Q$ and Gr$_Q$ algorithms. The developed technique demonstrated exponential ((7.1)) and non-polynomial ((7.2)) IL for the algorithms correspondingly.

Expression (34) estimates amount of information being lost by quantum algorithm, which is encoded with $E$, after processing through the semiclassical limit. It implies that at least the description of the IL requires the additional memory of the $H (E|\zeta^\otimes N)$ size which is upper bounded with (35). At the same time, such a description requires at least the same increase of amount of elementary logical steps (by one per each additional memory cell to write it down). So we conclude that the technique presented in the paper might shed some light on the NP problem (in case we consider some NP-complete algorithm, see (7.2)) and on the algorithm complexity classification.

Any quantum algorithm under dequantization keeps the number of elementary logical operations the same with no change in efficiency in its common sense. But the description of its IL requires additional memory and, consequently, time (measured in the number of elementary logical steps). The interrelation between both the efficiencies is unclear, since the dequantized algorithm and its IL description do not coincide.

The algorithmic entropies, see [27], may be used to describe “distance” between the desired and the calculated result in case of using quantum or classical algorithm. The entropies are used to estimate the probability of obtaining the desired result; they are defined for the states calculated with some algorithm. Our approach differs a lot from this one since we investigate the changes of the elementary logic operations while taking the limit $\hbar \to 0$.

The Kolmogorov complexity approach is useful for estimation of the difference between quantum and classical calculation. It gives the minimized in size program that realizes the corresponding algorithm. Such an approach helps to define conditions on the calculations, which are easy in quantum but are hard in classical case. For more details see [23] and other ones [24, 25, 26].

However, our approach differs from the Kolmogorov’s one. Dequantization of elementary QL operations allows to estimate the corresponding entropy for any logical
expression. It gives the amount of information loss during the reduction of quantum algorithm to the classical one. It has much in common with (but can not be interpreted as comparison of) the corresponding Kolmogorov complexities for the quantum and classical algorithms solving the same problem. The number of elementary operations does not change when in the semiclassical limit. The similarity origins from the re-estimation of quantum gates in terms of classical ones. But, after the dequantization algorithm may solve another problem (like FFT\textsubscript{Q}), thus pointing out the differences with the Kolmogorov approach.

We illustrate this statement with the help of the classical discrete fast Fourier transform (FFT). As it is known, FFT\textsubscript{Q} is a polynomial time algorithm. It needs $O(N^2 + N)$ operations, while FFT needs $O(N2^N)$. According to [7], the number of elementary operations during dequantization remains the same, i.e. polynomial. However, some amount of information is lost, and this amount can be estimated. We suggest that the only explanation for this is the algorithm changeover. In particular FFT\textsubscript{Q} transforms into the Legendre transform (but not into FFT) [35]; for some more information see [36].

Such algorithm simplification after dequantization is explained by the fact that QL algebra can be split up on some Boolean subalgebras, each of which is similar to the CL algebra [8]. But statements from different QL subalgebras do not commute, thus providing the largest IL possible.

It has been widely believed that entanglement is a quantum resource responsible for high efficiency of quantum algorithms. In our approach the (non-commuting in general) projective operators are used only, with no direct relation to entanglement. One may say that the non-commuting projectors project the state to different subspaces (say $H_1$ and $H_2$) such that the basis vectors from $H_1$ are represented as entangled in the basis of $H_2$. But there are doubts this can be stated and proved in general. In [38] a simulation of the Shor’s factoring algorithm was made, and the authors found no significant role of entanglement in providing the exponential speed-up of the algorithm. Based on this and on our own results, we suppose that entanglement can not be considered as the resource of the computational speed-up in quantum calculation, and state that high computational efficiency of quantum algorithms is highly interrelated with the presence of non-commuting statements which can not be simulated efficiently by CL. However, the last item is true if IL is strongly interconnected with the computational efficiency only and requires further research. Both the efficiencies, in spite of having much in common, differ from each other.

Some questions still remain open, and it seems reasonable to solve them. Here they are:

• How are the efficiency and IL are interconnected with each other?

• If some optimal quantum algorithm gives an exponential IL, whether it implies that the classical algorithm for the same problem is exponential in time?

• Can the presented approach be used for the comparison of quantum and classical
algorithm complexity classes, and correlation ascertainment between these classes?

- Generally any quantum algorithm transforms into another one, that solves another problem, under the semiclassical limit. But, what about the reversion: can one obtain some quantum algorithm (or the class of them), being given the classical one? Some investigation on the topic of transition from subsets of CL to compatible (i.e. determined with mutually commuting operator sets) linear subspaces of QL are presented in paper [34]; it is called lifting in the manuscript. In our opinion, such a reversion should be ambiguous due to the differences between subsets and linear subspaces. The point is that there is no recipe to go to the incompatible subspaces. In our opinion, formalization and further development of the approach presented in [39] might be helpful while constructing the recipe. However it is not known for sure whether it can be solved or not at least for some classes of quantum algorithms. In particular one can try to build the quantum analog of the Legendre transform. Due to ambiguity one is expected to derive some class of quantum algorithms but not FFTQ only. One more interesting point is to look for the quantum analogs of inefficient classical algorithms such as FFT or factorization and to verify whether the analogs will be inefficient in QL too.

Summing up the questions mentioned above we conclude that the problem of the reverse transition to dequantization is worth of further investigation.

Acknowledgments

We are thankful to E. D. Belokolos for all the valuable discussions during preparation of this work and to O. Fialko for all the remarks which helped to improve it a lot.
