Abstract

The Large Hadron Collider has recently discovered a Higgs-like particle having a mass around 125 GeV and also indicated that there is an enhancement in the Higgs to diphoton decay rate as compared to that in the standard model. We have studied implications of these discoveries in the bilinear R-parity violating supersymmetric model, whose main motivation is to explain the non-zero masses for neutrinos. The R-parity violating parameters in this model are ϵ and b_ϵ , and these parameters determine the scale of neutrino masses. If the enhancement in the Higgs to diphoton decay rate is true, then we have found $\epsilon \gtrsim 0.01$ GeV and $b_\epsilon \sim 1$ GeV² in order to be compatible with the neutrino oscillation data. Also, in the above mentioned analysis, we can determine the soft masses of sleptons (m_L) and CP-odd Higgs boson mass (m_A). We have estimated that $m_L \gtrsim 300$ GeV and $m_A \gtrsim 700$ GeV. We have also commented on the allowed values of ϵ and b_ϵ , in case there is no enhancement in the Higgs to diphoton decay rate. Finally, we present a model to explain the smallness of ϵ and b_ϵ .

1 Introduction

The ATLAS and CMS collaborations of Large Hadron Collider (LHC) have recently discovered a bosonic particle whose mass being around 125 GeV [1]. The data from the LHC is strongly favouring the spin of this bosonic particle to be zero and it is consistent with the Higgs boson [2], which is necessary to achieve the electroweak symmetry breaking. The ATLAS and CMS groups have analyzed the decay properties of this Higgs-like particle into various standard model fields. An indication for the excess of events in the Higgs to diphoton channel as compared to that in the standard model (SM) has been reported. Explicitly, by defining the quantity

$$R_{\gamma\gamma} = \frac{[\sigma(pp \rightarrow h) \times \text{BR}(h \rightarrow \gamma\gamma)]_{\text{observed}}}{[\sigma(pp \rightarrow h) \times \text{BR}(h \rightarrow \gamma\gamma)]_{\text{SM}}}, \quad (1)$$

where h is the Higgs boson, the ATLAS and CMS had earlier reported that $R_{\gamma\gamma} = 1.8 \pm 0.5$ and 1.56 ± 0.43 [1], respectively. The above quoted values for $R_{\gamma\gamma}$ have been recently updated in March 2013 at the conference Rencontres de Moriond. The ATLAS group has claimed $R_{\gamma\gamma} = 1.65^{+0.34}_{-0.30}$ [3], which indicates a slight enhancement in the $h \rightarrow \gamma\gamma$ channel. However, the CMS group has reported that $R_{\gamma\gamma}$ could be $0.78^{+0.28}_{-0.26}$ or $1.11^{+0.32}_{-0.30}$, depending on the type of the analysis [4]. The values quoted by the CMS group imply that the discovered Higgs boson is consistent with the SM within the uncertainties. We can hope that the future analysis at ATLAS and CMS can resolve the differences in $R_{\gamma\gamma}$. At this moment, it is worth to analyse by assuming that the discovery made at the LHC favours new physics.

New physics has been motivated by several considerations and some of them are gauge hierarchy problem and smallness of neutrino masses. Gauge hierarchy problem can be solved by proposing supersymmetry [5]. In supersymmetric models the Higgs boson mass can be around the electroweak scale and it is protected from radiative corrections. The weakly interacting neutrinos are found to have non-zero masses which should not exceed 1 eV. The non-zero masses for neutrinos and upper limits on them have been established by neutrino oscillation experiments [6], cosmological observations [7] and β -decay experiments [8]. Since the neutrino masses should be smaller than the electroweak scale by at least twelve orders of magnitude, the smallness of their masses indicate a new mechanism for mass generation.

To solve both the gauge hierarchy problem and smallness of neutrino masses, bilinear R-parity violating supersymmetric (BRPVS) model is a viable option. For a review on the BRPVS model, see Ref. [9]. This model is a minimal extension of the minimal super-

symmetric standard model (MSSM). In the BRPVS model, additional bilinear terms of the forms $\epsilon \hat{L} \hat{H}_u$ and $b_\epsilon \tilde{L} H_u$ are added to the superpotential and scalar potential respectively. Here $\hat{L}(\tilde{L})$ and $\hat{H}_u(H_u)$ are superfields (scalar components) of lepton and up-type Higgs doublets respectively. The above mentioned bilinear terms violate lepton number and also the R-parity. ϵ is a mass parameter and b_ϵ is a mass-square parameter. Provided that the ϵ and b_ϵ are very small, the masses of neutrinos can be shown to be consistent with the observed neutrino oscillation data [10, 11, 12]. One may explain the smallness of ϵ and b_ϵ by proposing additional symmetries [13] or by embedding this model in a high scale physics [14].

The BRPVS model has rich phenomenology [15, 16]. In this work we want to study the affects of recent discoveries at the LHC on the parameter space of the BRPVS model. As mentioned above that the BRPVS model is an extension of MSSM and the additional parameters in it are ϵ and b_ϵ . Moreover, both ϵ and b_ϵ should be very small in order to account for the smallness of neutrino masses. As a result of this, in the BRPVS model, the contribution to the Higgs boson mass and also to the quantity $R_{\gamma\gamma}$ are dominantly determined by the MSSM parameters. In order to have light Higgs boson mass $m_h \sim 125$ GeV, the stop masses should be considerably high as well as large mixing is needed in the stop sector [17, 18, 19]. However, parameters in the squark sector do not affect the neutrino masses in the BRPVS model. On the other hand, to have $R_{\gamma\gamma} > 1$ it has been shown that relatively light stau masses and large left-right mixing in the stau sector are required [17]. Essentially, this would mean that the soft parameters of slepton masses (m_L), higgsino mass parameter (μ) and the ratio of vacuum expectation values (vevs) of the two neutral Higgs fields ($\tan\beta$) determine $R_{\gamma\gamma}$. We will show that CP-odd Higgs boson mass (m_A) also has a role to play in the enhancement of Higgs to diphoton decay rate. Shortly below we will explain that the parameters which determine $R_{\gamma\gamma}$ can affect the neutrino masses in the BRPVS model. It is to remind that in the singlet extension of MSSM, enhancement in $R_{\gamma\gamma}$ can be made not necessarily with light staus [20].

In the BRPVS model, one neutrino state acquires non-zero mass at tree level due to mixing between flavor neutrinos and neutralinos [11, 12]. The remaining two neutrino states acquire masses at 1-loop level due to mixing between sneutrinos and the three neutral Higgs bosons [11, 12]. Explicitly, apart from ϵ and b_ϵ , the neutrino masses in this model are dominantly depended on the neutralino parameters ($M_{1,2}$, μ , $\tan\beta$), m_L and m_A . From the discussion in the previous paragraph, we can understand that the parameters which determine the neutrino masses in the BRPVS model have a role to play in the enhancement of Higgs to diphoton decay rate. From this perspective, we can

understand that the requirement of $R_{\gamma\gamma} > 1$ can lead to certain allowed values for ϵ and b_ϵ , which determine the overall scales of neutrino masses.

Both the ATLAS and CMS groups of the LHC are yet to confirm whether $R_{\gamma\gamma} > 1$ or not. Hence we have also analyzed the case $R_{\gamma\gamma} \leq 1$. In either of these cases we will see that the allowed values of ϵ and b_ϵ are small, and their smallness can be motivated from a high scale physics. While motivating these parameters from a high scale physics, we can also predict allowed ranges for m_L , m_A and also about other supersymmetric parameters.

The paper is organized as follows. In the next section, we give a brief overview of the BRPVS model and also describe the neutrino masses in this model. In the same section we will also explain the relevant quantities regarding the Higgs boson mass and $R_{\gamma\gamma}$. In Sec. 3, we describe our results on ϵ and b_ϵ which are compatible with neutrino oscillation data and also with $R_{\gamma\gamma}$. We then motivate these results from a high scale physics. We conclude in Sec. 4.

2 The BRPVS model

The superpotential of the BRPVS model is

$$W = Y_u^{ij} \hat{Q}_i \hat{U}_j \hat{H}_u - Y_d^{ij} \hat{Q}_i \hat{D}_j \hat{H}_d - Y_e^{ij} \hat{L}_i \hat{E}_j \hat{H}_d + \mu \hat{H}_u \hat{H}_d + \epsilon_i \hat{L}_i \hat{H}_u, \quad (2)$$

where the indices i, j run from 1 to 3. The superfields \hat{Q} , \hat{U} and \hat{D} are doublet, singlet up-type and singlet down-type quark fields, respectively. \hat{L} and \hat{E} are doublet and singlet charged lepton superfields, respectively. \hat{H}_u and \hat{H}_d are up- and down-type Higgs superfields, respectively. As already explained in the previous section, the superpotential terms $\hat{L}_i \hat{H}_u$ are the bilinear R-parity violating terms. The addition of these R-parity violating terms makes the superpotential of BRPVS model to differ from that of MSSM. Another difference between the BRPVS model and the MSSM is that the soft scalar potential in the BRPVS model has additional terms which correspond to the $\hat{L}_i \hat{H}_u$ -terms. The form of the soft scalar potential in the BRPVS model is

$$\begin{aligned} V_{\text{soft}}^{\text{BRPVS}} &= V_{\text{soft}}^{\text{MSSM}} + \left[(b_\epsilon)_i \tilde{L}_i H_u + \text{c.c.} \right], \\ V_{\text{soft}}^{\text{MSSM}} &= \frac{1}{2} \left(M_1 \tilde{B} \tilde{B} + M_2 \tilde{W} \tilde{W} + M_3 \tilde{g} \tilde{g} + \text{c.c.} \right) + m_{H_u}^2 H_u^* H_u + m_{H_d}^2 H_d^* H_d + \\ &\quad + (m_Q^2)_{ij} \tilde{Q}_i^* \tilde{Q}_j + (m_U^2)_{ij} \tilde{U}_i^* \tilde{U}_j + (m_D^2)_{ij} \tilde{D}_i^* \tilde{D}_j + (m_L^2)_{ij} \tilde{L}_i^* \tilde{L}_j + (m_E^2)_{ij} \tilde{E}_i^* \tilde{E}_j \\ &\quad + \left[(A_U)_{ij} \tilde{Q}_i \tilde{U}_j H_u + (A_D)_{ij} \tilde{Q}_i \tilde{D}_j H_d + (A_E)_{ij} \tilde{L}_i \tilde{E}_j H_d + b_\mu H_u H_d + \text{c.c.} \right]. \end{aligned} \quad (3)$$

The explicit form of the soft terms in the MSSM are given in the form of $V_{\text{soft}}^{\text{MSSM}}$.

2.1 Neutrino masses in the BRPVS model

In this subsection we will describe the neutrino masses, which are generated mainly due to the bilinear R-parity violating terms. In fact, these bilinear terms violates lepton number, and as a result, the sneutrinos can acquire non-zero vevs. However, without loss of generality, we work in a particular basis where the vevs of sneutrinos are kept to be zero.

The ϵ -term of Eq. (2) generate mixing between flavor neutrinos (ν_i) and higgsino. In a basis where $\psi_N = (\tilde{B}, \tilde{W}^3, \tilde{H}_u^0, \tilde{H}_d^0, \nu_1, \nu_2, \nu_3)^T$, at the tree level we get the following mixing masses: $\mathcal{L} = -\frac{1}{2}\psi_N^T M_N \psi_N + \text{h.c.}$, where

$$M_N = \begin{pmatrix} M_{\chi^0} & m \\ m^T & 0 \end{pmatrix}, \quad (5)$$

$$M_{\chi^0} = \begin{pmatrix} M_1 & 0 & \frac{1}{\sqrt{2}}g_1 v_u & -\frac{1}{\sqrt{2}}g_1 v_d \\ 0 & M_2 & -\frac{1}{\sqrt{2}}g_2 v_u & \frac{1}{\sqrt{2}}g_2 v_d \\ \frac{1}{\sqrt{2}}g_1 v_u & -\frac{1}{\sqrt{2}}g_2 v_u & 0 & -\mu \\ -\frac{1}{\sqrt{2}}g_1 v_d & \frac{1}{\sqrt{2}}g_2 v_d & -\mu & 0 \end{pmatrix}, \quad m = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \epsilon_1 & \epsilon_2 & \epsilon_3 \\ 0 & 0 & 0 \end{pmatrix}. \quad (6)$$

Here, g_1, g_2 are the gauge couplings corresponding to the gauge groups $U(1)_Y$ and $SU(2)_L$, respectively. The vevs of Higgs scalar fields are defined as: $\langle H_d^0 \rangle = v_d = v \cos \beta$, $\langle H_u^0 \rangle = v_u = v \sin \beta$, where $v = 174$ GeV is the electroweak scale. Assuming that ϵ_i are very small compared to the TeV scale, at leading order, after integrating away the components of neutralinos, we get the neutrino mass matrix as $m_\nu = -m^T M_{\chi^0}^{-1} m$. However, this leading neutrino mass matrix will give only one non-zero mass eigenvalue [11, 12]. In a realistic scenario we need at least two non-zero mass eigenvalues for neutrinos [6]. It can be shown that the other two neutrino states get non-zero masses due to radiative contributions [11, 12]. At 1-loop level, neutrinos get non-zero masses because of mixing between sneutrinos and neutral Higgs boson states [11, 12], and this mixing is driven by the soft b_ϵ -term of Eq. (3). It has been shown in Ref. [11, 12] that at 1-loop level, the dominant contribution to neutrino masses come from diagrams involving two insertions of b_ϵ , provided the tree level mass eigenvalue is dominant over the loop contribution. Based on this, below we present the complete expression for neutrino mass matrix. In this expression we assume degenerate masses for sneutrinos.

The neutrino mass matrix in the BRPVS model, up to leading contributions, can be written as [11, 12]

$$(m_\nu)_{ij} = a_0 \epsilon_i \epsilon_j + a_1 (b_\epsilon)_i (b_\epsilon)_j, \quad (7)$$

where the indices i, j run from 1 to 3. The first term in the above equation is due to the tree level effect, which is described in the previous paragraph, and the second term is from 1-loop diagrams. The expressions for a_0 and a_1 are [11, 12]

$$\begin{aligned} a_0 &= \frac{m_Z^2 m_{\tilde{\gamma}} \cos^2 \beta}{\mu(m_Z^2 m_{\tilde{\gamma}} \sin 2\beta - M_1 M_2 \mu)}, \quad m_{\tilde{\gamma}} = \cos^2 \theta_W M_1 + \sin^2 \theta_W M_2, \\ a_1 &= \sum_{i=1}^4 \frac{(g_2(U_0)_{2i} - g_1(U_0)_{1i})^2}{4 \cos^2 \beta} (m_{N^0})_i \left(I_4(m_h, m_{\tilde{\nu}}, m_{\tilde{\nu}}, (m_{N^0})_i) \cos^2(\alpha - \beta) \right. \\ &\quad \left. + I_4(m_H, m_{\tilde{\nu}}, m_{\tilde{\nu}}, (m_{N^0})_i) \sin^2(\alpha - \beta) - I_4(m_A, m_{\tilde{\nu}}, m_{\tilde{\nu}}, (m_{N^0})_i) \right), \end{aligned} \quad (8)$$

where m_Z is the Z boson mass, θ_W is the Weinberg angle, and the m_h , m_H and m_A are the light, heavy and pseudo-scalar Higgs boson masses, respectively. The unitary matrix U_0 diagonalizes the neutralino mass matrix as $(U_0^T M_{\chi^0} U_0)_{ij} = (m_{N^0})_i \delta_{ij}$, where $(m_{N^0})_i$ are the neutralino mass eigenvalues. $m_{\tilde{\nu}}$ is the mass of sneutrino field. α is the mixing angle in the CP-even Higgs sector. The function I_4 is given by

$$\begin{aligned} I_4(m_1, m_2, m_3, m_4) &= \frac{1}{m_1^2 - m_2^2} [I_3(m_1, m_3, m_4) - I_3(m_2, m_3, m_4)], \\ I_3(m_1, m_2, m_3) &= \frac{1}{m_1^2 - m_2^2} [I_2(m_1, m_3) - I_2(m_2, m_3)], \\ I_2(m_1, m_2) &= -\frac{1}{16\pi^2} \frac{m_1^2}{m_1^2 - m_2^2} \ln \frac{m_1^2}{m_2^2}. \end{aligned} \quad (9)$$

Since we have assumed degenerate masses for sneutrinos, the neutrino matrix in Eq. (7) generate only two non-zero masses, which is sufficient to explain the solar and atmospheric neutrino mass scales [6]. By taking the supersymmetric mass parameters to be few 100 GeV in a_0 and a_1 of Eq. (7), we can estimate the magnitudes of the unknown parameters ϵ_i and $(b_\epsilon)_i$, in order to have a neutrino mass scale of 0.1 eV. Taking into account of the partial cancellations of Higgs boson contributions in a_1 [12] of Eq. (7), for $\tan \beta \sim 10$, we get $\epsilon_i \lesssim 10^{-3}$ GeV and $(b_\epsilon)_i \sim 1$ GeV². As already described before, the estimated magnitudes of ϵ and b_ϵ are very small in order to explain the smallness of neutrinos masses, and in this work, we analyze if these estimated magnitudes are compatible with the Higgs to diphoton decay rate measured at the LHC.

2.2 Higgs to diphoton decay in the BRPVS model

We have already explained before that the BRPVS model is an extension of MSSM, where the additional terms are ϵ - and b_ϵ -terms of Eqs. (2) and (3), respectively. We have argued before that both the parameters ϵ and b_ϵ need to be very small in order to explain the

smallness of neutrino masses. As a result of this, in the BRPVS model, the masses and decay widths of Higgs boson states are almost same as that in the MSSM. The leading contribution to light Higgs boson mass up to 1-loop level is given by [21]

$$m_h^2 = m_Z^2 \cos^2 2\beta + \frac{3m_t^4}{4\pi^2 v^2} \ln \frac{M_S^2}{m_t^2} + \frac{3m_t^4 X_t^2}{4\pi^2 v^2 M_S^2} \left(1 - \frac{X_t^2}{12M_S^2}\right), \quad (10)$$

where m_t is the top quark mass, $M_S = \sqrt{m_{\tilde{t}_1} m_{\tilde{t}_2}}$ and $X_t = A_t - \mu/\tan\beta$, $A_t = (A_U)_{33}$. Here, $m_{\tilde{t}_{1,2}}$ are masses of the stops. The second and third terms in the above equation arise due to 1-loop corrections from top and stops. The tree level contribution to m_h is ≈ 91 GeV and in order to have $m_h \sim 125$ GeV, the loop contributions from top and stops should be substantially large. As a result of this, the light Higgs boson mass is dominantly determined by parameters in the squark sector and the top mass. These parameters do not play any role in determining the neutrino masses in the BRPVS model. However, to be consistent with the recent Higgs boson mass of ~ 125 GeV, the above mentioned parameters should be fixed accordingly in the BRPVS model. It is to remind that the loop contribution from top and stop would be maximum if $X_t = \sqrt{6}M_S$. This choice of parameter space is known as maximal mixing scenario [21]. In our analysis, which will be discussed below, we have considered the maximal mixing scenario in order to have $m_h \sim 125$ GeV.

On the other hand, in order to have enhancement in the Higgs to diphoton decay rate, the quantity defined in Eq. (1) has a role to play on neutrino masses. Since the dominant production for light Higgs boson at the LHC takes place through gluon fusion process, we reformulate $R_{\gamma\gamma}$ as

$$R_{\gamma\gamma} \approx \frac{[\Gamma(h \rightarrow gg) \times \text{BR}(h \rightarrow \gamma\gamma)]_{\text{MSSM}}}{[\Gamma(h \rightarrow gg) \times \text{BR}(h \rightarrow \gamma\gamma)]_{\text{SM}}}. \quad (11)$$

In the above expression, we have used $\sigma(gg \rightarrow h)$ to be proportional to the decay width $\Gamma(h \rightarrow gg)$. In the MSSM, the supersymmetric contribution to $\Gamma(h \rightarrow gg)$ is from squarks, while the decay width of $h \rightarrow \gamma\gamma$ gets supersymmetric contribution from squarks, charged sleptons, charged Higgs bosons and charginos. For complete expressions, up to leading order, for $\Gamma(h \rightarrow gg)$ and $\Gamma(h \rightarrow \gamma\gamma)$ in the SM as well as in MSSM, see Ref. [21].

A scan of parameter space in the MSSM has been done in [17] and it has been reported that to have $R_{\gamma\gamma} > 1$ the masses of staus should be light and the left-right mixing in the stau sector should be large. We will show later that $R_{\gamma\gamma}$ has some sensitivity to the CP-odd Higgs boson mass. The masses and mixing in the stau sector are determined by the parameters m_L^2 , m_R^2 , A_E , μ and $\tan\beta$. From the previous subsection, we can notice that the magnitudes of ϵ and b_e fix the neutrino mass eigenvalues in the BRPVS model. Apart

from this, the tree level neutrino masses are depended on the neutralino parameters. Also, the 1-loop contribution to neutrino masses are determined by the masses of neutralinos, sneutrinos and neutral Higgs bosons. It is to be noticed that the sneutrino masses are determined by the soft parameter m_L^2 .

In the previous paragraph we have explained how the neutrino masses in the BRPVS model are correlated with the $R_{\gamma\gamma}$. We have studied this correlation and in the next section we present our results. Apart from this correlation, one may also study additional bounds arising from vacuum stabilization [22], which we leave it for future studies.

3 Results

In this section we present our results on the correlation between neutrino masses and $R_{\gamma\gamma}$ in the BRPVS model. We divide this section into three parts. In Sec. 3.1 we describe the diagonalization procedure of the neutrino mass matrix of Eq. (7), from which we obtain expressions for neutrino mass eigenvalues in terms of model parameters. In Sec. 3.2 we illustrate our method of calculating the $R_{\gamma\gamma}$ by varying the model parameters. After scanning over model parameters, we can obtain the allowed parameter space of the BRPVS model, in order for the neutrino oscillation data to be compatible with $R_{\gamma\gamma} > 1$. As stated before that the LHC has not yet confirmed $R_{\gamma\gamma} > 1$, so we make brief comments about the possibility of $R_{\gamma\gamma} \leq 1$. From our numerical results we can see that the allowed values for ϵ and b_ϵ should be very small. We try to motivate the smallness of these values from a high scale physics, which we describe in Sec. 3.3.

3.1 Neutrino mass eigenvalues

After diagonalizing the neutrino mass matrix of Eq. (7), we should obtain mass eigenvalues as well as the mixing angles. The mixing angles are incorporated in the well known Pontecorvo-Maki-Nakagawa-Sakata unitary matrix, U_{PMNS} , which is the diagonalizing matrix of Eq. (7). We parametrize the U_{PMNS} as it is suggested in [23]. Among the three neutrino mixing angles, θ_{12} and θ_{23} are found to be large, whereas, the third mixing angle θ_{13} is non-zero and is relatively small [24]. From the recent global fit to various neutrino oscillation data [25], we can still choose tri-bimaximal values for θ_{12} and θ_{23} [26]. Hence, we take $\sin \theta_{12} = \frac{1}{\sqrt{3}}$, $\sin \theta_{23} = \frac{1}{\sqrt{2}}$. As for the $\sin \theta_{13}$, at 3σ level, its fitted value can be between 0.13 to 0.18 [25]. In our analysis we take $\sin \theta_{13}$ to be anywhere in this 3σ range. For simplicity, we assume the Dirac CP-odd phase, δ , and the Majorana phases to

be zero.

From the diagonalization of mass matrix in Eq. (7), we obtain the following relation

$$m_\nu = U_{\text{PMNS}}^* m_\nu^{\text{D}} U_{\text{PMNS}}^\dagger, \quad (12)$$

where $m_\nu^{\text{D}} = \text{Diag}(m_1, m_2, m_3)$ and $m_{1,2,3}$ are the mass eigenvalues of neutrinos. For a given set of neutrino mass eigenvalues and mixing angles, the above matrix equation can be solved, since it involves 6 relations in terms of 6 unknown parameters $(\epsilon_i, (b_\epsilon)_i)$. One possible solution to the above matrix equation is given in [27], in the limit of $s_{13} \equiv \sin \theta_{13} = 0$. Since, now it has been established that $s_{13} \neq 0$ [24], below we describe an approximate way of solving the above matrix relation. Although $s_{13} \neq 0$, from the previous paragraph we can see that $s_{13} \sim 0.1$ and hence higher powers of s_{13} are at least one order of magnitude smaller than that of s_{13} . Based on this observation, we can expand $\cos \theta_{13} = \sqrt{1 - s_{13}^2} \approx 1 - \frac{1}{2}s_{13}^2 + \dots$. Using this expansion and also fixing the θ_{12} and θ_{23} to their tri-bimaximal values, we can expand U_{PMNS} in the following way.

$$\begin{aligned} U_{\text{PMNS}} &= U_0 + U_1 s_{13} + U_2 s_{13}^2 + \dots, \\ U_0 &= \begin{pmatrix} \sqrt{\frac{2}{3}} & \frac{1}{\sqrt{3}} & 0 \\ -\frac{1}{\sqrt{6}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{3}} & \frac{1}{\sqrt{2}} \end{pmatrix}, \quad U_1 = \begin{pmatrix} 0 & 0 & 1 \\ -\frac{1}{\sqrt{3}} & -\frac{1}{\sqrt{6}} & 0 \\ -\frac{1}{\sqrt{3}} & -\frac{1}{\sqrt{6}} & 0 \end{pmatrix}, \\ U_2 &= \begin{pmatrix} -\frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{12}} & 0 \\ 0 & 0 & -\frac{1}{\sqrt{8}} \\ 0 & 0 & -\frac{1}{\sqrt{8}} \end{pmatrix}. \end{aligned} \quad (13)$$

From the above expansion of U_{PMNS} , we can realize that the right hand side of Eq. (12) can be expressed as a power series in terms of s_{13} . Such a matrix relation in Eq. (12) can be solved if we also express the left hand side of it in a similar power series expansion. Hence, we may propose the following series expansions for ϵ_i and $(b_\epsilon)_i$.

$$\begin{aligned} \epsilon_i &= \epsilon_{i,0} + \epsilon_{i,1} s_{13} + \epsilon_{i,2} s_{13}^2 + \dots, \\ (b_\epsilon)_i &= (b_\epsilon)_{i,0} + (b_\epsilon)_{i,1} s_{13} + (b_\epsilon)_{i,2} s_{13}^2 + \dots. \end{aligned} \quad (14)$$

Here, we can assume that the coefficients $\epsilon_{i,0}$, $\epsilon_{i,1}$, $\epsilon_{i,2}$, etc in the expansion for ϵ_i have same order of magnitude to one another. This also applies to the coefficients in the power series expansion for $(b_\epsilon)_i$. Below we show one solution for Eq. (12), where we solve ϵ_i and $(b_\epsilon)_i$ up to $\mathcal{O}(s_{13})$.

Plugging Eq. (14) in Eq. (12), up to $\mathcal{O}(s_{13})$, we get the following relations.

$$[U_0 m_\nu^D U_0^T]_{ij} = a_0 \epsilon_{i,0} \epsilon_{j,0} + a_1 (b_\epsilon)_{i,0} (b_\epsilon)_{j,0}, \quad (15)$$

$$[U_0 m_\nu^D U_1^T + U_1 m_\nu^D U_0^T]_{ij} = a_0 (\epsilon_{i,0} \epsilon_{j,1} + \epsilon_{i,1} \epsilon_{j,0}) + a_1 ((b_\epsilon)_{i,0} (b_\epsilon)_{j,1} + (b_\epsilon)_{i,1} (b_\epsilon)_{j,0}). \quad (16)$$

One solution to the matrix relation in Eq. (15) is given below [27]

$$\begin{aligned} \epsilon_{1,0} = 0, \epsilon_{2,0} = \epsilon_{3,0} = \epsilon, \quad (b_\epsilon)_{1,0} = (b_\epsilon)_{2,0} = -(b_\epsilon)_{3,0} = b_\epsilon, \\ m_1 = 0, \quad m_2 = 3a_1 (b_\epsilon)^2, \quad m_3 = 2a_0 \epsilon^2. \end{aligned} \quad (17)$$

As already described before, we can understand that m_3 and m_2 are determined by tree level and 1-loop level contributions, respectively, to the neutrino masses in the BRPVS model. The mass eigenvalue m_1 has come out be zero, since we have assumed degenerate masses for sneutrinos. Using the solution at leading order in Eq. (17), we can reduce the six independent relations of Eq. (16) into five, which are shown below.

$$\begin{aligned} (b_\epsilon)_{1,1} = 0, \quad (b_\epsilon)_{2,1} = (b_\epsilon)_{3,1}, \quad \epsilon_{2,1} = -\epsilon_{3,1}, \\ -\frac{m_2 - 3m_3}{3\sqrt{2}} = a_0 \epsilon \epsilon_{1,1} + a_1 b_\epsilon (b_\epsilon)_{2,1}, \quad -\frac{m_2}{3\sqrt{2}} = a_0 \epsilon \epsilon_{2,1} + a_1 b_\epsilon (b_\epsilon)_{2,1} \end{aligned} \quad (18)$$

The last two relations of Eq. (18) can be solved for infinitesimally many possible values of $\epsilon_{1,1}$, $\epsilon_{2,1}$ and $(b_\epsilon)_{2,1}$. We obtain one simple solution by choosing $\epsilon_{2,1} = 0$. As a result of this, for the given set of neutrino mixing angles which we have described above, a solution to the matrix relation of Eq. (12), solved up to $\mathcal{O}(s_{13})$, is

$$\begin{aligned} \epsilon_1 = \epsilon[\sqrt{2}s_{13} + \mathcal{O}(s_{13}^2)], \quad \epsilon_2 = \epsilon[1 + \mathcal{O}(s_{13}^2)], \quad \epsilon_3 = \epsilon[1 + \mathcal{O}(s_{13}^2)], \quad (b_\epsilon)_1 = b_\epsilon[1 + \mathcal{O}(s_{13}^2)], \\ (b_\epsilon)_2 = b_\epsilon[1 - \frac{1}{\sqrt{2}}s_{13} + \mathcal{O}(s_{13}^2)], \quad (b_\epsilon)_3 = b_\epsilon[-1 - \frac{1}{\sqrt{2}}s_{13} + \mathcal{O}(s_{13}^2)]. \end{aligned} \quad (19)$$

Here, ϵ and b_ϵ determine the non-zero neutrino mass eigenvalues of the BRPVS model, which are given in Eq. (17). We believe the procedure described above can be extended to solve ϵ_i and $(b_\epsilon)_i$ up to second and higher order powers of s_{13} .

3.2 Computation of Higgs to diphoton decay rate

As already explained that the Higgs to diphoton decay rate and the masses of scalar Higgs bosons in the BRPVS model are almost same as that in the MSSM. The enhancement related to this decay rate, as quantified in Eq. (11), and also the masses of Higgs bosons have been computed with the HDECAY code [28]. In our numerical analysis, we have fixed off-diagonal elements of soft mass-squared and A -terms of Eq. (4) to be zero,

which is also incorporated in the HDECAY code. In order to have the light Higgs boson mass to be around 125 GeV, we have fixed $(m_Q^2)_{33} = (m_U^2)_{33} = (m_D^2)_{33} = (800 \text{ GeV})^2$, $(A_U)_{33} = \sqrt{6(m_Q^2)_{33} + \mu \cot \beta}$ and $(A_D)_{33} = 0$. The specific choice for $(A_U)_{33}$ has been motivated by the maximal mixing in the stop sector [21]. We have fixed the top quark mass to be 173.2 GeV. We have not changed the above parameters, since they do not affect the neutrino masses in the BRPVS model. Indeed, for the above set of parameters in the squark sector, we have almost got $m_h \sim 125 \text{ GeV}$, by varying the other parameters in the model. As explained before, the neutrino masses in the BRPVS model are determined by neutralino parameters $(M_1, M_2, \mu, \tan \beta)$ and by the masses of neutral Higgs bosons and sneutrinos. We have chosen $M_1 = \frac{5}{3} \tan^2 \theta_W M_2$ and we have varied M_2 from 100 GeV to 1 TeV in steps of 100 GeV. As mentioned before that in order to have $R_{\gamma\gamma} > 1$, the mixing in the stau sector should be large, which is determined by $\mu, \tan \beta$ and $(A_E)_{33}$. In our analysis, we have varied μ from 100 GeV to 2 TeV in steps of 50 GeV and $\tan \beta$ has been varied from 5 to 60 in steps of 5. We have fixed $(A_E)_{33} = 0$. As explained before, while solving for the neutrino mass eigenvalues, we have assumed degenerate masses for sneutrinos. This would imply that $(m_L^2)_{ij} = m_L^2 \delta_{ij}$. For right-handed slepton masses, we have assumed $(m_E^2)_{ij} = m_E^2 \delta_{ij}$ and we have fixed $m_L^2 = m_E^2$. We vary the parameters m_L and m_A , which determine the sneutrino mass as well as the masses of CP-odd and heavy Higgs bosons.

In the previous paragraph we have specified parameters of the model in order to compute m_h and $R_{\gamma\gamma}$. In fact, for fixed values of m_L and m_A , we scan over the neutralino parameters. In the scanning procedure, we have demanded that some constraints need to be satisfied. Among these, we have applied constraint from the muon anomalous magnetic moment, $(g - 2)_\mu$ [29]. The current world average value of $(g - 2)_\mu$ differs from its corresponding SM value by about 3σ [29]. This discrepancy in $(g - 2)_\mu$ is quantified by Δa_μ . In the MSSM, at 1-loop level, Δa_μ gets contribution from neutralino-charged slepton and chargino-sneutrino loops [30]. Since we have justified before that in the BRPVS model the additional parameters ϵ_i and $(b_\epsilon)_i$ are very small, hence the contribution to Δa_μ in the BRPVS model is almost same as that in the MSSM. As a result of this, we have used the above mentioned loop contributions to Δa_μ [30] in our numerical analysis. Below we describe the four constraints which we have applied in our scanning procedure.

- (i) m_h should be in the range of 123 to 127 GeV,
- (ii) either $R_{\gamma\gamma} > 1$ or $R_{\gamma\gamma} \leq 1$,
- (iii) masses of sleptons should be greater than 100 GeV,

(iv) Δa_μ should be in the range of $(1.1 - 4.7) \times 10^{-9}$.

The constraints (i), (iii) and (iv) have been applied in every case. Regarding the constraint (ii), we will specifically mention below whether $R_{\gamma\gamma} > 1$ or $R_{\gamma\gamma} \leq 1$ has been applied. For those points in the parameter space which satisfy the above four constraints, we calculate ϵ and b_ϵ which determine the neutrino masses through Eq. (17). We have chosen the following values for neutrino mass eigenvalues in order to be consistent with the neutrino oscillation data [6]:

$$m_1 = 0, \quad m_2 = \sqrt{\Delta m_{\text{sol}}^2}, \quad m_3 = \sqrt{\Delta m_{\text{atm}}^2}. \quad (20)$$

Here, the solar and atmospheric mass scales (central values), from a global fit to neutrino oscillation data [25], are given as $\Delta m_{\text{sol}}^2 = 7.62 \times 10^{-5} \text{ eV}^2$ and $\Delta m_{\text{atm}}^2 = 2.55 \times 10^{-3} \text{ eV}^2$, respectively.

In Fig. 1 we have shown allowed values of ϵ and b_ϵ for different values of m_L and m_A . In Fig. 1(d) we have applied the constraint $R_{\gamma\gamma} \leq 1$, while in other plots of Fig. 1 the constraint $R_{\gamma\gamma} > 1$ has been applied. In Fig. 1(a) m_L has been kept to a very low value of 200 GeV, and in Figs. 1(b) and 1(c) $m_L = 300$ and 400 GeV, respectively. As explained earlier, the allowed points in these plots are satisfied by the requirement $R_{\gamma\gamma} > 1$. We have found that for $m_L = 150$ GeV, the constraint $R_{\gamma\gamma} > 1$ is not satisfied. From the plots of Fig. 1(a)–(c), we can notice that the most likely value of ϵ is $\gtrsim 0.01$ GeV. This value of ϵ is at least one order larger than its expected value from the neutrino masses, which is described at the end of Sec. 2.1. For $R_{\gamma\gamma} > 1$, the lowest value of ϵ can be found in Fig. 1(a), which is ≈ 0.007 GeV, and at these points M_2 should be as low as 100 GeV. On the other hand, in future, if LHC has not found any excess in the Higgs to diphoton decay rate, then from Fig. 4(d) we can notice that we can satisfy the neutrino oscillation data for ϵ between about 10^{-4} to 0.1 GeV. In Fig. 4(d) we have fixed $m_L = 400$ GeV. By decreasing m_L , the allowed space for ϵ and b_ϵ is slightly different from that of Fig. 4(d). Hence, from the measurement of Higgs to diphoton decay rate, if $R_{\gamma\gamma} > 1$ then ϵ should be at least $\sim 10^{-2}$ GeV. Otherwise, if $R_{\gamma\gamma} \leq 1$ then ϵ can be as low as $\sim 10^{-4}$ GeV.

From the plots of Fig. 1(a)–(c), we can notice that when we increase m_L by keeping m_A fixed, the average value of ϵ is increasing. By increasing m_L , the lower limit on $\tan \beta$ and μ will increase in the case of $R_{\gamma\gamma} > 1$, which we will describe below. As a result of this, the quantity a_0 of Eq. (8), which is inversely related to ϵ , will decrease.

In Sec. 2.1, from the neutrino mass scale we have estimated that b_ϵ is $\sim 1 \text{ GeV}^2$. In the case of $R_{\gamma\gamma} > 1$, from the plots of Fig. 1(a)–(c), we can notice that for $m_A \gtrsim 700$

Figure 1: Allowed values of ϵ and b_ϵ . In plots (a), (b) and (c) we have fixed $m_L = 200$, 300 and 400 GeV, respectively, and we have applied $R_{\gamma\gamma} > 1$. In plot (d), $R_{\gamma\gamma} \leq 1$ has been applied and $m_L = 400$ GeV. In each of these plots red, green and blue color points represent $m_A = 1000$, 700 and 500 GeV, respectively.

GeV, b_ϵ can be in the range of 0.5 to 2 GeV^2 . For $R_{\gamma\gamma} > 1$, the lowest value of b_ϵ has been found to be about 0.05 GeV^2 , which can be seen in Fig. 1(c). In Fig. 1(d) we have $R_{\gamma\gamma} \leq 1$, and the allowed value of b_ϵ can be around 1 GeV^2 by appropriately choosing the m_A . For instance, if we have to achieve $\epsilon \sim 10^{-3}$ GeV and $b_\epsilon \sim 1$ GeV^2 , then m_A should be $\lesssim 500$ GeV.

In Figs. 1(a)–(c), for a given value of m_L , b_ϵ is increasing with m_A . The reason for this is that b_ϵ is inversely related to a_1 , and from Eq. (8) we can understand that a_1 decreases with m_A . Similarly, from Figs. 1(a)–(c), by keeping m_A fixed, we can notice that the average value of b_ϵ is decreasing with m_L . We will shortly explain below that by increasing m_L the lower limit on $\tan\beta$ and μ will increase in the case of $R_{\gamma\gamma} > 1$. Hence,

although the function I_4 of a_1 decreases with increasing m_L , the factor $\frac{1}{\cos^2 \beta}$ in a_1 will compensate this decrease, and the net result is that a_1 increases with m_L .

In Fig. 2 we have plotted allowed values of μ and $\tan \beta$. The points in Fig. 2(a) are allowed by the constraint $R_{\gamma\gamma} > 1$, whereas the points in Fig. 2(b) satisfy $R_{\gamma\gamma} \leq 1$. In the plots of Fig. 2 there are no allowed points for $\tan \beta = 5$. We have found that for such a low $\tan \beta$ the mass of light Higgs boson is below 123 GeV and hence do not satisfy the constraint (i). In Fig. 2(a), we can notice that by increasing the value of m_L , the

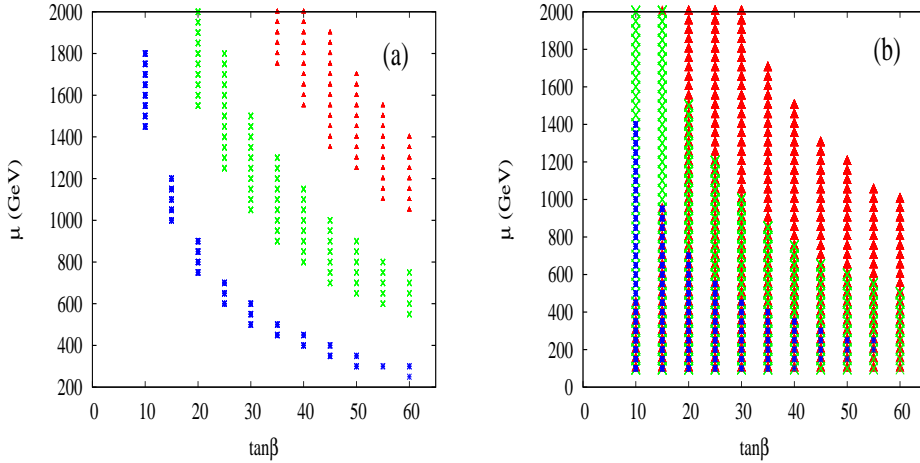

Figure 2: Allowed values of μ and $\tan \beta$ for $m_A = 1$ TeV. In plots (a) and (b) we have applied the constraints $R_{\gamma\gamma} > 1$ and $R_{\gamma\gamma} \leq 1$, respectively. The red, green and blue points are for $m_L = 400, 300$ and 200 GeV, respectively.

lower limit on μ and $\tan \beta$ would increase. We may understand this from the fact that the stau masses should be as light as possible, and moreover, the mixing in the stau sector should be large in order to have $R_{\gamma\gamma} > 1$ [17]. Hence, by increasing the soft mass m_L , the quantity $\mu \times \tan \beta$ should proportionately be increased in order to decrease the lightest stau mass and also to increase the mixing in the stau sector. From Fig. 2(a), we can notice that for a specific value of $\tan \beta$ the allowed value of μ lies in a certain range. We have seen that the lower and upper limits of this range are restricted by the constraints (ii) and (iii). For instance, for $m_L = 300$ GeV and $\tan \beta = 30$, the allowed range for μ is from 1050 to 1500 GeV. In this case, for $\mu < 1050$ GeV we may not satisfy $R_{\gamma\gamma} > 1$. On the other hand, for $\mu > 1500$ GeV the lightest stau mass becomes less than 100 GeV. In Fig. 2(a) we have fixed $m_A = 1$ TeV. By decreasing m_A , we have found that $\tan \beta$ is not restricted, however, for each $\tan \beta$ the corresponding lower limit on μ will increase. To illustrate this point, by considering the case of $m_A = 700$ GeV, $m_L = 300$ GeV and $\tan \beta$

$= 30$, the allowed range for μ has been found to be between 1150 to 1500 GeV. Hence, these results indicate that by decreasing m_A the $R_{\gamma\gamma}$ value will decrease.

As stated before, in Fig. 2(b) we have applied the constraint $R_{\gamma\gamma} \leq 1$. In this plot we can see that μ can be as low as 100 GeV. Numerically, we have noticed that $R_{\gamma\gamma}$ increases with μ and hence after a certain large value of μ , $R_{\gamma\gamma} \leq 1$ may not be satisfied. In the case of $m_L = 400$ GeV, in Fig. 2(b), for $\tan\beta = 10$ and 15, large values of μ are not allowed by the constraint (iv). In fact, allowed points in Fig. 2(b) indicate that $R_{\gamma\gamma} \leq 1$ can be satisfied for large $\tan\beta$ and relatively large μ values. For these large values of μ and $\tan\beta$, the calculated values of ϵ can be as high as 0.1 GeV, which can be seen in Fig. 1(d). For low $\tan\beta$ and moderate values of μ , ϵ can be $\lesssim 10^{-3}$ GeV.

In Fig. 3, we show the correlation between enhancement in the Higgs to diphoton decay rate ($R_{\gamma\gamma}$) and the bilinear parameter ϵ . From Figs. 3(a)–(c), we can observe that for a low value of $m_L = 200$ GeV, the maximum value for $R_{\gamma\gamma}$ is ≈ 1.1 . As noted before, in the case of $R_{\gamma\gamma} > 1$, the lowest value of ϵ is ≈ 0.007 GeV, which is found for $m_L = 200$ GeV. For this lowest value of ϵ the $R_{\gamma\gamma}$ value is barely greater than 1.0. From Figs. 3(a)–(c), we can notice that the maximum value of $R_{\gamma\gamma}$ is increasing with m_L . We have stated before that by increasing m_L , the values of μ and $\tan\beta$ would increase. For large values of μ and $\tan\beta$, the coupling strengths of staus to the light Higgs boson would increase [17]. As a result of this, $R_{\gamma\gamma}$ is increasing with m_L . The maximum values of $R_{\gamma\gamma}$ in Figs. 3(b) and 3(c) are 1.41 and 1.92 respectively. We may increase $R_{\gamma\gamma}$ to more than 2.0 by increasing m_L to 500 GeV. But in order to have large mixing and lower masses in the stau sector, we have to proportionately increase μ and $\tan\beta$. In this work we have scanned μ and $\tan\beta$ up to 2 TeV and 60, respectively, and have not considered cases of $m_L \geq 500$ GeV. However, from the above mentioned arguments, for $R_{\gamma\gamma} > 1$, we can speculate that by increasing m_L to 500 GeV the value of ϵ would be around 0.1 GeV.

In Fig. 3(d), we have applied the constraint $R_{\gamma\gamma} \leq 1$. We can notice from this plot that for $\epsilon \sim 10^{-3}$ GeV, $R_{\gamma\gamma}$ is different for different values of m_A . From this perspective we can argue that, if $R_{\gamma\gamma} \leq 1$ is found to be true, then a precise measurement of $R_{\gamma\gamma}$ can be used to determine ϵ and m_A .

3.3 Smallness of ϵ and b_ϵ

In this subsection, we try to motivate the smallness of ϵ and b_ϵ from a high scale physics. Essentially we will explore what the Higgs to diphoton decay rate can tell us about the high scale physics parameters. As it is noted in [14], by assuming supersymmetry breaking at

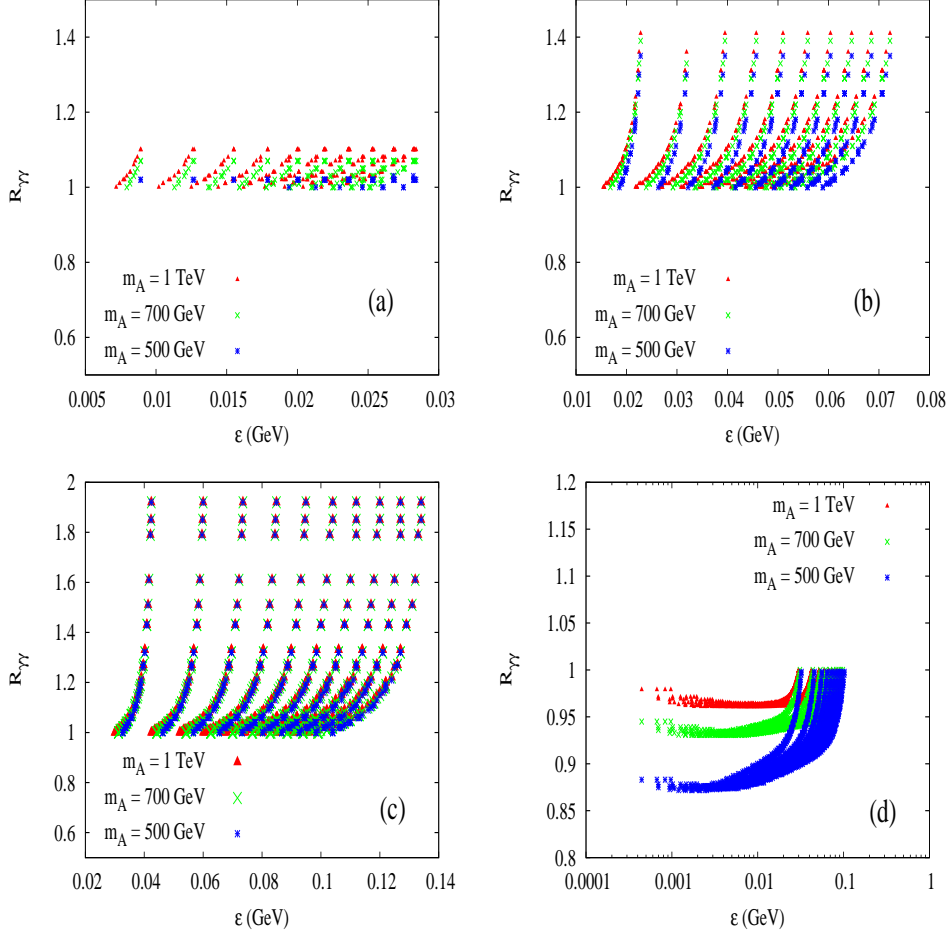

Figure 3: Allowed values of ϵ versus $R_{\gamma\gamma}$. In the plots (a), (b) and (c), the value of $m_L = 200, 300$ and 400 GeV, respectively. In these plots we have applied the constraint $R_{\gamma\gamma} > 1$. In plot (d), $m_L = 400$ GeV and the constraint $R_{\gamma\gamma} \leq 1$ has been applied. In each of these plots red, green and blue color points represent $m_A = 1000, 700$ and 500 GeV, respectively.

an intermediate energy scale $\Lambda \sim 10^{11}$ GeV, we can explain the μ -parameter, soft terms in scalar potential as well as ϵ - and b_ϵ - terms. Here we briefly describe important ingredients from Ref. [14]. By introducing SM gauge singlet superfields \hat{S} , \hat{X}_1 and \hat{X}_2 , we may write the superpotential as

$$W = \Lambda^2 \hat{S} + \frac{1}{M_P} \hat{X}_1^3 \hat{X}_2 + \frac{\hat{X}_1^2}{M_P} \hat{H}_u \hat{H}_d + \frac{\hat{X}_2^3}{M_P^2} \hat{L} \hat{H}_u + \dots \quad (21)$$

Here, $M_P = 2.4 \times 10^{18}$ GeV is the Planck scale. There can be $\mathcal{O}(1)$ couplings in the above terms, which we have neglected. In the above equation we have written only the necessary terms for our purpose, and these terms can be justified by introducing additional symmetries, say gauged $U(1)'$. \hat{S} must be singlet under this additional $U(1)'$, but $\hat{X}_{1,2}$ can be charged under $U(1)'$. The vevs of the scalar components of these SM gauge singlet superfields can be arranged as [14]: $\langle S \rangle \sim M_P$, $\langle X_{1,2} \rangle = \Lambda_{1,2} \sim \Lambda$. The first term of Eq. (21) breaks supersymmetry spontaneously by acquiring an auxiliary vev to \hat{S} which is of the order of Λ^2 . This auxiliary vev can generate soft terms in the scalar potential with mass parameters $m_{\text{soft}} \sim \frac{\Lambda^2}{M_P}$. Here, the generation of soft terms in the scalar potential is based on the Polonyi mechanism [31]. The scalar vevs of $\hat{X}_{1,2}$ generate the μ - and ϵ -parameters which are $\mu \sim \frac{\Lambda_1^2}{M_P}$ and $\epsilon \sim \frac{\Lambda_2^3}{M_P^2}$. Here, we have followed the Kim-Nilles mechanism for the generation of μ -term [32]. The auxiliary vevs of $\hat{X}_{1,2}$ can generate b_μ and b_ϵ which are $b_\mu \sim \frac{\Lambda_1^3 \Lambda_2}{M_P^2}$ and $b_\epsilon \sim \frac{\Lambda_1^3 \Lambda_2^2}{M_P^3}$.

In the previous paragraph, we have given motivation for the generation of ϵ and b_ϵ parameters as well as other supersymmetric parameters from a high scale physics. Now we have to fix the high scale physics parameters in order to fit the low energy data. Since we expect $m_{\text{soft}} \sim \mu \sim \text{TeV}$, for $\Lambda \sim \Lambda_1 \sim 0.5 \times 10^{11}$ GeV we can explain the TeV scale masses for supersymmetric fields. If we take $\Lambda_2 \sim 10^{11}$ GeV we can get $\epsilon \sim 10^{-3}$ GeV. From Figs. 1 and 3, we can say that a value of $\epsilon \sim 10^{-3}$ GeV is consistent with $R_{\gamma\gamma} \leq 1$. In order to achieve $R_{\gamma\gamma} > 1$, ϵ should be $\gtrsim 0.01$ GeV. Hence, by taking $\Lambda_2 \sim 3.9 \times 10^{11}$ GeV we can get $\epsilon \sim 10^{-2}$ GeV. So, if $R_{\gamma\gamma} > 1$ then there is a little hierarchy between Λ_1 and Λ_2 , otherwise, this hierarchy can be reduced.

In future, if LHC has found that $R_{\gamma\gamma}$ is significantly larger than 1.0, then from Figs. 3(a)–(c) we can say that m_L should be larger than about 300 GeV. For m_L between 300 to 400 GeV, from Figs. 1(b) and 1(c) we can have $b_\epsilon \sim 1 \text{ GeV}^2$, provided m_A is $\gtrsim 700$ GeV. Now, for $\Lambda_1 \sim 0.5 \times 10^{11}$ GeV and $\Lambda_2 \sim 3.9 \times 10^{11}$ GeV, we can get $b_\mu \sim 8 \text{ TeV}^2$ and $b_\epsilon \sim 1 \text{ GeV}^2$. Hence, for the case of $R_{\gamma\gamma} > 1$, we can motivate consistent supersymmetric mass spectrum and 0.1 eV scale for neutrino masses from a high scale

physics by proposing two different intermediate scales. The hierarchy between these two scales should be at least 8.

If there is no enhancement in the Higgs to diphoton decay rate, from Fig. 1(d), we can notice that ϵ can be between $\sim 10^{-3}$ to 0.1 GeV. From the above discussion, to achieve $\epsilon \sim 0.1$ GeV from high scale physics, there need to be little hierarchy between the intermediate scales $\Lambda_{1,2}$. This hierarchy can be minimal for $\epsilon \sim 10^{-3}$ GeV. For $\epsilon \sim 10^{-3}$ GeV, in Fig. 1(d), b_ϵ can be around 1 GeV² if $m_A \sim 500$ GeV. For this set of values, from Fig. 3(d), we can notice that $R_{\gamma\gamma}$ is little less than 0.9. Hence, if we believe in the motivation of ϵ and b_ϵ from high scale physics, the high energy scales in this scenario depend on the value of $R_{\gamma\gamma}$. Moreover, in the above described analysis, we can also estimate m_L and m_A by knowing the $R_{\gamma\gamma}$. So the future runs at the LHC can give us clue about this scenario by precisely finding the $R_{\gamma\gamma}$.

We make short comments about measuring the parameters ϵ and b_ϵ in experiments. Since both these parameters indicate that R-parity is violated, a consequence of that is that the lightest supersymmetric particle (LSP) is unstable. Depending on the parameter space, either the lightest neutralino or the lightest charged slepton can be the LSP in this model [16]. The decay life time of LSP is determined by ϵ and b_ϵ . Hence the signals of the decay of LSP in this model should give an indication about these bilinear parameters [16], from which we can verify the neutrino mass mechanism and also its correlation to the Higgs to diphoton decay rate.

4 Conclusions

Recently the LHC has discovered a Higgs-like particle whose mass is around 125 GeV. It has also been indicated that there is an enhancement in the Higgs to diphoton decay rate as compared to that in the SM. We have studied implications of these discoveries in the BRPVS model. This model is a minimal extension of the MSSM where the bilinear terms $\epsilon \hat{L} \hat{H}_u$ and $b_\epsilon \tilde{L} H_u$ are added to the superpotential and scalar potential of the model, respectively. The main objective of this model is to explain the smallness of neutrino masses, where the neutrino mass eigenvalues can be shown to be dependent on neutralino parameters, soft mass for charged sleptons (m_L) and CP-odd Higgs boson mass (m_A) [11, 12], apart from the bilinear parameters ϵ and b_ϵ .

In our analysis, we have scanned over the neutralino parameters and varied m_L and m_A accordingly. We have also fixed the soft masses for third generation squarks, in order to have light Higgs boson mass to be around 125 GeV. We then have studied implications of

enhancement in the Higgs to diphoton decay rate ($R_{\gamma\gamma}$) in the BRPVS model. Explicitly we have found that in order to be compatible with $R_{\gamma\gamma} > 1$ and the neutrino oscillation data, the unknown bilinear parameter should be $\epsilon \gtrsim 10^{-2}$ GeV. We have also found that to achieve $R_{\gamma\gamma}$ between about 1.5 to 2.0, m_L should be between 300 to 400 GeV, provided μ and $\tan\beta$ are scanned up to 2 TeV and 60 respectively. We have not obtained specific bounds on m_A . However, from the order of estimations we expect b_ϵ to be around 1 GeV² and to achieve this with the above mentioned m_L , m_A can be in the range of 700 to 1000 GeV.

Since $R_{\gamma\gamma} > 1$ is not yet confirmed by LHC, we have also analyzed the case of $R_{\gamma\gamma} \leq 1$. In this later case, we have found that ϵ can be between $\sim 10^{-3}$ to 0.1 GeV. The corresponding b_ϵ can be around 1 GeV² by appropriately choosing m_A to be from 500 to 1000 GeV. Moreover, we have also found that $R_{\gamma\gamma}$ can be as low as 0.85.

From the above discussion, we can notice that ϵ and b_ϵ need to be very small in GeV units. We have motivated smallness of these two parameters from a high scale physics, and at the same time we have also explained the TeV scale masses for supersymmetric fields. We have found that to explain $\epsilon \sim 10^{-2}$ GeV and $b_\epsilon \sim 1$ GeV² there need to be two different intermediate scales ($\sim 10^{11}$ GeV) with a hierarchy of factor of 8 between them.
