(Dated: February 29, 2024)

It is shown that the strong Coulomb coupling in intrinsic suspended semiconducting transition metal dichalcogenides can exceed the critical value needed for an excitonic ground state. The dipole-allowed optical excitations then correspond to intra-excitonic transitions such that the optically bright excitonic transitions near the Dirac points have a p -like symmetry whereas the s -like states are dipole forbidden. The large intrinsic coupling strength seems to be a generic property of the semiconducting transition metal dichalcogenides and strong Coulomb-coupling signatures in the form of the optical selection rules can be observed even in samples grown on typical substrates like SiO_2 . For the examples of WS_2 and WSe_2 , excellent agreement of the computed excitonic resonance energies with recent experiments is demonstrated.

INTRODUCTION

Monolayers of transition metal dichalcogenides (TMDs) are novel two-dimensional (2D) semiconductors. Similar to graphene, these materials display exciting new physical properties, distinct from their bulk counterparts[1–14]. The linear optical spectra are dominated by strong resonances with peak absorption values of more than 10% of the incoming light. Furthermore, the absence of inversion symmetry allows for efficient second harmonic generation (SHG). Though initially assigned to free-particle transitions, meanwhile the excitonic nature of the strong optical response is widely accepted. On the basis of recent linear and nonlinear optical experiments on WS_2 [1-3], the respective authors report large binding energies for the energetically lowest, optically bright excitons ranging from 0.32-0.71 eV. At the same time, strong deviations from the usual hydrogenic Rydberg series are observed. Due to the difficulty to directly measure the single-particle bandgap energy, the binding energies have been deduced either from the energetic separation between different resonances or by the comparison with theoretical predictions.

In general, the proper analysis of the measured spectra depends critically on the correct identification of the optically active states. For this purpose, one derives optical selection rules that result from the conservation of the total angular momentum in the excitation and emission processes. The Γ -point transitions in conventional direct-gap GaAs-type semiconductors occur between the sp^3 -hybridized near-parabolic s -like conduction and p -like valence bands. The near-bandgap optical properties are well described by the so-called Elliot formula[15], expressing the energetic position and oscillator strength of the excitonic transitions in terms of the excitonic wave functions. As a result of the simple dipole selection rules, only s -like excitonic states couple to the light field. This leads to the well-known excitonic Rydberg series where the lowest optical active state is the $1s$ exciton resonance.

The derivation of the Elliot formula[15] is based on the implicit assumption that the system is excited from the non-interacting ground state. In contrast, if one considers an excitonic insulator[16–20], the ground state itself is excitonic and light absorption or emission involves intra-excitonic transitions that are governed by fundamentally different optical

selection rules. The energetically lowest transition from an $1s$ -type excitonic ground state will lead to optically excited p -type excitons.

In this paper, we present strong evidence that not only for suspended TMDs, but also for TMDs on a SiO_2 substrate, the optically active states correspond to the p -type excited states of a two-dimensional (2D) hydrogenic Rydberg series, while the lowest lying $1s$ -exciton is merged with the ground-state level. Our predictions are based on the analysis of the Hamiltonian for 2D massive Dirac Fermions with Coulomb interaction. To support our theory, we compare its predictions with recent experiments on WS_2 [13, 14, 27] and WSe_2 [28], demonstrating that the assumption of bright p -states allows for a simple interpretation of a wide range of different experimental results.

MICROSCOPIC THEORY

Starting point of our analysis is the low-energy Hamiltonian for the bandstructure in the vicinity of the Dirac-points. Dictated by the symmetry properties of the hexagonal lattice, the lowest order $\mathbf{k} \cdot \mathbf{p}$ Hamiltonian has the form[7]

$$H_0 = \sum_{\tau, \mathbf{k}} \hat{\Psi}_{\tau \mathbf{k}}^\dagger \left(at\mathbf{k} \cdot \hat{\sigma}_\tau + \frac{\Delta}{2} \hat{\sigma}_z - \tau \lambda \frac{\hat{\sigma}_z - 1}{2} \hat{s}_z \right) \hat{\Psi}_{\tau \mathbf{k}}, \quad (1)$$

where $\tau = \pm 1$ is the so-called valley index identifying the two non-equivalent Dirac points, and $\hat{\Psi}_{\tau \mathbf{k}}^\dagger$ is the tensor product of the electron spin state and a two-component quasi-spinor. The Pauli matrices $\hat{\sigma}_\tau = (\tau \hat{\sigma}_x, \hat{\sigma}_y)$ and $\hat{\sigma}_z$ act in the pseudo-spin space and \hat{s}_z in the real spin space, respectively. The basis functions for the pseudo-spinors are a linear combination of the relevant atomic orbitals that contribute to the valence and conduction bands and depend on the specific material system under consideration. Within a tight-binding model, the parameters Δ , t and a correspond to the bias in on-site energies, the effective hopping matrix element, and the lattice constant, respectively. Furthermore, 2λ is the spin-splitting of the valence band due to the intra-atomic spin-orbit coupling (SOC). The Hamiltonian (1) is valid for the entire class of monolayer hexagonal structures including graphene with a zero gap and

negligible SOC, h-BN with a large gap and also negligible SOC, and the variety of TMDs with a gap in the optical range and strong SOC.

Independent of the explicit expressions for the pseudospinor basis functions, the Hamiltonian describing the light-matter (LM) interaction can be found by the minimal substitution $\hbar\mathbf{k} \rightarrow \hbar\mathbf{k} - e\mathbf{A}/c$. Defining the Fermi velocity by

$v_F = at/\hbar$, one obtains

$$H_I = -e \frac{v_F}{c} \sum_{\tau, \mathbf{k}} \hat{\Psi}_{\tau\mathbf{k}}^\dagger \mathbf{A} \cdot \hat{\sigma}_\tau \hat{\Psi}_{\tau\mathbf{k}}. \quad (2)$$

Using the eigenstates of H_0 , the LM Hamiltonian can be written as

$$H_I = -e \frac{v_F}{c} \sum_{s\tau\mathbf{k}} \frac{\hbar v_F k}{2\epsilon_{s\tau\mathbf{k}}} (e^{-i\tau\theta_{\mathbf{k}}} A^\tau + e^{i\tau\theta_{\mathbf{k}}} A^{-\tau}) (c_{s\tau\mathbf{k}}^\dagger c_{s\tau\mathbf{k}} - \nu_{s\tau\mathbf{k}}^\dagger \nu_{s\tau\mathbf{k}}) \\ + e \frac{v_F}{c} \sum_{s,\tau,\mathbf{k}} \frac{1}{2\epsilon_{s\tau\mathbf{k}}} \left\{ \left((\epsilon_{s\tau\mathbf{k}} - \frac{\Delta_{s\tau}}{2}) e^{-i\tau\theta_{\mathbf{k}}} A^\tau - (\epsilon_{s\tau\mathbf{k}} + \frac{\Delta_{s\tau}}{2}) e^{i\tau\theta_{\mathbf{k}}} A^{-\tau} \right) c_{s\tau\mathbf{k}}^\dagger \nu_{s\tau\mathbf{k}} + h.c. \right\}. \quad (3)$$

Here, $c_{s\tau\mathbf{k}}^\dagger$ ($\nu_{s\tau\mathbf{k}}^\dagger$) creates an electron with spin s and valley index τ in the conduction (valence) band, $\Delta_{s\tau} = \Delta - s\tau\lambda$ is the spin and valley dependent gap, $\epsilon_{s\tau\mathbf{k}} = \sqrt{(\frac{\Delta_{s\tau}}{2})^2 + (\hbar v_F k)^2}$ is the relativistic dispersion of a quasi-particle with rest energy $m_{s\tau} v_F^2 = \Delta_{s\tau}/2$, $A^\tau = A_x + i\tau A_y$, and $\theta_{\mathbf{k}}$ is the angle in k -space defined by $\tan\theta_{\mathbf{k}} = \frac{k_y}{k_x}$.

In Eq. (3), the first line describes the intraband and the second line the interband transitions, respectively. Contributions proportional to A^τ correspond to the absorption of a photon with circular polarization σ^τ . In zero-gap materials like graphene or silicene, the transition matrix elements for both intra- and interband absorption are equal in magnitude. Differences in the transition probabilities exclusively result from the different occupation numbers in the initial state. In contrast, in a wide gap system, the leading orders of the transition matrix elements are given by $(\epsilon_{s\tau\mathbf{k}} - \frac{\Delta_{s\tau}}{2})/2\epsilon_{s\tau\mathbf{k}} \approx (\hbar v_F k)^2/\Delta_{s\tau}^2$, $\hbar v_F k/2\epsilon_{s\tau\mathbf{k}} \approx \hbar v_F/\Delta_{s\tau}$, and $(\epsilon_{s\tau\mathbf{k}} + \frac{\Delta_{s\tau}}{2})/2\epsilon_{s\tau\mathbf{k}} \approx 1$. Keeping only contributions up to first order in $\hbar v_F k/\Delta$ gives

$$H_I \approx -\frac{1}{c} \sum_{s\tau\mathbf{k}} \mathbf{A} \cdot \mathbf{j}_{s\tau\mathbf{k}} (c_{s\tau\mathbf{k}}^\dagger c_{s\tau\mathbf{k}} - \nu_{s\tau\mathbf{k}}^\dagger \nu_{s\tau\mathbf{k}}) \\ - e \frac{v_F}{c} \sum_{s\tau\mathbf{k}} \left\{ e^{i\tau\theta_{\mathbf{k}}} A^{-\tau} c_{s\tau\mathbf{k}}^\dagger \nu_{s\tau\mathbf{k}} + h.c. \right\}, \quad (4)$$

where the intraband contributions have been rewritten with the aid of the intraband current matrix element $\mathbf{j}_{s\tau\mathbf{k}} = -\frac{e}{\hbar} \nabla_{\mathbf{k}} \epsilon_{s\tau\mathbf{k}}$. From this simplified LM Hamiltonian, Eq. (4), one recognizes clearly that the valence-to-conduction-band excitations at the K^\pm valley require the absorption of a σ^\mp polarized photon, as has been shown by Xiao et al.[7].

The optically induced current can be obtained from the LM Hamiltonian via $\mathbf{j} = -c \langle \frac{\delta H_I}{\delta \mathbf{A}} \rangle$ and contains both intra- and interband transitions. From Eq. (4) it is clear that a finite macroscopic interband current requires an even part of the microscopic transition amplitudes $P_{s\tau\mathbf{k}} = e^{-i\tau\theta_{\mathbf{k}}} \langle \nu_{s\tau\mathbf{k}}^\dagger c_{s\tau\mathbf{k}} \rangle$, while intraband transitions contribute to the macroscopic current only if $g_{s\tau\mathbf{k}} = \langle \nu_{s\tau\mathbf{k}}^\dagger \nu_{s\tau\mathbf{k}} \rangle - \langle c_{s\tau\mathbf{k}}^\dagger c_{s\tau\mathbf{k}} \rangle$ contains an odd part.

The microscopic transition amplitudes $P_{s\tau\mathbf{k}}$ and the Pauli blocking factor $g_{s\tau\mathbf{k}}$ can be computed from the Heisenberg equations of motion yielding the semiconductor Bloch equations (SBE)[15]. Using Eq. (4) and the standard Coulomb interaction Hamiltonian, one obtains

$$i\hbar\partial_t P_{s\tau\mathbf{k}} = 2 \left(\Sigma_{s\tau\mathbf{k}} - \frac{1}{c} \mathbf{A} \cdot \mathbf{j}_{s\tau\mathbf{k}} \right) P_{s\tau\mathbf{k}} \\ - g_{s\tau\mathbf{k}} \left(\sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'} - e \frac{v_F}{c} A^{-\tau} \right), \quad (5)$$

$$i\hbar\partial_t g_{s\tau\mathbf{k}} = 2P_{s\tau\mathbf{k}}^* \left(\sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'} - e \frac{v_F}{c} A^{-\tau} \right) - c.\alpha(6)$$

where $\Sigma_{s\tau\mathbf{k}} = \epsilon_{s\tau\mathbf{k}} + \frac{1}{2} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} g_{s\tau\mathbf{k}'}$ denotes the renormalized single particle energy that includes the Coulomb renormalization of the band-gap.

Regime of weak Coulomb coupling

Assuming the noninteracting ground state as the initial state before optical excitation, the linear response SBE for the polarization is given by

$$i\hbar\partial_t P_{s\tau\mathbf{k}} = 2\Sigma_{s\tau\mathbf{k}} P_{s\tau\mathbf{k}} - \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'} - e \frac{v_F}{c} A^{-\tau}. \quad (7)$$

Since the populations are at least second order in the exciting field, we use $g_{s\tau\mathbf{k}} = 1$. The expansion into the eigenstates of the Wannier equation with the relativistic single-particle dispersion

$$2\Sigma_{s\tau\mathbf{k}} \phi_\mu^{s\tau}(\mathbf{k}) - \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \phi_\mu^{s\tau}(\mathbf{k}') = E_\mu^{s\tau} \phi_\mu^{s\tau}(\mathbf{k}) \quad (8)$$

yields

$$\chi^\sigma(\omega) = -\frac{e^2 v_F^2}{\omega^2} \sum_{s,\mu} \frac{\mathcal{F}_\mu^{s,-\sigma}}{\hbar(\omega + i\gamma) - E_\mu^{s,-\sigma}} \\ + \frac{e^2 v_F^2}{\omega^2} \sum_{s,\mu} \frac{\mathcal{F}_\mu^{s,\sigma}}{\hbar(\omega + i\gamma) + E_\mu^{s,\sigma}}. \quad (9)$$

for the linear susceptibility χ , describing the optical response via

$$j^\sigma = \frac{\omega^2}{c} \chi^\sigma(\omega) A^\sigma. \quad (10)$$

Here, the oscillator strength is given as $\mathcal{F}_\mu^{s,\tau} = |\sum_{\mathbf{k}} \phi_\mu^{s,\tau}(\mathbf{k})|^2$.

The fully relativistic Wannier equation (8) corresponds to the k -space representation of the Dirac Coulomb problem. In real space, the wave functions are two-component spinors[23, 24]

$$\hat{\Psi}_{jn}^{s\tau}(\mathbf{r}) = \begin{pmatrix} e^{i(j-\tau/2)\varphi} A_{jn}^{s\tau}(r) \\ e^{i(j+\tau/2)\varphi} B_{jn}^{s\tau}(r) \end{pmatrix}$$

obeying the wave equation

$$\left(2v_F \hat{\sigma} \cdot \mathbf{p} + \Delta_{s\tau} \hat{\sigma}_z - \frac{e^2}{r} \right) \Psi_{jn}^{s\tau}(\mathbf{r}) = E_{jn}^{s\tau} \Psi_{jn}^{s\tau}(\mathbf{r}). \quad (11)$$

Here j is the eigenvalue of the total angular momentum $\hat{L}_z + \frac{\tau}{2} \hat{\sigma}_z$, and n is the principle quantum number. We can identify the set of quantum numbers $\{\mu\} = (j, n)$ such that, e.g., an s -type wave function has $j = \pm 1/2$. The eigenfunctions $\phi_{jn}^{s\tau}$ of Eq. (8) correspond to the solutions of Eq. (11) with positive energy and are given by

$$\begin{aligned} \phi_{jn}^{s\tau}(\mathbf{k}) &= \sqrt{\frac{\epsilon_{s\tau\mathbf{k}} + \frac{\Delta_{s\tau}}{2}}{2\epsilon_{s\tau\mathbf{k}}}} e^{i(j-\tau/2)\theta_{\mathbf{k}}} A_{jn}^{s\tau}(k) \\ &+ \sqrt{\frac{\epsilon_{s\tau\mathbf{k}} - \frac{\Delta_{s\tau}}{2}}{2\epsilon_{s\tau\mathbf{k}}}} e^{i(j+\tau/2)\theta_{\mathbf{k}}} B_{jn}^{s\tau}(k) \\ &\approx e^{i(j-\tau/2)\theta_{\mathbf{k}}} A_{jn}^{s\tau}(k), \end{aligned} \quad (12)$$

while the solutions corresponding to negative energies are of no physical relevance here.

For the 2D Coulomb interaction potential, the eigenvalues of the relativistic hydrogen problem are given by[23, 24]

$$E_{nj}^{s\tau} = \Delta_{s\tau} \left\{ \frac{n + \sqrt{j^2 - \left(\frac{\alpha}{2}\right)^2}}{\sqrt{\left(\frac{\alpha}{2}\right)^2 + \left(n + \sqrt{j^2 - \left(\frac{\alpha}{2}\right)^2}\right)^2}} \right\}$$

with $n = 0, 1, \dots$ and $j = \pm 1/2, \pm 3/2, \dots$. Here, $\alpha = e^2/\kappa\hbar v_F$ is the coupling constant and κ is the effective dielectric constant of the environment. The eigenvalues are real for those j -values where $j^2 - (\frac{\alpha}{2})^2 \geq 0$. For small values of α , the eigenvalue spectrum reduces to that of the nonrelativistic Rydberg series

$$E_{nj}^{s\tau} = \Delta_{s\tau} - \alpha^2 \Delta_{s\tau} / 8(n + |j|)^2 = \Delta_{s\tau} - \alpha^2 \Delta_{s\tau} / 8(N - 1/2)^2$$

with $N = n + |j| + 1/2 = 1, 2, \dots$

From the expression (9) for the linear susceptibility, one can derive the exciton spectrum and optical selection rules

for dipole allowed optical transitions. At the poles of Eq. (9), the reflection and absorption spectra display resonances. The oscillator strength is a measure for the transition probability from the noninteracting groundstate to the excitonic state with quantum number μ .

Thus, we see that only excitonic transitions with s -type orbital angular momentum are dipole allowed. Furthermore, the resonant contributions for a given circular polarization component σ stem from the $K^{-\sigma}$ valley, while the nonresonant contributions stem from the K^σ valley. This opens the possibility of a valley selective excitation with circularly polarized light. Moreover, the dependence of the resonance energies $E_\mu^{s,\sigma}$ on the product of the spin and valley index couples the valley dynamics to the spin dynamics. Both effects have been predicted in 7–12 and demonstrated experimentally for various monolayers of TMDs.

Regime of Strong Coulomb Coupling

Interestingly, in the regime of strong Coulomb coupling characterized by $\alpha > 1$, the optical spectrum contains no s -type wave functions with $j = \pm 1/2$. In this case, total angular momentum conservation cannot be fulfilled for optical transitions from the noninteracting groundstate such that no one-photon transitions should be possible.

To check if any of the TMD systems can be in the regime of strong Coulomb coupling, we use the material parameters given in Ref. 7. Thus, we obtain the nominal values $\alpha = 3.29/\kappa$ for WS₂, $\alpha = 3.66/\kappa$ for WSe₂ and $\alpha = 4.11/\kappa$ for MoS₂ respectively. In free standing monolayers of TMDs, these values are very large and even on top of a typical substrate like SiO₂ with $\kappa = (3.9 + 1)/2$, the effective coupling exceeds the critical value. Thus, the assumption of a noninteracting ground state predicts the *absence of the one-photon optical transitions* for all of these systems, clearly contradicting the experimental findings.

However, in the regime of strong Coulomb coupling, the real part of the lowest exciton energy $E_{0\pm\frac{1}{2}}$ vanishes, i.e., it is degenerate with the noninteracting groundstate and the system transitions into an excitonic insulator state. This excitonic insulator state is a BEC-like condensate of excitons, i.e. a coherent superposition of the noninteracting groundstate and all exciton states with $\Re[E_\mu] = 0$ [16–20]. This state exhibits a static interband polarization $P_{s\tau\mathbf{k}}^{[0]} = \Omega_{s\tau\mathbf{k}}^{[0]} / 2\mathcal{E}_{s\tau\mathbf{k}}$ and static blocking factor $g_{s\tau\mathbf{k}}^{[0]} = \Sigma_{s\tau\mathbf{k}}^{[0]} / \mathcal{E}_{s\tau\mathbf{k}}$ that can be obtained as nontrivial solutions of the gap equations[25, 26]

$$\Omega_{s\tau\mathbf{k}}^{[0]} = \frac{1}{2} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \frac{\Omega_{s\tau\mathbf{k}'}^{[0]}}{\mathcal{E}_{s\tau\mathbf{k}'}} \quad (13)$$

$$\Sigma_{s\tau\mathbf{k}}^{[0]} = \epsilon_{s\tau\mathbf{k}} + \frac{1}{2} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \frac{\Sigma_{s\tau\mathbf{k}'}^{[0]}}{\mathcal{E}_{s\tau\mathbf{k}'}} \quad (14)$$

Here, $\mathcal{E}_{s\tau\mathbf{k}} = \sqrt{\Omega_{s\tau\mathbf{k}}^{[0]2} + \Sigma_{s\tau\mathbf{k}}^{[0]2}}$ is the dispersion of the Bogoliubov bands.

The static groundstate polarizations and populations induce a coupling between the linearized equations for the optical polarization and populations and add an additional source term to the equation of motion for the optical interband transition amplitude. Explicitly, we have

$$\begin{aligned} i\hbar\partial_t P_{s\tau\mathbf{k}}^{[1]} &= 2\Sigma_{s\tau\mathbf{k}}^{[0]} P_{s\tau\mathbf{k}}^{[1]} - g_{s\tau\mathbf{k}}^{[0]} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'}^{[1]} \\ &\quad + 2P_{s\tau\mathbf{k}}^{[0]} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} g_{s\tau\mathbf{k}'}^{[1]} - \Omega_{s\tau\mathbf{k}}^{[0]} g_{s\tau\mathbf{k}}^{[1]} \\ &\quad - e \frac{v_F}{c} g_{s\tau\mathbf{k}}^{[0]} A^{-\tau} - \frac{2}{c} \mathbf{A} \cdot \mathbf{j}_{s\tau\mathbf{k}} P_{s\tau\mathbf{k}}^{[0]}, \end{aligned} \quad (15)$$

$$i\hbar\partial_t g_{s\tau\mathbf{k}}^{[1]} = 2\Omega_{s\tau\mathbf{k}'}^{[0]} P_{s\tau\mathbf{k}}^{[1]*} + 2P_{s\tau\mathbf{k}}^{[0]*} \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'}^{[1]} - c.c. \quad (16)$$

As the additional source term is proportional to the intraband current matrixelement with odd parity, it mixes states with different parity. Though the odd terms of the linear interband polarization do not couple to the optical field directly, they serve as source terms for the optically induced intraband current. Eqs. (15) and (16) can be decoupled by the transformation

$$\begin{aligned} \Pi_{s\tau\mathbf{k}}^{[1]} &= \frac{\mathcal{E}_{s\tau\mathbf{k}} + \Sigma_{s\tau\mathbf{k}}^{[0]} P_{s\tau\mathbf{k}}^{[1]}}{\mathcal{E}_{s\tau\mathbf{k}}} - \frac{\mathcal{E}_{s\tau\mathbf{k}} - \Sigma_{s\tau\mathbf{k}}^{[0]} P_{s\tau\mathbf{k}}^{[1]*}}{\mathcal{E}_{s\tau\mathbf{k}}} - \frac{\Omega_{s\tau\mathbf{k}}^{[0]} g_{s\tau\mathbf{k}}^{[1]}}{\mathcal{E}_{s\tau\mathbf{k}}}, \\ \Gamma_{s\tau\mathbf{k}}^{[1]} &= \frac{\Omega_{s\tau\mathbf{k}}^{[0]}}{\mathcal{E}_{s\tau\mathbf{k}}} (P_{s\tau\mathbf{k}}^{[1]} + P_{s\tau\mathbf{k}}^{[1]*}) + \frac{\Sigma_{s\tau\mathbf{k}}^{[0]} g_{s\tau\mathbf{k}}^{[1]}}{\mathcal{E}_{s\tau\mathbf{k}}}, \end{aligned}$$

yielding

$$\begin{aligned} i\hbar\partial_t \Pi_{s\tau\mathbf{k}}^{[1]} &= 2\mathcal{E}_{s\tau\mathbf{k}}^{[0]} - \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \Pi_{s\tau\mathbf{k}'}^{[1]} \\ &\quad - 2e \frac{v_F}{c} g_{s\tau\mathbf{k}}^{[0]} A^{-\tau} - \frac{4}{c} \mathbf{A} \cdot \mathbf{j}_{s\tau\mathbf{k}} P_{s\tau\mathbf{k}}^{[0]}, \end{aligned} \quad (17)$$

$$i\hbar\partial_t \Gamma_{s\tau\mathbf{k}}^{[1]} = 0. \quad (18)$$

Hence, the solutions of Eq. (17) can be expanded in terms of the eigenfunctions of the Bogoliubov-Wannier equation

$$2\mathcal{E}_{s\tau\mathbf{k}} \psi_{\mu}^{s\tau}(\mathbf{k}) - \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \psi_{\mu}^{s\tau}(\mathbf{k}') = E_{\mu}^{s\tau} \psi_{\mu}^{s\tau}(\mathbf{k}'), \quad (19)$$

where the dispersion of the noninteracting bands has been replaced by the Bogoliubov quasi-particle dispersion. The groundstate polarization obeys $2\mathcal{E}_{s\tau\mathbf{k}} P_{s\tau\mathbf{k}}^{[0]} - \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} P_{s\tau\mathbf{k}'}^{[0]} = 0$ such that it can be expanded into the eigenfunctions of the Bogoliubov-Wannier equation with the eigenvalue $E_{\mu}^{s\tau} = 0$. Hence, we make the ansatz

$$P_{s\tau\mathbf{k}}^{[0]} = \sum_{\mu, E_{\mu}=0} P_{s\tau\mu}^{[0]} \psi_{\mu}^{s\tau}(\mathbf{k}), \quad (20)$$

$$\Pi_{s\tau\mathbf{k}}^{[1]} = \sum_{\mu} \Pi_{s\tau\mu}^{[1]} \psi_{\mu}^{s\tau}(\mathbf{k}), \quad (21)$$

Inserting the ansatz into Eq. (17) yields

$$\Pi_{s\tau\mu}^{[1]}(\omega) = -2e \frac{v_F}{c} A^{-\tau} \frac{(\gamma_{\mu}^{s\tau})^*}{\hbar\omega - E_{\mu}} - \frac{4}{c} \frac{\mathbf{A} \cdot \mathbf{j}_{\mu}^{s\tau}}{\hbar\omega - E_{\mu}}. \quad (22)$$

Here, $\gamma_{\mu}^{s\tau} = \sum_{\mathbf{k}} g_{s\tau\mathbf{k}}^{[0]} \psi_{\mu}(\mathbf{k})$ is the coupling strength of the macroscopic interband polarization to the optical field. For an s -type groundstate ($1 < \alpha < 3$), the populations also have spherical symmetry and the coupling strength vanishes for all non s -type excitation states, i.e. for all real exciton resonances. Generally, if $\alpha < (2n+1)/2$, the groundstate populations are composed of exciton states with $|j| \leq (2n+1)/2$, while real exciton resonances require $|j| \geq (2n+1)/2$. Thus, in the strong Coulomb coupling regime, the first term on the RHS of Eq. (22) vanishes.

Reversing the transformation 17, we can compute the optical susceptibility for the excitonic insulator state

$$\begin{aligned} \chi^{\sigma}(\omega)_{EI} &= -\frac{1}{\omega^2} \sum_{s,\mu} \frac{|\mathbf{j}_{\mu}^{s-\sigma}|^2}{\hbar(\omega + i\gamma) - E_{\mu}^{s,-\sigma}} \\ &\quad + \frac{1}{\omega^2} \sum_{s,\mu} -\frac{|\mathbf{j}_{\mu}^{s\sigma}|^2}{\hbar(\omega + i\gamma) + E_{\mu}^{s,\sigma}}. \end{aligned} \quad (23)$$

Here, all contributions have intraband character.

As can be recognized from Eq. (23), the poles of the linear susceptibility for the excitonic insulator state occur at the spectrum of the exciton Hamiltonian with Bogoliubov dispersion. The dominant effect of the exciton condensation on the single quasi-particle dispersion is a renormalization of the gap. Hence, the spectrum can be obtained in very good approximation from Eq. 11, provided one uses the appropriate renormalized gap. The major difference as compared to the optical susceptibility, Eq.(9), for the uncorrelated groundstate is the oscillator strength, which is now given by the intraband current matrix element between the excited exciton state and the excitonic groundstate

$$\mathbf{j}_{\mu}^{s\tau} = \sum_{\mathbf{k}} \psi_{\mu}^{s\tau*}(\mathbf{k}) \mathbf{j}_{s\tau\mathbf{k}} P_{s\tau\mathbf{k}}^{[0]} \equiv \langle \mu s\tau | \mathbf{j} | 0 \rangle.$$

This matrix element connects that part of the groundstate with largest $|j| \leq \alpha/2$ to the excited states with $|j'| = |j| + 1 > \alpha/2$ such that dipole allowed transitions increase (decrease) the total angular momentum by one. Explicitly, in the regime with $1 < \alpha < 3$, optical transitions connect the s -type excitonic groundstate $j = \tau/2, l = 0$ with the excited excitonic states $j' = 3\tau/2, l = \tau$, corresponding to p -like states. Thus, combining the results of the weakly and strongly interacting regimes, the modified optical selection rules can be summarized by the condition

$$(2(|l| - 1) < \alpha < 2(|l| + 1)) \quad (24)$$

for the optically active states.

ANALYSIS OF EXPERIMENTAL OBSERVATIONS

To test our general theory, we compare its predictions with the observations of several recent experiments on WS₂ [13, 14, 27] and WSe₂ [28]. As commonly adopted, we refer to A and B excitons for the lower and higher direct exciton transitions with a spin and valley index combination $s\tau = 1, -1$ respectively.

While the effective fine structure constant can be extracted from the tight binding parameters and the dielectric screening, to compute the energetic positions of the bright states requires the additional knowledge of the Coulombic bandgap renormalization. Whereas the bandgap renormalization diverges for an ideal, strictly 2D Coulomb potential, it is finite for any real system where the Coulomb matrix elements must be evaluated from the gap equations with the atomic orbitals used to represent the pseudo spinor space in Eq. (1). This leads to a quasi-2D Coulomb interaction

$$V(\mathbf{q}) = \frac{2\pi e^2}{\mathcal{A}\kappa} \frac{F(qd)}{q}, \quad (25)$$

where \mathcal{A} is the normalization area and $F(qd)$ is a monotonically decreasing form factor with $F(0) = 1$ and $\lim_{x \rightarrow \infty} xF(x) = 0$. The form factor leads to a regularization of the $1/r$ singularity at small distances and the parameter d can be interpreted as the effective thickness of the monolayer. Since its explicit expression depends on the specific atomic orbitals contributing to the valence and conduction band, we do not calculate the bandgap but rather use it as a fit parameter.

Linear Reflection experiments

We start with the analysis of the bright excitonic states in WS₂ on SiO₂ corresponding to the lowest A exciton with spin and valley combination $s\tau = 1$ [13]. With the material parameters for WS₂ $t = 1.37$ eV, $2\lambda = 0.43$ eV, $a = 3.197$ Å given in Ref. [7], an effective dielectric constant $\kappa = (1 + 3.9)/2$ for the SiO₂ substrate, and using $E_{gap} = 2.36$ eV, we find a binding energy of 0.25 eV for the lowest bright exciton transition with $(n, j) = (0, \pm 3/2)$. Using $E_{gap} = 2.36$ eV, we present in Fig. 1 the computed result for the spectral position of the lowest five bright exciton transitions. The red diamonds show the experimental data points taken from Ref. 13. For comparison, we also show the predicted values assuming nonrelativistic bright s -states. (Note that the $j = \pm 1/2$ series gives complex eigenvalues of the relativistic wave equation and thus cannot be used for comparison.) Our computed results show remarkably good agreement with the experimental observations given the fact that only the effective bandgap was used as a single fit parameter. In contrast, the results based on the assumption that the series has s -type character are completely off the scale, in particular for the energetically lowest states.

Assuming that the observed spin splitting corresponds to the difference in the renormalized bandgaps, we obtain

FIG. 1. (color online) Spectral position of the energetically lowest bright excitonic transitions with $j = \pm 3/2$ in WS₂. The blue squares are the computed results for p-type excitons, the red dots show the experimental data taken from [13], and the green diamonds indicate the theoretical predictions if one assumes s -type bright states, respectively. The dashed and dotted lines are guides to the eye. The x-axis label denotes the number M of the experimentally observed bright exciton resonances and is related to the principle quantum number via $N = M - 1$. The inset to the figure shows the results for the energetically higher states with a finer energy resolution.

TABLE I. Excitonic resonance positions extracted from experimental data together with the theoretical predictions where the gap of the A-exciton has been used as single fit parameter to match the experimental data. For WS₂, the band gap has been fitted to match the data of Ref. 13 (see Fig. 1 and the discussion in the text). For WSe₂, the lowest bright resonance position has been fitted to the data of Ref. 28. The data of Ref. 27 correspond to room temperature and show a red shift of approximately 0.1 eV as compared to the linear reflection spectra at 10K. The labeling corresponds to the main quantum number N of the N th excitonic level, which is usually used in semiconductor optics.

$E_{gap}^B = 2.79$ eV which can be used to compute the spectral positions of the B-excitons. The ratio of the binding energy is fixed by the ratio of the renormalized gaps, i.e. $E_0^B/E_0^A = E_{gap}^B/E_{gap}^A$, giving a binding energy of 0.30 eV for the lowest bright B exciton. Thus the $2p$ resonance is predicted to occur at $E_{2p}^B = 2.49$ eV, which is also in very good agreement with the experimental findings [13]. In table I, a list of the lowest theoretically predicted resonance positions of both A and B exciton is given.

FIG. 2. (color online) Comparison of one and two photon spectra of WS_2 measured by different groups. Part a) shows the deravative of the reflection contrast measured by Chernikov et al.[13], part b) the the linear reflection contrast (black line) together with the TP-PLE spectrum (red dots) measured by Ye et al. [14], and part c) the linear absorption (black line) and TP-PLE (red dots) measured by Zhu et al. [27]. To compensate for temperature dependent shifts of the band gaps, we shifted the data such that the lowest resonance of the A excitons are aligned. On the upper axis, we assigned the quantum numbers assuming bright p states. The onsets of the band gaps are denoted by A_G and B_G . The dotted line are guides to the eye and show the energetic position of some selected states.

Two Photon Experiments

To provide further evidence for the theoretically predicted selection rules, we also analyze recent experiments probing dark states by two-photon spectroscopy which can only access excitonic states with a parity opposite to those excited by a single photon process[14, 27, 28]. In Ref. 14 and 27, linear reflection and TP-PLE have been performed on WS_2 flakes having nominally the same material parameters as those in Ref.13. The resulting experimental data are shown in Fig. 2.

In Ref. 27, the linear reflection has been measured for different temperatures, showing two clearly recognizable peaks

for $T = 10\text{K}$ at 2.1 eV and 2.5 eV, respectively. These peaks agree well with the dominant peaks in the reflection spectrum of Ref. 13 and can be assigned to the A and B exciton respectively. At room temperature, both peaks experience a red shift of approximately 0.1 eV, most likely resulting from a temperature dependent bandgap renormalization. The TP-PLE measurements have been performed at room temperature and cover the spectral range between 2.4 and 3.0 eV. Within this spectral range two peaks in the TP-PLE spectrum are observed at approximately 2.4 and 2.6 eV, and a significant gap at approximately 2.73 eV. In Ref. 14, the A and B excitonic resonances occur at 2.04 and 2.45 eV in the linear reflection spectrum respectively. Thus, the energetic separation of the two dominant peaks is in good agreement with Refs. 13 and 27. The small deviations in the absolute values are most likely due to different experimental conditions. The TP-PLE spectrum covers the range between 1.9 and 2.6 eV and thus complements the measurements of Ref. 27. Within this energy range, the TP-PLE spectrum exhibits pronounced maxima between 2.25 – 2.29 eV and at 2.45 eV. Remarkably, both experiments observe a large TP-PLE signal resonant with the lowest bright transition of the B exciton, whereas the TP-PLE in Ref. 14 shows no significant signal at the lowest bright A exciton.

In Ref. 28, TP-PLE measurements have been performed in conjunction with SHG experiments on WSe_2 . This material system has very similar properties as WS_2 , in particular it has the same symmetries and similar spin-splitting of the valence bands. Using PLE, the resonance position of the A exciton is determined as 1.75 eV, whereas in TP-PLE, the dominant peak occurs at approximately 1.9 eV. In agreement with the observation in Ref. 14, the TP-PLE spectrum shows no significant signal at the transition energy of the lowest bright A exciton. In contradiction to the results of Ref. 14, the TP-PLE spectrum does not show a significant signal at the transition energy of the lowest bright B exciton. In contrast, the SHG spectrum exhibits two dominant peaks at 1.75 eV, i.e. at the lowest bright resonance, and at 2.16 eV, and less prominent peaks at 1.9, 2.02 and 2.3 eV.

In Refs. 14, 27, and 28, the experiments have been analyzed under the assumption of bright s -excitons. This assumption is seemingly supported by the absence of a TP-PLE signal at the resonance frequency of the lowest bright A exciton transition[14], and at the lowest A and B exciton[28] respectively. Thus, the resonances observed in TP-PLE spectra are assigned to p -like states. Since the lowest p -state should be energetically well above the lowest s -state, all resonances observed in the TP-PLE spectra of WS_2 are therefore assigned to excited states of the A exciton, including those resonant with the lowest bright B exciton and above. This assignement directly contradicts the Rydberg series observed by Chernikov et al.[13], where all excited states and the onset of the band gap of the A-exciton are found *below* the B- exciton.

Remarkably, all the above mentioned experimental observations can be explained quite naturally by the selection rules predicted by our theory. In the strongly interacting regime, the

lowest bright exciton state is p -type and nondegenerate, as s -type wave functions do not exist. The higher states are at least two-fold degenerate, and a two-photon absorption excites a d -type excited state. Thus, if the groundstate is excitonic, the lowest excited state should be dark in a two-photon experiment, exactly as is the case for the lowest s -exciton in a weakly interacting system. However, if the coupling constant is slightly below the critical value, the $j = 1/2$ states become bright and the state with $(n, j) = (0, 3/2)$ becomes (nearly) degenerate with the $(n, j) = (1, 1/2)$ state, which is the first excited s -type state. Simultaneously, the p -state can only be reached via a two-photon transition, while the corresponding degenerate s -state would be bright. Thus, the observation of a TP-PLE signal at the resonance position of the lowest bright B-exciton in the WS₂ sample seems to indicate that the WS₂ sample is at the edge of an excitonic insulator, with the lowest B1s exciton transition somewhere in the (far) infrared.

In Table I, we summarize the reported observations and compare our theoretically predicted resonance positions of WS₂ and WSe₂ with the experimentally available data. The theoretical values have been obtained using the material parameters of Ref. [7], $\kappa = (1 + 3.9)/2$ with the band gap as a single fit parameter. Note, that we assigned quantum numbers to the respective resonance positions that result from our theoretical assignment and do not necessarily correspond to the labeling in the respective original publications. Resonances that could not be resolved by the specific experiment remain as empty spaces in Table I, while those resonances that could in principle occur in the experiment but are not observed are indicated by an 'x'. As can be recognized from the table, not only the agreement between theory and experiment is remarkable, but also the data obtained by the different experimental techniques on different samples is brought into almost perfect mutual agreement as soon as one adopts our interpretation in terms of optically active p -states.

DISCUSSION

The results discussed in the previous sections are based on the model Hamiltonian (1) treating the electrons and holes in the vicinity of the K -points as massive Dirac Fermions. The strength of this model Hamiltonian is its simplicity, allowing for an analytical solution of the exciton problem and thus providing insight into the optical properties of Coulomb-interacting chiral quasi-particles that are difficult to obtain numerically. The obvious disadvantage is that it contains several simplifications that might restrict the application of the model to real material systems. In the following, we give a brief discussion of the approximations underlying our analysis, and estimate its validity and restrictions.

Inherent to the massive Dirac model is a single-particle dispersion that has a perfect electron-hole symmetry. The effect of an eventual electron-hole asymmetry is twofold: It modifies the single-particle dispersion and therewith the homogeneous part of the Wannier equation and it alters the dipole matrix el-

ement, i.e. the light-matter interaction. The latter effect may weaken the optical selection rules, i.e. unlike for the case of a perfect electron-hole symmetry, one- and two-photon processes can address the same states, while the first effect yields a modified exciton spectrum.

For the exciton equation, the relevant quantity is the energy difference between the conduction and valence band. In a conventional semiconductor with parabolic bands, this leads to an exciton dispersion and binding energy that depend on the reduced mass of the electron-hole pair only. Adding a term to the single-particle Hamiltonian of the form

$$H_{as}^{s\tau} = \sum_{\mathbf{k}} \hat{\Psi}_{a\tau\mathbf{k}}^\dagger k^2 \begin{pmatrix} \alpha_{s\tau} & 0 \\ 0 & \beta_{s\tau} \end{pmatrix} \hat{\Psi}_{s\tau\mathbf{k}},$$

that has been proposed in Refs. 35–37 to account for different electron and hole masses within the chiral two-band model, it is straightforward to show that, up to corrections of the order $\mathcal{O}(k^4)$, the exciton dispersion corresponds to that of a relativistic, symmetric electron-hole pair with a Fermi velocity $v_F^* = v_F \sqrt{\frac{m_0}{2m_r}}$ and effective mass $m^* = \Delta/2v_F^{*2}$. Here, $m_0 = \Delta/2v_F^2$ and m_r is the reduced mass of the electron-hole pair. It is worth to note that the so defined effective mass is not directly related to the electron and hole masses but describes the *pair* properties only. Using the parameters for WS₂ given in [37], this gives $v_F^* = 1.066v_F$ and a nominal coupling constant $\alpha^* = 3.08$ which is still well above the critical value. Thus, although a possible electron-hole asymmetry may lead to a violation of the optical selection rules, the massive Fermion model is well suited to describe the exciton spectrum even for asymmetric electrons and holes, provided one uses the effective Fermi-velocity.

To obtain the spectral position of the excitons, we utilize the solutions of the resulting relativistic Wannier equation where we include only the substrate background screening but neglect all other screening effects. In general, screening effects arise both from filled valence bands that are not considered explicitly in the model Hamiltonian, and screening of the conduction and valence band under consideration. The Coulomb matrix elements used to set up the interacting model Hamiltonian should contain only the first type of contributions which can be considered to lead to a constant background dielectric constant. For a film of vanishing thickness d , this contribution can be neglected[38]. The second type of contributions should then be computed selfconsistently, using the Coulomb matrix elements screened by the background dielectric constant.

For the massive Dirac-Hamiltonian (1), the RPA dielectric function of the TMD monolayer is given by [24],

$$\epsilon(q) = \kappa \left(1 + \frac{4}{\pi} \frac{1}{qa_B} P \left(\frac{\alpha}{2} qa_B \right) \right),$$

where κ is the effective dielectric screening of the substrate and $a_B = 2\hbar v_F/\alpha\Delta$ is the 2D exciton Bohr radius. An analytical expression for $P(Q)$ is given in Ref. 24. In the nonrelativistic limit $\frac{\alpha}{2} qa_B \ll 1$, $P(Q) \approx \frac{\pi Q^2}{3}$, yielding

$\epsilon(q) = 1 + \frac{1}{3}\alpha^2 a_B q$. In this regime, the intrinsic screening corresponds to the anti-screening proposed by [33, 34] with an anti-screening length $r_0 = \frac{1}{3}\alpha^2 a_B$. Using the nominal values of α in suspended TMDs, the anti screening length is typically $\propto 1 - 1.5a \approx 3 - 5 \text{ \AA}$, which corresponds roughly to the physical thickness of the monolayer. For supported samples, the anti-screening length is reduced correspondingly.

The anti-screening is typical for a truly 2D-dielectric material and weakens the strength of the Coulomb interaction on a length scale small compared to the anti-screening length. Thus, for the weakly bound excitons with a spatial extension large compared to the 2D-exciton Bohr radius, we expect the anti-screening effect to be of minor importance. This expectation is indirectly confirmed by the excellent agreement of the experimentally observed resonance positions and our theoretical predictions.

At this point, we mention that the anti-screening model has also been employed to understand the observed non-hydrogenic series in TMDs based on an analysis in terms of optically bright s -states, using the anti-screening length as fit parameter [13, 39]. For WS_2 on SiO_2 , reasonable agreement with the experimental observations could be obtained using $r_0 = 75 \text{ \AA}$, which is much larger than the physical thickness.

In the ultrarelativistic regime, $\frac{\alpha}{2}qa_B \gg 1$, $P(Q) \approx \pi^2 Q/4$ and the dielectric function $\epsilon(q) = 1 + 2\alpha/\pi$ reduces to a constant, as in graphene. For large q -values, intrinsic screening therefore may play a significant role and eventually prevent the phase transition into the excitonic state.

Nevertheless, the weakly bound states are not affected by this screening, nor by other deviations of the full electron spectrum beyond the quadratic approximation. Thus, the excited states still have $|j| > \alpha/2$. Hence, assuming a noninteracting groundstate and a nominal value of $\alpha > 1$, the excited exciton states should be dark and the only bright resonance in a linear optical experiment should correspond to the $1s$ exciton. Since the experiments do not observe this feature but rather show a whole series of excitonic resonances, this serves as a clear indication that the groundstate is indeed excitonic and the bright exciton resonances correspond to p -type wave functions with $|j| = 3/2$.

CONCLUSION

In conclusion, we presented a general theory which assigns a p -like symmetry to the wave functions of the optically active excitonic transitions in recently investigated TMDs. This theory is supported by recently published experimental data, including the observation of a series of resonances in the linear reflectrum spectrum of WS_2 [13], two photon absorption in WS_2 [14, 27] and WSe_2 [28]. This observation of optically active p -transitions is not only of crucial importance for the correct interpretation of experimental data, but impressively demonstrates that in the TMDs investigated here, the Coulomb interaction is strong enough to induce an excitonic ground state. The dipole allowed excited states of such an excitonic

insulator correspond to intra-excitonic transitions and are governed by the corresponding optical selection rules. Even for systems in the weakly interacting regime without an excitonic ground state, the lowest excitonic transition should be in the THz or infrared regime and the observed optical resonances correspond to excited exciton levels with main quantum number $N \geq 2$.
