## ABSTRACT

We present the results of a calculation of the thermal spectrum from a 2D, moving mesh, high-accuracy, viscous hydrodynamical simulation of an accreting supermassive black hole binary. We include viscous heating, shock heating, and radiative cooling, evolving for longer than a viscous time so that we reach a quasi-steady accretion state. In agreement with previous work, we find that gas is efficiently stripped from the inner edge of the circumbinary disk and enters the cavity along accretion streams, which feed persistent “mini-disks” surrounding each black hole. We also find that emission from the shock-heated mini-disks and accretion streams prevents any deficit in high-energy emission that may be expected inside the circumbinary cavity, and instead leads to a characteristic brightening of the spectrum beginning in soft X-rays.

## 1 INTRODUCTION

Supermassive black hole (SMBHs) binaries have gained significant attention as potential sources of both gravitational and electromagnetic radiation. It is currently believed that SMBHs with masses between  $10^6$  and  $10^9 M_{\odot}$  reside in nearly all nearby galaxy nuclei (Kormendy & Richstone 1995; Ferrarese & Ford 2005). Mergers of such galaxies are expected to give rise to bound SMBH binary systems in the merged galaxy remnant, following a phase of dynamical friction in which the SMBHs become gravitationally bound (see the recent review by Mayer 2013).

It is expected that there is an abundance of dense gas in the nuclei of merged galaxies (Barnes & Hernquist 1992; Springel, Di Matteo & Hernquist 2005) and that this gas can form a circumbinary accretion disk (Artymowicz & Lubow 1996; Armitage & Natarajan 2002; Milosavljević & Phinney 2005). Such binaries may provide a unique opportunity to observe electromagnetic signatures originating from the interaction of the binary with the surrounding accretion disk. The gravitational radiation originating from the SMBH binary inspiral should also be detectable by Pulsar Timing Arrays (PTAs) (Hobbs et al. 2010; Kocsis & Sesana 2011; Tanaka, Menou & Haiman 2012; Lommen 2012; Sesana et al. 2012) or by a space interferometer such as eLISA (Amaro-Seoane et al. 2013), provided the binary has maintained a circumbinary disk past the decoupling epoch (Barausse & Rezzolla 2008; Noble et al. 2012; Kocsis, Haiman & Loeb 2012)

A number of “dual” systems, in which two SMBHs occupy the same galaxy, but are too widely separated to be gravitationally bound, have been observed (Komossa et al. 2003; Comerford et al. 2013; Liu et al. 2013; Woo et al. 2014), as well as several candidate binary systems (see e.g. Liu, Li & Komossa (2014) and references therein). Proposed

electromagnetic signatures of such binaries include spatially resolving two AGN-like point-sources, identifying double-peaked broad emission lines, spatial structures in radio jets, and characteristic time variability in quasar emission.

In this paper we focus on characteristic changes to the thermal continuum emission brought about by the presence of a binary. Such signatures have been discussed previously (Liu, Wu & Cao 2003; Milosavljević & Phinney 2005; Hayasaki, Mineshige & Ho 2008; Lodato et al. 2009; Shapiro 2010; Liu & Shapiro 2010; Tanaka, Menou & Haiman 2012; Gültekin & Miller 2012; Kocsis, Haiman & Loeb 2012; Tanaka 2013; Roedig, Krolik & Miller 2014), but we present the first calculation of a SMBH thermal spectrum directly from simulation results. We find that our spectra differ qualitatively from prior predictions due to the large amount of emission from hot gas residing in minidisks surrounding each BH, as well as in the accretion streams which penetrate the cavity. This gas causes a surplus, rather than a deficit, in the high-energy regions of the composite spectrum.

## 2 METHODS

Our initial disk configurations consist of the “middle region” Shakura-Sunyaev solution for a steady-state, geometrically thin, optically thick accretion disk, assuming a gas pressure dominated fluid with electron scattering as the dominant opacity. We modify this solution by exponentially reducing the density and pressure by a factor of  $\exp[-(r/r_0)^{-10}]$  to create a hollow cavity within  $r \lesssim r_0 \equiv 2.5a$ , where  $a$  is the binary separation. In the early stage of our simulations, the inner cavity wall migrates inward due to viscosity, accretion streams form, and a quasi-steady state is reached. The fluid evolves according to the 2D viscous Navier Stokes

equations, assuming an  $\alpha$ -law viscosity prescription and accounting for the binary potential in the expression for the disk scale height  $h$ ,

$$\nu = \alpha c_s h = \alpha \frac{P}{\Sigma} \left( \frac{Gm_1}{r_1^3} + \frac{Gm_2}{r_2^3} \right)^{-1/2}, \quad (1)$$

where  $\Sigma$  is the surface density,  $P$  is the vertically integrated pressure,  $m_i$  is the mass of each BH,  $r_i$  is the distance to each BH, and  $\alpha$  is the viscosity parameter, which we choose to be  $\alpha = 0.1$ .

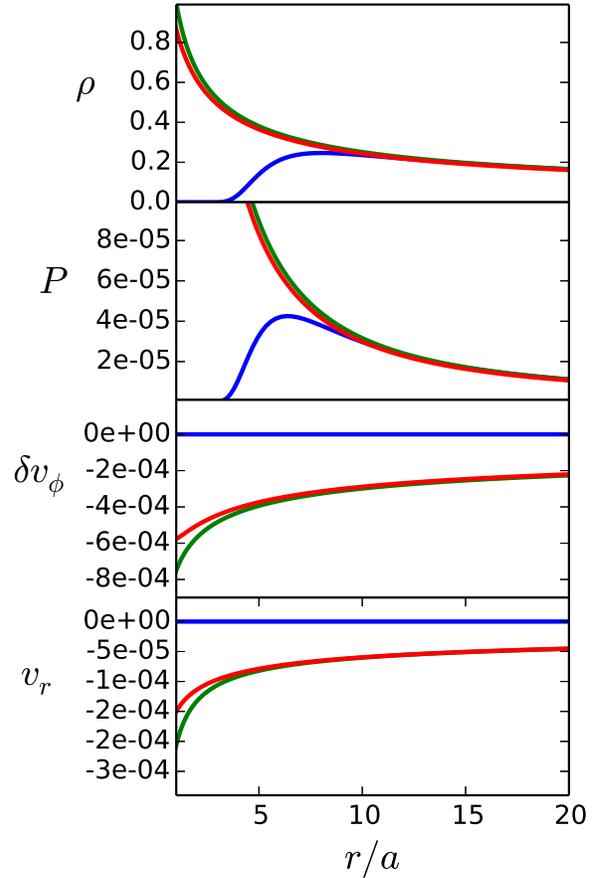

The *DISCO* code (Duffell & MacFadyen 2014) allows one the freedom to specify the motion of the computational cells. For this problem we choose a rotation profile which matches the nearly Keplerian fluid motion outside the cavity, while transitioning to uniform rotation at the binary orbital frequency inside the cavity.

Our numerical methods are similar to those described in Farris et al. (2014), with several important differences. We have replaced the isothermal prescription with a full evolution of the energy equation, assuming a  $\Gamma$ -law equation of state of the form  $P = (\Gamma - 1)\epsilon$ , where  $\epsilon$  is the internal energy density, and the adiabatic index is set to  $\Gamma = 5/3$ . We have added the appropriate radiative cooling and viscous heating terms to the energy equation. The cooling rate for an optically thick, geometrically thin disk is  $q_{cool} = 4/3\tau^{-1}T^4$ , where  $T$  is the mid-plane temperature, and  $\tau$  is the optical depth for electron scattering ( $\tau = \Sigma\sigma_T/m_p$ ). For a Shakura-Sunyaev disk around a single BH, this is in balance with the local viscous heating rate,  $q_{vis} = 9/8\alpha P\Omega$  (Frank, King & Raine 2002). We therefore parametrize our simulations by choosing the Mach number at  $r = a$ ,  $\mathcal{M}_a \equiv (GM/a)^{1/2}/\sqrt{P(a)/\Sigma(a)}$ , and scaling the cooling rate accordingly,

$$q_{cool} = \frac{9}{8}\alpha\Omega(a)P(a)\mathcal{M}_a^4 \left( \frac{P}{\Sigma v_a^2} \right)^4 \left( \frac{\Sigma}{\Sigma(a)} \right)^{-1}. \quad (2)$$

For the simulations in this paper, we set  $\mathcal{M}_a = 32$ . Details of our implementation of viscous heating in the energy equation are straightforward, and will be described in detail in an upcoming paper. With these improvements, we can self-consistently determine the temperature and emission everywhere in the disk due to both viscous heating and shock heating. We have tested that the code can reproduce the analytic steady-state Shakura-Sunyaev solution around a single BH (see Fig. 1). This demonstrates our ability to accurately balance viscous heating and radiative cooling.

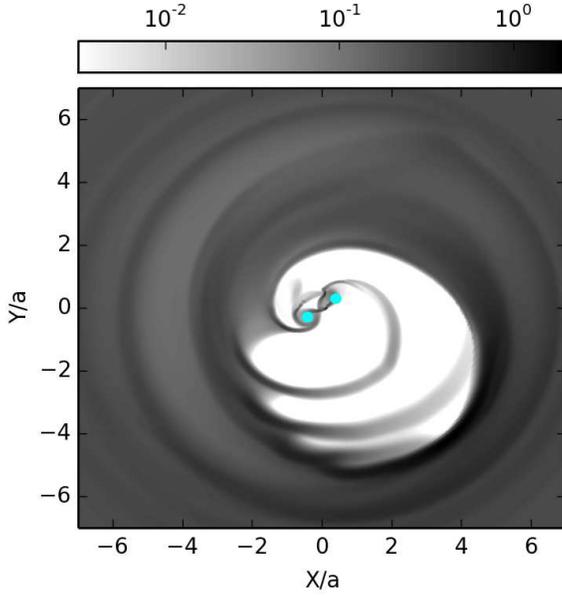

In Figure 2, we plot a snapshot of the gas density near the binary at  $t = 2700t_{bin}$ , after the disk has relaxed to a quasi-equilibrium state. We note that the cavity has grown lopsided, as observed in, e.g. MacFadyen & Milosavljević (2008); Cuadra et al. (2009); Roedig et al. (2012); Shi et al. (2012); Noble et al. (2012); Farris et al. (2014). See Farris et al. (2014) and Shi et al. (2012) for a description of the mechanism driving the growth of this lopsidedness. The results are qualitatively similar to those of Farris et al. (2014), with prominent streams entering the cavity and feeding persistent minidisks around each BH. By treating the radiative cooling of the disk self-consistently, we are able to calculate profiles of the electromagnetic emission from these disks. In Fig 3 (top panel) we plot a 2D profile of the bolometric luminosity per unit surface area. We note that the brightest component of the

**Figure 1.** Results of Shakura-Sunyaev solution. The initial condition, shown in blue, has an inner cavity, but outside  $r \gtrsim 5a$ , it matches the analytic solution for a gas-pressure dominated Shakura-Sunyaev disk with scale height  $h/r = 0.03$  around a single BH with electron scattering as the dominant opacity. The approximate (to first order in  $1/\mathcal{M}_a$ ) analytic solution for density  $\rho$ , pressure  $P$ , deviation from Keplerian azimuthal velocity  $\delta v^\phi \equiv v^\phi - v_{kep}^\phi$  and radial velocity  $v_r$  is shown in green, and the relaxed simulation results are shown in red.

accretion flow is the hot minidisks, with significant emission coming from the shock-heated fluid in the accretion streams. We also plot the azimuthally integrated luminosity per annulus,  $dL/dr$  and compare with the expected Shakura-Sunyaev profile for a steady-state disk around a single BH. While the enhancement near  $r/a = 0.5$  is expected due to the hot minidisks surrounding each BH, it is surprising that there is no dip in  $dL/dr$  associated with the low density cavity, as has been widely assumed in the literature (see e.g. Milosavljević & Phinney 2005; Tanaka & Menou 2010). On the contrary, we find that the emission associated with the shock heating in the accretion streams is sufficient to bring the emission from within the cavity above that of a disk around a single BH.

For realistic circumbinary disks at cosmological distances, features inside the cavity are unlikely to be directly resolved observationally. However, features in the circumbinary disk profile can leave an imprint in the observed AGN spectrum. In an ordinary AGN disk, the gas temperature

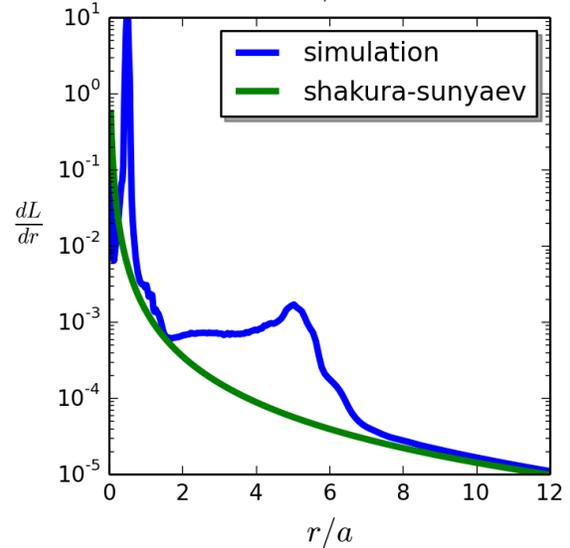

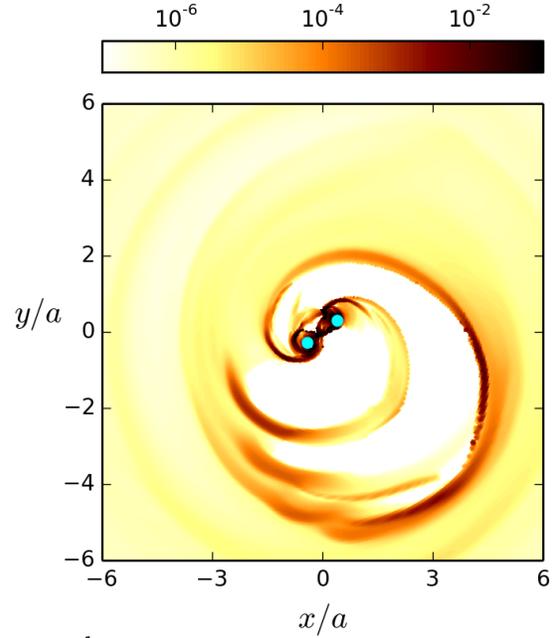

**Figure 2.** Snapshot of surface density  $\Sigma$  during quasi-steady state after  $t \approx 2700t_{bin} \approx t_{vis}$ . Surface density is normalized by the maximum value at  $t = 0$  and plotted on a logarithmic scale in the inner  $\pm 6a$ . Orbital motion is in the counter-clockwise direction.

depends strongly on radius, and thus thermal emission from an annulus at  $r$  contributes to the spectrum most strongly at  $h\nu \approx kT(r)$ . Consequently, it has been predicted that the missing emission from the circumbinary cavity can lead to a “notch” in the thermal spectrum (Roedig, Krolik & Miller 2014). We test this prediction in our simulations by calculating the spectrum assuming thermal blackbody emission at each point in the disk,

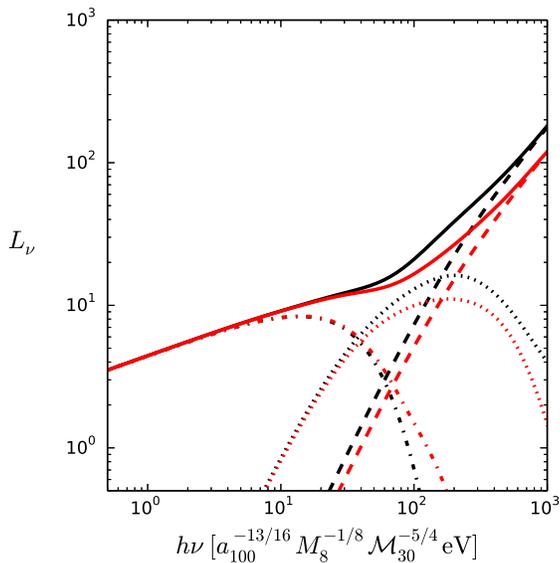

$$L_\nu = \int \frac{2h\nu^3}{c^2 \exp\left(\frac{h\nu}{kT_{\text{eff}}(r, \phi)}\right) - 1} dA \quad (3)$$

where the effective temperature  $T_{\text{eff}}(r, \phi) \equiv (q_{\text{cool}}(r, \phi)/\sigma)^{1/4}$ , and  $q_{\text{cool}}$  is the radiative cooling rate. We find no noticeable “notch” in the spectrum, as the low-frequency tail of the emission from the hot minidisks and the hot streams effectively washes out any deficits arising from the missing gas in the cavity. A spectrum computed from snapshots separated by  $\delta t \approx 3t_{bin}$  during the relaxed, quasi-steady state at  $t \approx 2700t_{bin}$  is shown in Figure 4. We find a strong enhancement in emission at high frequencies due to the shock heated minidisks. Scaled to a  $10^8 M_\odot$  binary with a separation near decoupling at  $a/M = 100$ , we find that the enhancement is significant in soft and hard X-rays. This X-ray enhancement has been predicted by Roedig, Krolik & Miller (2014), who estimated the characteristic frequency of minidisk “hot spot” emission by estimating the amount of energy released due to shock heating when accretion streams impact the minidisks. While our enhancements occur at somewhat lower energy compared to their estimate of  $\sim 100\text{keV}$ , this is likely due to our simplifying assumption of thermal blackbody emission throughout our domain, whereas they consider emission due to inverse Compton scattering. We

**Figure 3.** *Top Panel:* Snapshot of surface brightness  $dL/dA$  during quasi-steady state after  $t \approx 2700t_{bin} \approx t_{vis}$ , normalized by the value at  $r = a$  for a steady-state disk around a single BH. *Bottom Panel:* Radial profile of azimuthally integrated surface brightness,  $dL/dr$  time averaged over  $\approx 25$  orbits is plotted in blue, reference profile for a steady-state disk around a single BH plotted in green for comparison.

also expect that spectral enhancements are likely to extend to lower frequencies when one considers emission from the hot streams within the cavity. We decompose the spectrum into a component emitted from within the minidisk region inside a distance  $a/2$  of each black hole, a “cavity” component emitted from outside the minidisks, but within a distance of  $6a$  from the origin, and an “outer” region emitted from outside  $6a$ . We plot spectra at two different times, separated by  $\sim 3t_{bin}$  in order to demonstrate the time variability of the spectrum. While the emission from

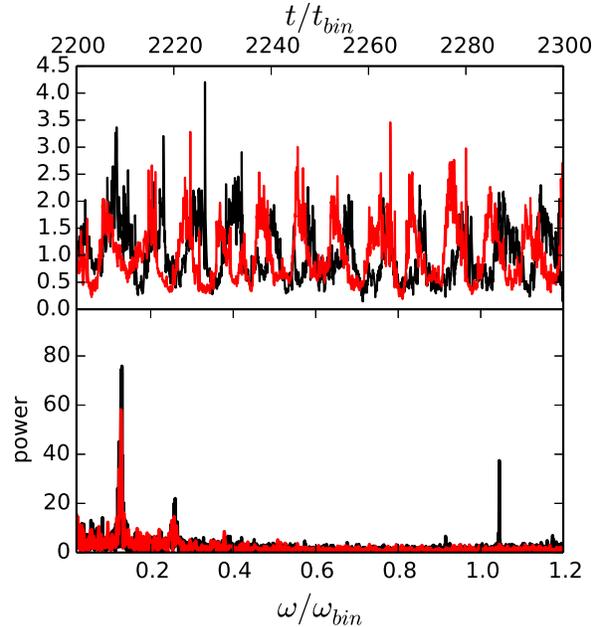

**Figure 4.** Thermal spectra computed from simulation snapshot at  $t \approx 2700t_{bin} \approx t_{vis}$ . Red curves are calculated from disk data at  $t \approx 3t_{bin}$  after that of black curves. The full spectra is represented by solid lines, the component arising only from minidisk regions within distance  $d < 0.5a$  of either BH is represented by dashed lines, the “cavity” emission is represented by dotted lines, and the emission from the “outer region” is represented by dashed-dotted lines.

the “outer” region is steady in time, the emission from the cavity and the minidisks shifts to higher frequencies as a high density “lump” falls on the binary, coinciding with a spike in  $\dot{M}$ . Such lumps have been noted in a number of previous simulations (MacFadyen & Milosavljević 2008; Roedig et al. 2011; Noble et al. 2012; Shi et al. 2012; Farris et al. 2014). In Figure 5, we plot the accretion rate  $\dot{M}$  and total luminosity  $L$  as a function of time, as well as the respective Lomb-Scargle periodograms. We see that the accretion rate remains roughly proportional to the luminosity, as both vary by a factor of  $\sim 4$ . In both cases the dominant mode in the periodogram is at  $\omega \approx 1/7\omega_{bin}$ , corresponding to the orbital frequency of the high density lump in the disk just outside the cavity.

### 3 DISCUSSION

Accreting SMBH binaries may constitute rare sources with observable electromagnetic as well as gravitational radiation. In order to distinguish electromagnetic emission from binaries from that of ordinary AGN, it is important to identify observable signatures that characterize binary accretion. The Shakura-Sunyaev model has been successful in explaining the continuum spectra of ordinary AGN. Here we present a generalization of this model by computing the blackbody spectrum from the results of 2D simulations of binary accretion.

Prior work has focused on deficits in the spectrum which correspond to missing emission from the circumbinary cavity. We find that emission from the hot streams

**Figure 5.** The time variable accretion rate (black) onto the binary, and total luminosity (red), are plotted in the top panel over a window of 100 orbits, and the corresponding Lomb-Scargle periodograms, computed over  $\sim 1000$  orbits, are plotted in the bottom panel.

which penetrate the cavity, along with the low-frequency tail of the emission from the shock-heated minidisks is sufficient to mask such “notches”. Other proposed signatures which depend on a high-frequency cutoff associated with an empty cavity such as the “Lyman edges” predicted by Generozov & Haiman (2014) are disfavored by our results as well (although this signature could become visible if the minidisks were radiatively inefficient). We find that enhanced X-ray emission from the minidisks is a more prominent and robust signature. Such “hot spots” have been previously predicted at somewhat higher frequencies using analytic arguments (Roedig, Krolik & Miller 2014), and were also predicted to arise from the tidally heated rim of the cavity (Lodato et al. 2009; Kocsis, Haiman & Loeb 2012), but we have provided the first self-consistent numerical simulations which demonstrate this feature. Instruments sensitive to X-ray emission from AGN such as *XMM-Newton*<sup>1</sup>, *NuSTAR*<sup>2</sup>, the upcoming *eROSITA*<sup>3</sup> all-sky survey, and the proposed *ATHENA*<sup>4</sup> X-ray observatory may be sensitive to these signatures. We also note that broad lines, which are powered by the hard radiation from the inner disk, may be enhanced by this emission, contrary to the unusually weak broad lines expected in the case of a dim cavity (Tanaka, Menou & Haiman 2012).

In future work, we intend to relax our black-body assumption and take into account radiative processes such as inverse Compton scattering that may be relevant. We also intend to include radiation pressure in our calcula-

<sup>4</sup> <http://www.the-athena-x-ray-observatory.eu/>

tions, which may become particularly relevant in the shock-heated minidisks. In this paper, we have focused our attention on equal-mass binaries, but we intend to study the dependence of spectral features on binary mass-ratio. We also intend to determine the dependence of these features on disk thicknesses. For computational efficiency, we have performed our simulations in 2D, assuming an  $\alpha$ -law viscosity as a proxy for the viscosity arising from magneto-hydrodynamic (MHD) turbulence. In future work, we intend to perform full 3D MHD simulations using the *DISCO* code (Duffell & MacFadyen 2014) in order to verify the validity of these approximations.
