We investigate the 2-dimensional Fermi surface of high-mobility $\text{LaAlO}_3/\text{SrTiO}_3$ interfaces using Shubnikov-de Haas oscillations. Our analysis of the oscillation pattern underscores the key role played by the Rashba spin-orbit interaction brought about by the breaking of inversion symmetry, as well as the dominant contribution of the heavy d_{xz}/d_{yz} orbitals on electrical transport. We furthermore bring into light the complex evolution of the oscillations with the carrier density, which is tuned by the field effect.

The conducting interface between the two band insulators LaAlO_3 (LAO) and SrTiO_3 (STO) has drawn a lot of attention as it presents a variety of exciting properties, among them superconductivity and a large spin-orbit coupling, both being tunable by an electric field [1]. As the 2DEG lies on the STO side, the conduction band of the system is dominated by the Ti $3d$ - t_{2g} orbitals as for bulk STO. However, at the interface, quantum confinement spectacularly alters the orbital ordering of the energy levels, as observed by X-ray spectroscopy [2]: for a given sub-band index, the states with predominantly d_{xy} symmetry have, on average, a lower energy than states derived from the d_{xz}/d_{yz} orbitals. Currently, experimental and theoretical estimates of the out-of-plane extent of the 2DEG vary from a few monolayers [3–5] to 10 nm [6–8] and, consequently, the number and precise energy arrangement of these sub-bands is still an open question. The asymmetric confining potential also brings about a breaking of inversion symmetry: its effect is to spin-split the electronic bands (Rashba effect) [9–11] with important consequences on the magnetotransport of the system [12–14].

In this letter, we report the observation and analysis of Shubnikov-de Haas (SdH) oscillations in high-mobility and low carrier density ($\approx 10^{12} \text{ cm}^{-2}$) interfaces. Quantum oscillations show two frequencies that we contend are due to the splitting of an electronic band induced by the Rashba spin-orbit interaction (SOi). The estimated SOi energy is comparable to the Fermi energy (E_F), defining an unusual regime when compared to semiconductor 2DEG. Electric field effect experiments also reveal that the evolution of the Landau levels (LLs) that is observed as one changes the carrier density is singular.

The LaAlO_3 layers were grown by pulsed laser deposition at 650°C , a lower temperature than for standard interfaces [15]. Hall bars for DC transport measurements were patterned and field-effect devices were realized using the STO single crystal substrate as the gate dielectric (see supplementary data). Magnetotransport measurements were performed in a dilution refrigerator equipped with a 8 T superconducting magnet.

Figure 1a displays a set of sheet resistance versus magnetic field (B) curves for temperatures ranging from 800 mK to 50 mK. As can be seen, the magnitude of the Shubnikov-

de Haas oscillations increases markedly as the temperature is lowered. At 50 mK and in high magnetic field, the amplitude of SdH oscillations is about 10–15% of the sheet resistance value. To change the carrier density, we apply a back-gate voltage ¹. Fig. 1c shows that upon carrier density tuning the transverse resistance R_{xy} varies linearly with magnetic field. From Fig. 1d, we see that ramping the gate voltage (V_g) up to large positive values leads to an increase of the inverse Hall coefficient. Analysing the Hall signal using a single-band model, we extract a carrier density at 50 mK that increases from 2.5 to $4.8 \times 10^{12} \text{ cm}^{-2}$ as V_g is swept from 79 to 107 V, i.e. as the sheet conductance (σ_{2D}) at 0 T increases from 1.6 to 5.27 mS. Concomitantly with this variation of the electron density, the electron mobility μ evolves from 3900 to 6900 $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$, as shown in Fig. 1e [14, 16, 17]. We note that these samples exhibit n_{2D} (μ) that are smaller (larger) than standard samples. Moreover, the modulation of the carrier density and mobility by electric field effect does not induce a transition from linear to non-linear Hall effect.

As can be seen in Fig. 1b, the changes in electron mobility and density strongly modify the structure of the SdH oscillations with a clear change in both the peak position and the period of the oscillations.

In order to proceed with the analysis of the SdH data presented in Fig. 1, we subtracted the background:

$$\Delta\sigma(B) = \frac{R_s(B)}{[R_s(B)]^2 + [R_{xy}(B)]^2} - \sigma_0(B) \quad (1)$$

with $R_s(B)$ and $R_{xy}(B)$ the measured longitudinal and transverse resistances, respectively, and $\sigma_0(B)$ a non-oscillating polynomial background. Examples of the resulting curves can be found in Fig. 4.

Looking at the SdH oscillations, we note (at least) two frequencies modulating the conductance. Hence, we first analyse the data considering a model with two parabolic bands for which the magnetoconductance can be calculated

¹ In the rest of the paper we use the sheet conductance at zero magnetic field and 50 mK (σ_{2D}) rather than the gate voltage (V_g) to define the state of the system.

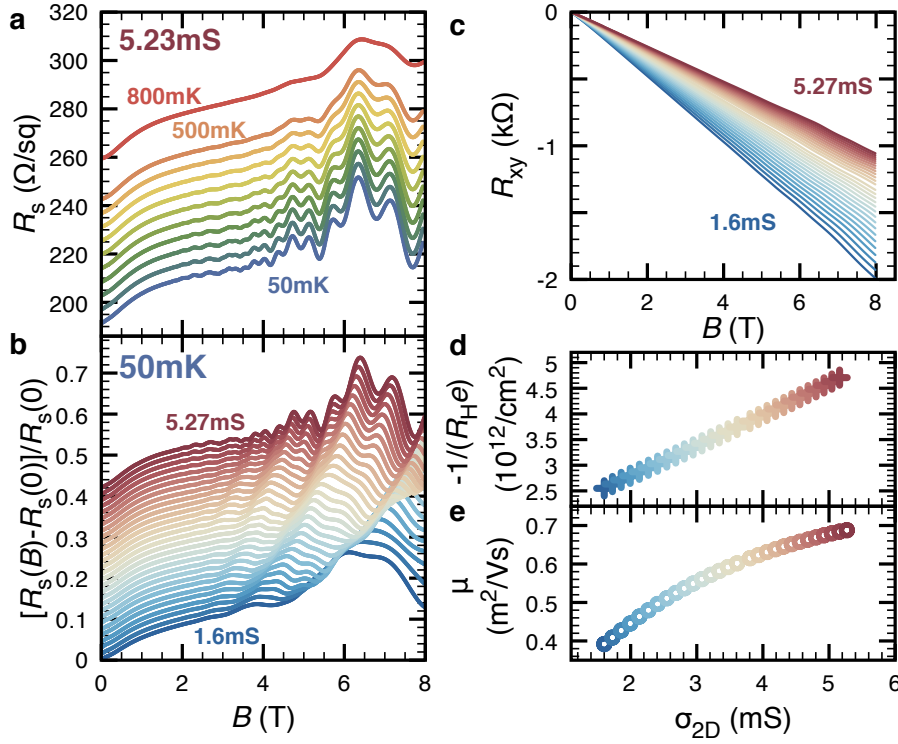

FIG. 1. Transport properties in a magnetic field. (a) Temperature evolution of the sheet resistance (R_s) versus magnetic field for a doping level corresponding to a sheet conductance of 5.23 mS and a mobility of $\mu \approx 7000 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ at 50 mK. Curves are offset for clarity. In this paper, the sheet conductance at 50 mK and 0 T (σ_{2D}) is used as a reference for the doping level. (b) $[R_s(B) - R_s(0)]/R_s(0)$ for different dopings, illustrating the evolution of the SdH oscillations with gate voltage. Curves are offset for clarity. (c) Hall resistance versus magnetic field at 50 mK for different dopings. (d) Inverse Hall coefficient and (e) the corresponding Hall mobility at 50 mK versus σ_{2D} .

using the Lifshitz-Kosevich (LK) formula [18]. We fit the data for the largest conductance introducing an arbitrary phase for each frequency.

As can be seen from Fig. 2a, a good fit to the data can be obtained using the two frequencies 18 T and 55.9 T². Panel b displays the derivatives of the theoretical and experimental curves allowing the positions of the maxima and minima to be compared. Considering the Onsager relation with a spin degeneracy of $\nu_s = 2$ and a valley degeneracy of $\nu_v = 1$, we find the carrier densities for the two bands to be 0.87 and $2.7 \times 10^{12} \text{ cm}^{-2}$, which yield a total carrier concentration of $\sim 3.6 \times 10^{12} \text{ cm}^{-2}$.

In the LK formalism, the temperature evolution of the oscillations can be directly related to the effective mass of the oscillating carriers. We extracted the high and low frequency (HF and LF) parts of the SdH oscillations shown in Fig. 2a. Selecting 17 and 4 extrema for the HF and LF, respectively, good agreement between theory and experiment

is obtained by choosing an effective mass of $2.7m_e$ for the HF and $1.25m_e$ for the LF (see supplementary data).

With the information extracted from this analysis, the electronic structure of our two-band model can be reconstructed and the splitting at the Fermi level between the heavy and the lighter bands determined:

$$\Delta E = |E_1(\bar{k}_F) - E_2(\bar{k}_F)|, E_i(k) = \frac{\hbar^2}{2m_i^*} (k^2 - k_{F,i}^2). \quad (2)$$

$k_{F,i}$ is the Fermi momentum in the i -th band obtained from the area $A_i = \pi k_{F,i}^2$ calculated using the Onsager relation, and $\bar{k}_F = (k_{F,1} + k_{F,2})/2$. We find $\Delta E \approx 2.45 \text{ meV}$.

The band structure obtained in the above two carrier model predicts a heavy band with a higher binding energy than the light one. This is in apparent contradiction with the well documented observation of orbital reconstruction at the LAO/STO interface [2].

Another possible scenario is that the calculated band splitting ΔE is in reality the Rashba spin-orbit splitting estimated for LAO/STO heterostructures [12, 13]. In what follows, we hence consider a model consisting of a single parabolic band split by the Rashba spin-orbit interaction.

In a Rashba scenario, the SOi splits the LLs of a single band into two families (\pm) of irregularly-spaced levels.

² We would like to emphasize that at our base temperature ($k_B T \approx 10^{-3} \text{ meV}$) the field dependence of the amplitude of the oscillations is mainly controlled by the Dingle term that compares the strength of the disorder to the cyclotron gap. Hence, the fitting shown in Fig. 2 is only sensitive to the product of m^* and the Dingle temperature.

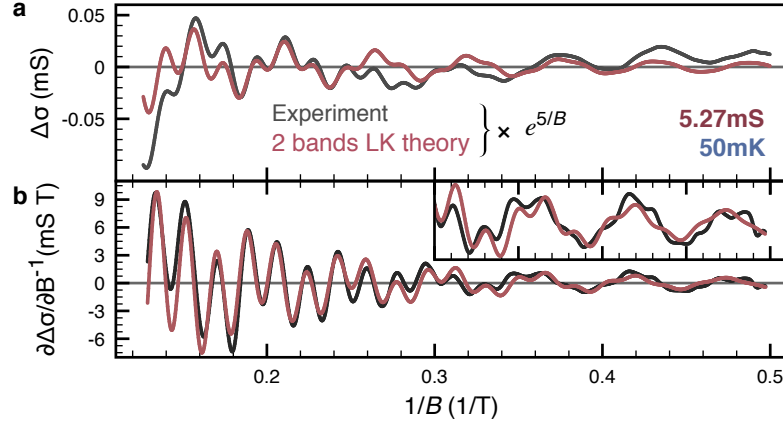

FIG. 2. (a) Comparison between $\Delta\sigma$ versus $1/B$ calculated within the two-band model (red) and the experimental data (black) for the doping with the highest conductance (5.27 mS) and at 50 mK. The exponential factor $e^{5/B}$ is used to magnify the low-field region. (b) Derivative with respect to B^{-1} of the curves presented in (a). (inset) Close-up on the low-field region of (b).

These energy levels are labeled by an integer $N \geq 0$ and read, for an isotropic Fermi surface and a k -linear splitting [20]:

$$E_{N=0} = E_c/2 - E_Z, E_{N>0}^{\pm} = NE_c \mp \sqrt{(E_c/2 - E_Z)^2 + NE_{\alpha}^2}. \quad (3)$$

$E_c = \hbar\omega_c^*$, $E_Z = (g^*/2)\mu_B B$ is the Zeeman splitting, $E_{\alpha} = \alpha\sqrt{2eB/\hbar}$ with α the Rashba coupling constant. The $N = 0$ state is fully spin-polarized, and the two series of LLs with $N > 0$ correspond to orthogonal mixtures of spin-up and spin-down states.

To compare the data with this second model, we computed numerically the DOS, the chemical potential, and the conductance for each magnetic field and temperature, using the formalism of Ref. 21. We considered a Gaussian broadening of the LLs with a variance $\gamma^{\pm}\sqrt{B}$. The results are displayed in Fig. 3. As can be seen, good agreement between the data and the theory is obtained (see supplementary data).

The carrier density extracted from this analysis is $n_{2D}^{\text{SDH}} = 1.83 \times 10^{12} \text{ cm}^{-2}$, lower than the one found using the Hall effect measurements. The magnitude of the obtained Rashba coupling constant ($\alpha = 3.4 \times 10^{-12} \text{ eV m}$) agrees very well with values obtained from weak localization analyses and from modelling of the transport data in parallel fields [12–14]. We note that, given the small value of k_F in our samples, a k -cubic Rashba interaction inducing a spin-splitting of $\approx 2 \text{ meV}$ would require a very large coupling constant, beyond values recently reported [22].

To obtain the effective mass, we selected three peaks from a region of magnetic fields where the amplitude of the oscillations is large. Fig. 3c shows that the data can be fit perfectly using an effective mass of $2.2 \pm 0.1 m_e$. This value may indicate that the electronic state of the oscillating carriers is not dominated by Ti d_{xy} orbitals, as one would then expect a lower effective mass ($\lesssim m_e$). Instead, the higher mass obtained in this analysis can be understood

by taking into account the contribution of d_{xz}/d_{yz} orbitals to the electronic states. We note that a recent analysis of photoemission spectra for interfaces grown at 650°C , complemented by *ab initio* calculations, was consistent with a 2DEG having occupied d_{xz}/d_{yz} electronic states at the Fermi energy [23]. This observation corroborates our recent results on standard LAO/STO interfaces, where a sharp decrease in the elastic scattering rate was correlated to the progressive appearance, at the Fermi level, of heavier carriers [14].

A lingering question pertains to the explanation of the lower carrier density and high mobility that are measured in samples prepared at low growth temperature, as compared to the “standard” ones discussed in the introduction. A puzzle related to this issue concerns the systematic discrepancy in the value of the carrier concentration that one finds when comparing Hall and SdH data [15, 19]. One may surmise that these observations point to the critical role played in transport by the two different types of electronic orbitals of the t_{2g} triplet. Spectroscopies and DFT calculations show that d_{xy} states are located close to the interface where disorder and lattice distortions likely result in low mobility [5]. Heavy d_{xz}/d_{yz} sub-bands extend deeper into the STO bulk and hence are less sensitive to these effects, giving rise to a much higher mobility; the presence of a large Rashba splitting could further help explain an enhancement of this mobility due to protection against backscattering. While both types of orbital can contribute to the magnetoresistance (analysis of our high-mobility samples support that), only the heavy d_{xz}/d_{yz} states have a high enough mobility to sustain SdH oscillations in our accessible range of magnetic fields.

Because the Zeeman energy enters equation (5) only as a squared term, for the LLs with $N > 0$, we find two solutions for the g^* -factor, namely 5.2 or -3.4 , values similar to the ones observed in semiconductor heterostructures. We note that g^* -factors significantly different from 2 were predicted

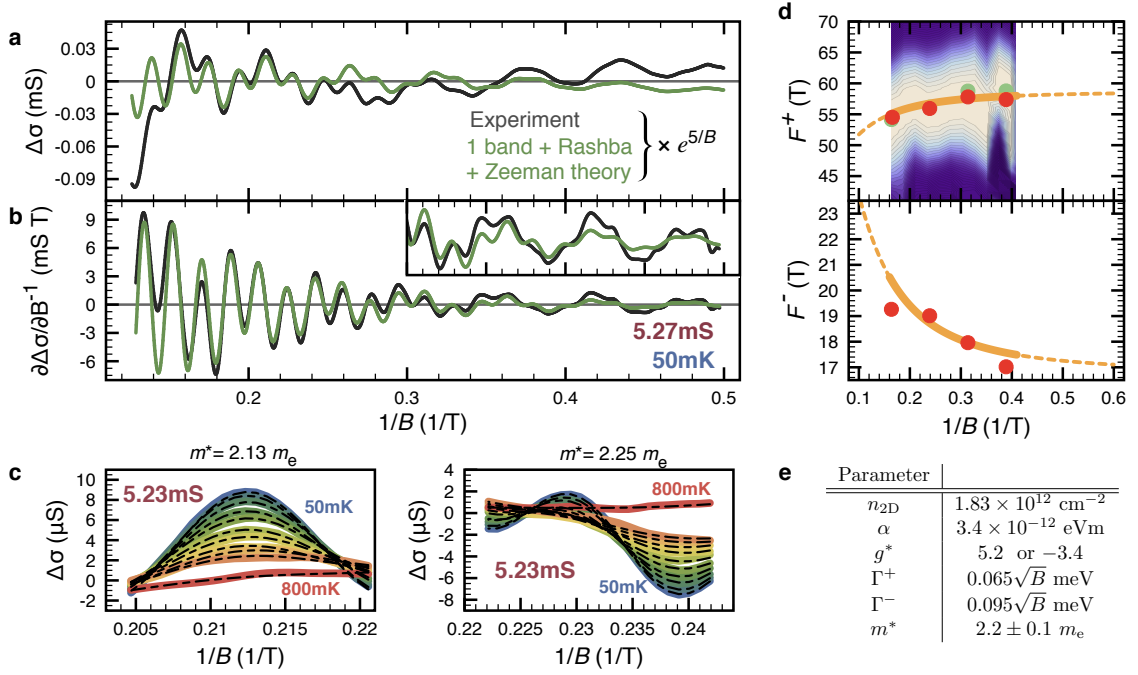

FIG. 3. (a) Comparison between $\Delta\sigma$ measured experimentally for $\sigma_{2D} = 5.27$ mS (black) and calculated using our single-band model with Rashba and Zeeman interactions (green). (b) Derivative with respect to B^{-1} of the curves presented in (a). The exponential factor $e^{5/B}$ is used to magnify the low-field region. (inset) Close-up on the low-field region of (b). (c) Temperature dependence of the oscillations over the two ranges of applied field used to extract the effective mass. Black dashed lines are the theoretical curves computed using $m^* \sim 2.2m_e$, while the thick coloured lines are the experimental data. (d) Magnetic field dependence of F^+ (top) and F^- (bottom). Red and green dots correspond, respectively, to the estimation made via the band pass filtered and differentiated signals. The background is a color plot based on the short time Fourier Transform of $\Delta\sigma$. (e) Summary of the fitting parameters.

by *ab initio* calculations in bulk STO [24]. In this second scenario, we can also estimate the Rashba splitting and the Fermi energy. Interestingly, we find that both are of the same order of magnitude: $\Delta_R = 2.2$ meV and $E_F = 1.65$ meV, a situation very different from the one of many semiconductor 2DEGs, where the Fermi energy dominates.

Owing to the complexity of the Rashba LLs spectrum, the oscillation frequencies (F^- , F^+ now linked to the $-$ and $+$ levels) are predicted to be field dependent [25, 26]. We have estimated, from the data, F^- and F^+ as a function of magnetic field using three different procedures (see supplementary data). Fig. 3d shows the estimated F^- and F^+ as a function of $1/B$ on top of the theoretical prediction (thick orange line). A very good agreement is obtained both in the amplitudes and in the signs of the frequency variations. We surmise that the field dependence of F^- and F^+ is the reason why the low field region of the quantum oscillations is fitted better by the Rashba model than by the two-band model (compare plots in inset of Fig. 2b and Fig. 3b). The fact that the pseudo-frequencies F^- and F^+ depend on B is pointing to SdH oscillations originating from a Rashba spin-split band and not from two bands.

We finally discuss the gate-voltage dependence of the SdH oscillations. Fig. 4a shows the change in conductance as a function of $1/B$ for various V_g (i.e. σ_{2D}). A clear evolution

of the SdH oscillations with decreasing doping is visible and is compatible with the shrinking of the Fermi surface expected from Hall measurements. With the help of the second derivative $-\Delta\sigma''(1/B) = -\partial^2\Delta\sigma/\partial(1/B)^2$ which amplifies F^+ , we identify all maxima from the “+” levels as a function of applied gate voltage. These maxima are indicated in Fig. 4a by black dots. We expect that the trajectories traced out by the black dots as a function of V_g correspond to the evolution of each LL as a function of the chemical potential. Strikingly, we see that these trajectories present sharp deviations or jumps upon decreasing V_g . This feature is clearly visible on the fan diagram of Fig. 4b featuring $-\Delta\sigma''(1/B)$ versus (B, σ_{2D}) which nicely illustrates the fact that the position of the “+” LLs follows a simple evolution only for limited regions of the diagram. Conversely, we observe that at precise locations the amplitude of the SdH oscillations is strongly suppressed.

There are many situations in which quantum oscillations rapidly change their phase and/or amplitude as a function of B . An example is the exchange interaction that enhances the g^* -factor for magnetic fields beyond a critical value [27–34]. Changes in the oscillation pattern can also occur when different LLs cross at a particular magnetic field: in this case anti-crossings can be observed [35–41]. These phenomena originate from many-body interactions. The deviations ob-

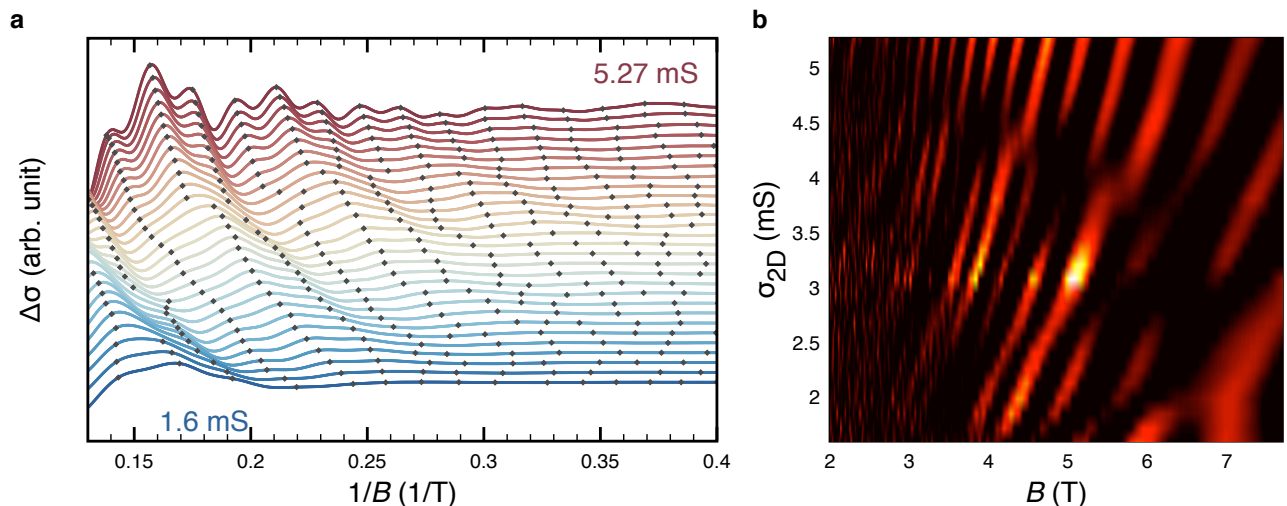

FIG. 4. (a) Analysis of the doping dependence of the SdH oscillations. Curves are shifted for clarity. Black dots indicate the position where maxima occur in $-\Delta\sigma''(1/B)$. (b) Fan diagram showing $-\Delta\sigma''(1/B)$; yellow corresponds to the maxima and black to negative values.

served in Fig. 4 point to an interaction whose energy scale is of the order of the LL splitting (≈ 0.1 meV at 2.5 T for the highest doping and the “+” levels). Further studies are needed to determine the nature of this interaction.

The study presented here unravels the remarkably complex behavior of the Shubnikov-de Haas oscillations seen at the LAO/STO interface. Our analysis reveals the important role played by the Rashba SOi on the electronic band structure and the peculiar regime hereby realized. Finally, the evolution of the LL spectrum as a function of doping and magnetic field displays sharp deviations that we cannot explain in our independent electron picture.

The authors would like to thank G. Seyfarth and D. Jaccard for help with the measurements and stimulating discussions, and are grateful to M. Lopes and S. C. Müller for their technical assistance. Large modulation of the Shubnikov-de Haas oscillations by the Rashba interaction at the LaAlO₃/SrTiO₃ interface - Supplemental Material

S1 – Growth conditions and sample geometry

LaAlO₃/SrTiO₃ interfaces were realized by growing 9 unit cells of LaAlO₃ on a (001) oriented TiO₂ terminated SrTiO₃ substrate using pulsed laser deposition. The deposition conditions were an oxygen pressure of 10⁻⁴ mbar, a substrate temperature of 650 °C, a repetition rate of the ablating laser of 1 Hz, and a fluence of 0.6 J cm⁻². The growth process was monitored *in-situ* using reflection high energy electron diffraction (RHEED). After growth, the sample was annealed for 1 hour in 0.2 bar of O₂ at a temperature of ~ 530 °C.

In order to avoid any photolithographic step after the layer deposition, we patterned the substrate with amorphous SrTiO₃ [1]. The dimensions of the Hall bars for magnetotransport measurements were 500 μm × 1000 μm (width × length). The field-effect devices were realized using the STO substrate as the gate dielectric adding a metallic contact on its backside (yellow rectangle, see Fig. 1). The blue arrow indicates the direction of the external magnetic field for all the magnetotransport measurements of this work.

FIG. 1. Schematic view of sample geometry.

S2 – Effective mass associated with the high- and low-frequency components of the SdH oscillations

In the LK formalism, the temperature evolution of the oscillations has the following functional form:

$$\Delta\sigma_i(B_m, T) \propto \frac{\alpha_{LK,i} T}{\sinh(\alpha_{LK,i} T)} \quad (4)$$

with $\alpha_{LK,i} = 2\pi^2 k_B / \hbar \omega_{c,i}^*$, $\omega_{c,i}^* = eB_m / m_i^*$, B_m the field at which the extremum is observed, i the band index, T the

FIG. 2. Extraction of the effective mass from the temperature dependence of the Shubnikov-de Haas oscillations in the two band model. Full lines correspond to the theoretical predictions taking m^* as effective mass. Dashed lines correspond to the theoretical predictions taking $m^* \pm 0.25m_e$.

temperature, and $-e$ the electronic charge.

Figure 2 illustrates the procedure that we followed to extract the effective mass using Eq. (4). The top (bottom) panel shows data obtained for the high-frequency (low-frequency) component of the magnetoconductance recorded at $\sigma_{2D} = 5.27$ mS. Each color is linked to the temperature evolution of a single oscillation.

S3 – Modeling the SdH oscillations in the case of a single band with Rashba/Zeman splitting

In order to determine the SdH oscillations pattern of the conductance for a single band with Rashba and Zeeman splittings, we start with the expression of the Landau levels presented in the main text,

$$\begin{aligned} E_{N=0} &= E_c/2 - E_Z \\ E_{N>0}^\pm &= NE_c \mp \sqrt{(E_c/2 - E_Z)^2 + NE_\alpha^2}, \end{aligned} \quad (5)$$

with $E_c = \hbar\omega_c^*$, $E_Z = (g^*/2)\mu_B B$ the Zeeman splitting, and $E_\alpha = \alpha\sqrt{2eB/\hbar}$ with α the Rashba coupling. Setting the values of m^* , g^* , α , and B defines the energy of the Landau levels (LLs) for a given magnetic field (vertical red/blue lines in Fig. 3, top). We broaden each level using a gaussian line shape with a variance $\Gamma^\pm = \gamma^\pm \sqrt{B}$, and perform the sum over all levels to obtain the density of states $g(E)$:

$$g(E) = \frac{eB}{2\pi\hbar} \sum_{N,s=\pm} \frac{1}{\sqrt{2\pi}\Gamma^s} \exp\left[-\frac{1}{2}\left(\frac{E - E_N^s}{\Gamma^s}\right)^2\right]. \quad (6)$$

The result is shown in Fig. 3, bottom.

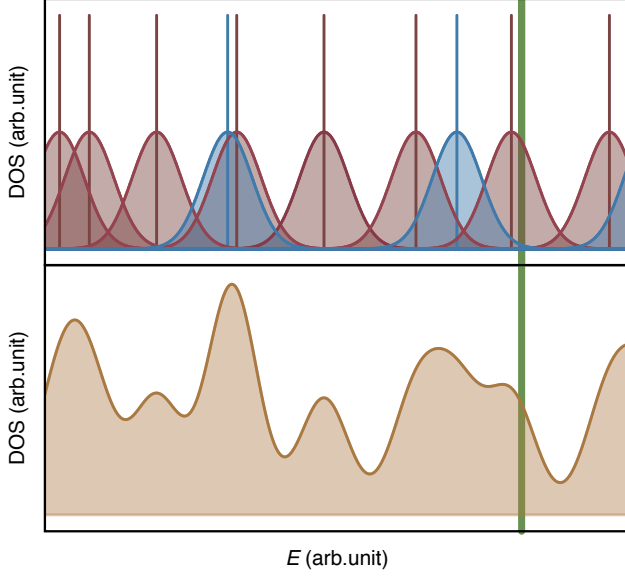

FIG. 3. (Top) Schematic view of the DOS for the two families (+, red; -, blue) of LLs in the Rashba model. (Bottom) Total DOS resulting from the sum of the + and - DOS. The green vertical line is the position of the Fermi level.

Different schemes are possible for the Landau-level broadening. In addition to the Gaussian with constant variance, Lorentzian and semi-elliptic line shapes have been considered [2]. In certain circumstances, a constant background was added to the total DOS. However, according to Ref. 3, many experiments revealed either a Gaussian line shape with a variance proportional to \sqrt{B} , or a Lorentzian one.

The Gaussian line shape is easier to treat numerically, thanks to the rapid decay of the Gaussian and the \sqrt{B} dependence of the variance allows a better fitting of our data.

The chemical potential μ (vertical green line in Fig. 3) is obtained by solving numerically the equation giving the carrier concentration at a given temperature,

$$n_{2D} = \int_{-\infty}^{\infty} dE f(E - \mu) g(E), \quad (7)$$

with $f(E) = (e^{E/k_B T} + 1)^{-1}$ the Fermi-Dirac distribution. Finally, the conductance is obtained via [21]:

$$\sigma_{xx} = \frac{e^2}{2\pi\hbar} \int_{-\infty}^{\infty} dE \left(-\frac{\partial f(E - \mu)}{\partial E} \right) \times \sum_{N,s=\pm} \left(N + \frac{1}{2} \right) \exp \left[-\left(\frac{E - E_N^s}{\Gamma^s} \right)^2 \right]. \quad (8)$$

We performed this calculation at each B in order to get the field dependence $\sigma_{xx}(B)$. Finally, the oscillating part $\Delta\sigma_{xx}(B)$ of the conductance was obtained by subtracting a

curve computed using a sufficiently high temperature T_{high} , at which the SdH oscillations are completely suppressed:

$$\Delta\sigma_{xx}(B, T) = \sigma_{xx}(B, T) - \sigma_{xx}(B, T_{\text{high}}). \quad (9)$$

This method was successfully applied, e.g., in Ref. 4.

S4 – Minimal parametrization of the Landau-level spectrum in the case of a Rashba/Zeeman split system

In the presence of a linear Rashba spin-orbit interaction and a Zeeman splitting, the LLs spectrum of a parabolic and isotropic band is given by Eq. (5). Introducing the energy scale $E_{c,1} \doteq E_c(B = 1 \text{ T})$ to normalize the energies, $\tilde{E} = E/E_{c,1}$, Eq. (5) can be simplified:

$$\tilde{E}_0 = \frac{E_c}{2E_{c,1}} - \frac{E_Z}{E_{c,1}} = \frac{B}{2} \left(1 - \frac{g^* m^*}{2m_e} \right) \doteq \frac{Ba}{2} \quad (10)$$

with $a = 1 - g^* m^*/(2m_e)$. Similarly,

$$\begin{aligned} \tilde{E}_N^{\pm} &= N \frac{E_c}{E_{c,1}} \mp \sqrt{\left(\frac{E_c}{2E_{c,1}} - \frac{E_Z}{E_{c,1}} \right)^2 + N \frac{E_a^2}{E_{c,1}^2}} \\ &= NB \mp \sqrt{\left(\frac{Ba}{2} \right)^2 + N \frac{2(am^*)^2}{e\hbar^3} \frac{1}{B}} \\ &= B \left(N \mp \frac{1}{2} \sqrt{a^2 + N \frac{D}{B}} \right) \end{aligned} \quad (11)$$

with $D = 8(am^*)^2/(e\hbar^3)$. We observe that, in the constant E_F approximation, only three parameters are required in order to determine the values B^* where the conductance is maximal³: those are \tilde{E}_F , a and D .

S5 – Using the LK formula to analyze the quantum oscillations in Rashba spin-orbit split bands

In this section we show that the LL spectrum generated by the Rashba spin-orbit interaction gives rise to SdH oscillations with two “pseudo-frequencies” that are field dependent.

It is well known that the LLs spectrum generated by a parabolic band is :

$$E_n = \hbar\omega_c^* \left(n + \frac{1}{2} \right) = \hbar \frac{eB}{m^*} \left(n + \frac{1}{2} \right) \quad (12)$$

Hence, in this model, the energy splitting between neighboring Landau levels is directly linked to the value of the effective mass and is independent of n . Indeed:

$$\frac{dE_n}{dn} = \hbar \frac{eB}{m^*} \quad (13)$$

³ Maxima in the conductance arise when a Landau level is at the Fermi energy, i.e., when B is such that one of the equations (10) or (11) is verified with $\tilde{E} = \tilde{E}_F$.

For a Rashba spin-split band the use of Eq. (11) leads to:

$$\frac{dE_{N>0}^{\pm}}{dN} = \hbar \frac{eB}{m^*} \left(1 \mp \frac{D}{4B} \frac{1}{\sqrt{a^2 + N \frac{D}{B}}} \right) \quad (14)$$

In this case, the splitting between LLs is N -dependent.

As we consider the conductance which is related to the DOS at the Fermi level, this spacing can be considered as almost constant for large N . More generally, we calculate, at a given magnetic field, the LL index at the Fermi level (N_F^{\pm}). Using the constant E_F approximation and restricting ourselves to $E_F \geq 0$ we get:

$$N_F^{\pm} = \frac{m^* E_F}{\hbar e B} + \frac{D}{8B} \pm \frac{\kappa}{8} \quad (15)$$

with:

$$\kappa = \sqrt{16a^2 + \frac{D}{B^2} \left(D + 16 \frac{m^* E_F}{\hbar e} \right)} \quad (16)$$

In turn, Eq. (15) can be used to define two “pseudo-frequencies” via:

$$F^{\pm}(1/B) = \frac{dN_F^{\pm}}{d(1/B)} \quad (17)$$

We get:

$$F^{\pm}(1/B) = \frac{m^* E_F}{e \hbar} + \frac{D}{8} \pm \left(\frac{\kappa}{8} - \frac{2a^2}{\kappa} \right) B \quad (18)$$

We observe that $F^+(1/B)$ and $F^-(1/B)$ depend on the magnetic field strength; this is the reason why we call them “pseudo-frequencies”. This dependence is due to the non-linear spacing of the Rashba/Zeeaman split LLs. $F^+(1/B)$ is a decreasing function of B while $F^-(1/B)$ is an increasing function of B . As shown in the main text, even though this magnetic field dependence is weak, it can be evidenced in our experimental oscillations.

For the experimental determination of F^+ as a function of $1/B$ we used two techniques. The first one consists in using filtering techniques or the second derivative of $\Delta\sigma$ to isolate the oscillations associated to F^+ (red and green dots in Fig. 3d of the main text), dividing the field range in 4 regions of equal size in $1/B$ and fitting the oscillations (in each region) with a cosine of constant frequency. The second one is to compute the short time Fourier transform (FT) of $\Delta\sigma$ (color plot in Fig. 4a of the main text). For F^- , due to the limited number of oscillations, we could only apply the first technique.

Coming back to Eq. (14), the splitting between LLs at the Fermi level in a Rashba/Zeeaman scenario is obtained by inserting Eq. (15) into Eq. (14):

$$\left(\frac{dE_{N>0}^{\pm}}{dN} \right)_{E=E_F} = \hbar \frac{eB}{m^*} \left(1 \mp D \frac{1}{B\kappa \pm D} \right) \quad (19)$$

which, if we define

$$m_{\pm}^* = m^* \left(1 \pm \frac{D}{B\kappa} \right) \quad (20)$$

can be rewritten in the same form as Eq. (13):

$$\left(\frac{dE_{N>0}^{\pm}}{dN} \right)_{E=E_F} = \hbar \frac{eB}{m_{\pm}^*} \quad (21)$$

Hence, in a magnetotransport experiment, if m_{\pm}^* does not vary too much with magnetic field, a Rashba/Zeeaman split LLs spectrum can be interpreted as two independent series of LLs of the form given by Eq. (12) (i.e. an analysis of the quantum oscillations using the LK formula will not fail altogether). However, in this case, the effective mass associated with $F^+(1/B)$ is larger than the effective mass associated with $F^-(1/B)$. This is exactly what we find.

We note that, with the parameters extracted from the fit shown in Fig. 3 of the main text, we find that the dependence of m_{\pm}^* on magnetic field is only of 5–10% between 2 and 8 T, which is below our experimental resolution.

Formula similar to the ones found in this section can be found in Refs. 25 and 26.

S6 – Determination of the effective masses associated with the quantum oscillations stemming from inter-sub-band scattering

In a 2DEG with more than one sub-band populated, inter-sub-band scattering was shown to bring additional components to the Shubnikov-de Haas oscillations [6, 7]. More recently, this effect was also discussed for systems composed of a unique Rashba spin-orbit split band [8]: the (pseudo-)frequencies associated to this phenomenon are $F^+ + F^-$ and $F^+ - F^-$. Moreover, according to theory, the two components related to the inter-sub-band scattering have a different temperature behavior; a higher effective mass is associated to the one at $F^+ + F^-$ than to the one at $F^+ - F^-$.

In Fig. 4, we present an analysis of the temperature dependence of the oscillations associated with the maxima of the FT that we indeed can observe at $F^+ + F^-$ and $F^+ - F^-$, for the measurement at the doping with the highest conductance (5.27 mS). We used band pass filters (whose limits are illustrated in Fig. 4) to select the different components of our spectrum. We obtain an effective mass of $1.75m_e$ and $2.5m_e$ for the component at $F^+ - F^-$ and $F^+ + F^-$, respectively. Due to the weak contribution of these frequencies to the total FT a non-negligible weight from the neighboring peaks is probably biasing our estimations.

Using the formula in [8], and the parameters of the fit presented in Fig. 3 of the main text, we calculate a mass of $\approx 1.2m_e$ (at $B = 5$ T) for the peak at $F^+ - F^-$, in reasonable agreement with our result.

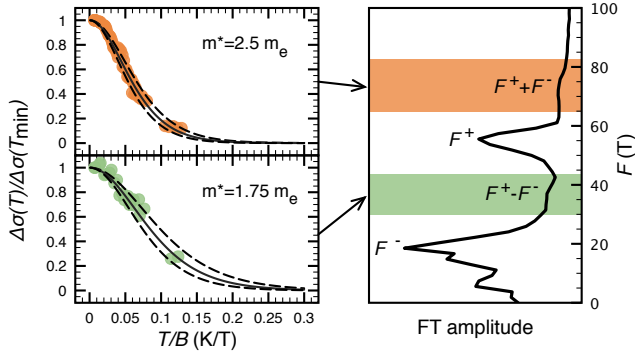

FIG. 4. (Left) Temperature dependence of the FT components located at $F^+ - F^-$ and $F^+ + F^-$, for the measurement at the doping with the highest conductance (5.27 mS). Full lines correspond to the theoretical predictions taking m^* as effective mass. Dashed lines correspond to the theoretical predictions taking $m^* \pm 0.25m_e$. (Right) Fourier transform of the same measurement. Colored regions define the limits of the band-pass filters.
