Abstract

Electronic structures of a superconductor without inversion symmetry, $LaPdSi_3$, and its non-superconducting counterpart, $LaPdGe_3$, have been calculated employing the full-potential local-orbital method within the density functional theory. The investigations were focused on analyses of densities of states at the Fermi level in comparison with previous experimental heat capacity data and an influence of the antisymmetric spin-orbit coupling on the band structures and Fermi surfaces (FSs) being very similar for both considered here compounds. Their FSs sheets originate from four bands and have a holelike character, but exhibiting pronounced nesting features only for superconducting $LaPdSi_3$. It may explain a relatively strong electron-phonon coupling in the latter system and its lack in non-superconducting $LaPdGe_3$.

Keywords: A. intermetallics, B. superconducting properties, E. electronic structure, calculation

1. Introduction

The investigations of specific conditions for superconductivity (SC) in non-centrosymmetric compounds were initiated in 2004 y. by the discovery of heavy-fermion SC in $CePt_3Si$ with the superconducting critical temperature, $T_c = 0.75$ K [1]. The lack of inversion symmetry of a crystal introduces the so-called antisymmetric spin-orbit coupling (ASOC) that may lead to some unconventional character of SC, i.e., revealing a mixture of spin-singlet and spin-triplet pairings [2, 3].

Among compounds adopting the tetragonal $BaNiSn_3$-type structure [4], the phenomenon of superconductivity has been reported for $LaPdSi_3$ (T_c = 2.60-2.65 K [5, 6]), $LaPtSi_3$ (T_c = 1.52 K [6]), $LaIrSi_3$ (T_c = 0.77 K [7]), $LaRhSi_3$ (T_c = 2.16 K [8]), $BaPtSi_3$ (T_c = 2.25 K [9]), $CaPtSi_3$ (T_c = 2.3 K [10]), $CaIrSi_3$ (T_c = 3.3 K [11]), $SrPdGe_3$ (Tc = 1.49 K [12]), and $SrPtGe_3$ (Tc = 1.0 K [12]). Despite the lack of centrosymmetry in the crystal structure, all these systems exhibit a typically BCS-like SC, except for $CaIrSi_3$ [11] having a weakly anisotropic superconducting gap. In turn, in this family, pressure-inducted heavy-fermion SC has been detected in $CeIrSi_3$ (T_c = 1.6 K [7]), $CeIrGe_3$ (T_c = 1.6 K [13]), $CeRhSi_3$ ($T_c \approx$ 0.72 [14]), and $CeCoGe_3$ (T_c = 0.7 [15]).

The $LaPdGe_3$ compound, recently reported by Troć et al. [16] as non-superconducting down to 0.3 K, can be considered as an isostructural reference system to the $LaPdSi_3$ superconductor. Interestingly, in the La-Pd-(Ge/Si) intermetallics, forming the layered $Immm$-type structures, the substitution of Si with Ge atoms clearly improves the SC properties [17, 18, 19, 20, 21]. This effect may be connected with some modifications of specific Fermi surface (FS) features enhancing an electron-phonon coupling [22]. Therefore, in this paper, electronic structures of $LaPdSi_3$ and $LaPdGe_3$ are probed from first principles to find any differences that might explain an unexpected suppression of SC in $LaPdSi_3$ by the substitution of Ge into Si atomic positions. Analysed are the Sommerfeld coefficients, calculated from densities of states (DOSs) at the Fermi level (E_F), γ_e, and their experimental values of specific heat data, γ. This allows for an estimation of electron-phonon enhancement factors, λ_{ep}. Furthermore, the FSs topology of the $LaPd(Si;Ge)_3$ is compared to that of other compounds crystallising in the $BaNiSn_3$-type structure as well as other non-centrosymmetric intermetallics, e.g. LaPtSi also exhibiting SC [23].

2. Computational details

Band structure calculations have been carried out with the full-potential local-orbital (FPLO-9) code [24]. The Perdew-Wang parametrisation (PW92 [25]) of the local density approximation (LDA) was applied in both scalar and fully relativistic modes. Experimental values of the lattice parameters of the $BaNiSn_3$-type (space group $I4mm$) unit cell (u.c.), $a = 0.4352$ nm, $c = 0.9661$ nm for $LaPdSi_3$ [5] and $a = 0.45079$ nm, $c = 0.98478$ nm for $LaPdGe_3$ [16] were assumed. The atomic (Wyckoff) positions have been fully optimised.

Valence-basis sets were automatically selected by the internal procedure of FPLO-9. Total energy values of considered systems were converged with accuracy to 1 meV for the 16x16x16 **k**-point mesh of the Brillouin zone (BZ), corresponding to 648 **k**-points in the irreducible part of the BZ.

3. Results and discussion

The optimised (LDA) atomic positions of $LaPdSi_3$ and $LaPdGe_3$, collected in Table 1, only insignificantly differ from the avaible experimental data [16]. Interestingly, the accordance of the optimised Wyckoff positions for $LaPdSi_3$ with the experimental values for $LaPdGe_3$ is even better than of those for the Ge-based system itself. This effect is related to the fact that the LDA usually yields an underestimation of the u.c. volume. Therefore, the experimental lattice parameters of $LaPdSi_3$, used in our calculations, are more suitable for the experimental atomic positions of $LaPdGe_3$.

The calculated DOSs of considered here systems, presented in Fig. 1, exhibit a similar shape with narrow peaks of the La 4f states located well above the Fermi level. The contribution of the La 5d electrons is minor in the whole range of the valence bands below E_F. These bands down to -3 eV are dominated by the Si 3p electron orbitals. In turn, the contribution of the Pd 4d electrons forms wide peaks centred at around -4.5 eV and -4.0 eV for the Si- and Ge-based systems, respectively. In $LaPdSi_3$, deep valence bands of the Si 3s electron orbitals (not displayed) are separated by a pseudogap around -6 eV, whereas in $LaPdGe_3$ the Ge 4s electron contribution is located at slightly lower energies (below -7 eV), thus the band-energy gap between -6 eV and -7 eV is completely open. A similar total DOS dependence is also exhibited by other La-Pd-(Si/Ge) intermetallics ($La_3Pd_4(Si;Ge)_4$ [22]), but with a less dominant influence of the Si/Ge p states.

The DOS in the vicinity of E_F in both compounds is prevailed by p-electrons coming from Si/Ge atoms like in the case of $CaPtSi_3$ [26, 27]. The calculated DOS at E_F, $N(E_F)$=1.42 states/eV/f.u., for $LaPdSi_3$ is only slighlty higher than that obtained for $LaPdGe_3$ (=1.32 states/eV/f.u.), both suggesting a weakly metallic character, being common for intermetallic superconductors and for other members of the $BaNiSn_3$-type family of compounds.

The calculated, γ_e, and experimental, γ, values of the Sommerfeld coefficients and T_c, as well as electron-phonon enhancement factors, λ_{ep}, derived from the relation: $\gamma = \gamma_e(1 + \lambda_{ep})$, are gathered in Table 2. The $\lambda_{ep} = 0.09$ for $LaPdGe_3$ indicates a negligible electron-phonon coupling. Therefore, the

BCS-like SC in this compound is impossible. It is worth to note that for $LaPdSi_3$ the obtained λ_{ep} values (=0.40-0.59) are comparable to that of $BaPtSi_3$ (0.49) and, generally, adequate for weakly-coupled superconductors. However, despite the fact that for $LaPdSi_3$ both the T_c and γ_e are close to those of $CaPtSi_3$, λ_{ep} (=0.21) of the latter compound is significantly lower than that of $LaPdSi_3$ (=0.59). This effect is not observed for $CaIrSi_3$, where the relatively high T_c (=3.3 K) may better correspond to the high γ_e(= 4.6 $mJ/mol/K^2$), but at the same time a resonably moderate value of λ_{ep} (=0.43) is obtained. A similar value of λ_{ep} (=0.33) has been also reported for LaPtSi with $T_c = 3.35$ K [23]. The low λ_{ep} value for $CaPtSi_3$ can be partly explained by worse quality of the polycrystalline samples.

The influence of an antisymmetric spin-orbit coupling on band structure of $LaPdSi_3$ is presented in Fig. 2. Although the ASOC-driven splitting is distinct in some regions, e.g. for the conduction bands around the Γ point (band splitting is of about 0.2 eV), the overall impact of ASOC on the band structure at E_F and, hence, also the FS of $LaPdSi_3$ is almost negligible. The pronounced ASOC effects are exhibited mainly by valence bands originating from the Pd 4d electrons, yielding relatively large contributions below -3 eV. The fully relativistic calculations for $BaPtSi_3$ [9] and $CaPtSi_3$ [27] also revealed only slight changes of the scalar relativistic band structures around E_F. Oppositely, in LaPtSi, adopting a different non-centrosymmetric structure of the $ThSi_2$-type, the ASOC-driven FS modifications are significant [23].

The Fermi surfaces of $LaPdSi_3$ and $LaPdGe_3$, consisting of four holelike sheets, calculated in the fully relativistic approach, are depicted in Fig. 3. Since in both considered systems, the ASOC-driven band splitting is small at E_F, the lift of the Kramers degeneracy in pairs of I-II and III-IV FS sheets is also negligible and the sheets within each pair remain almost identical. Moreover, the differences between the overall shape of the FS sheets of the Si-based superconductor and its Ge-based reference compound seem to be irrelevant. Similarly complex FS sheets to III-IV sheets presented in Fig. 3 have been reported for $BaPtSi_3$ [9], $CaPtSi_3$ [26, 27], and $LaIrSi_3$ [7]. However, the cylindrical shape of III-IV sheets centered at the X points, is a unique feature of FS exhibited by $LaPdSi_3$ and $LaPdGe_3$. This FS topology is connected with a band gap region around E_F, clearly seen in Fig. 2, along the X-P-Γ_3 line.

The sections of III-IV FS sheets for studied here compounds, presented in Fig. 4, reveal an almost ideal FS nesting with a vector $\mathbf{q} = (0.5, 0.5)\times(2\pi/a)$,

spanning the cylindrical surfaces. It is worth to underline that for $LaPdSi_3$ this specific nesting vector spans a large area, since the cylinders are distinctly flatter than those of the other system. This feature remains the same for both scalar (not displayed) and fully relativistic FS results. One can suspect that the relatively strong electron-phonon coupling in the Si-based compound may be related to the additional nesting-driven anomaly in phonon dispersion curves. This issue requires a further experimental verification. The analogous idea has also been postulated for other Pd-based superconductor $La_3Pd_4Ge_4$ [22]. Furthermore, in the non-centrosymmetric LaPtSi the influence of a similar FS-nesting-driven anomaly on BCS-like SC has been confirmed by calculations of the phonon dispersion curves [23]. Meanwhile, such nested FS areas have not been reported for other $BaNiSn_3$-type superconductors, thus this feature is generally not required for an occurrence of the SC in this family of compounds.

4. Conclusions

The electronic structures of superconducting $LaPdSi_3$ and its reference compound, $LaPdGe_3$, have been studied from first principles. Although the calculated densities of states of both systems are very similar, the comparison of estimated here Sommerfeld coefficients with those determined from heat capacity data suggests negligible electron-phonon coupling in the non-superconducting $LaPdGe_3$ compound. Moreover, the strength of an anti-symmetric spin-orbit coupling in the both studied systems is comparable to that of other compounds crystallising in the $BaNiSn_3$-type structure, but containing no heavy atoms. In turn, the spin-orbit splitting of their bands at the Fermi level is much weaker than that for LaPtSi (different non-centrosymmetric $ThSi_2$-type structure). Finally, the Fermi surfaces of both investigated compounds exhibit four holelike sheets with unique nesting features, being more pronounced for the superconducting $LaPdSi_3$ than those for its reference Ge-based system. Since in this superconductor the nested area of the calculated FS is substantially larger and its estimated electron-phonon coupling is much stronger than those in the other compound, the latter effect can be caused by a nesting-driven electron-phonon anomaly that could be observed in the phonon dispersion curves. Hence, this issue requires further experimental investigations.
