(Dated: March 3, 2022)

Quasi-free standing graphene (QFG) obtained by the intercalation of a hydrogen layer between a SiC surface and the graphene is recognized as an excellent candidate for the development of graphene based technology. In addition, the recent proposal of a direct equivalence between the *p*-type doping typically found for these systems and the spontaneous polarization (SP) associated to the particular SiC polytype, opens the possibility of tuning the number of carriers in the Dirac cones without the need of external gate voltages. However, first principles calculations which could confirm at the atomic scale the effect of the SP are lacking mainly due to the difficulty of combining a bulk property such as the SP with the surface confined graphene doping. Here we develop an approach based on standard density functional theory (DFT) slab calculations in order to quantify the effect of the SP on the QFG doping level. First, we present an accurate scheme to estimate the SPs by exploiting the dependence of the slab's dipole moment with its thickness. Next, and in order to circumvent the DFT shortcomings associated to polar slab geometries, a double gold layer is attached at the C-terminated bottom of the slab which introduces a metal induced gap state that pins the chemical potential inside the gap thus allowing a meaningful comparison of the QFG dopings among different polytypes. Furthermore, the slab dipole can be removed after adjusting the Au-Au interlayer distances. Our results confirm that the SP does indeed induce a substantial *p*-doping of the Dirac cones which can be as large as a few hundreds of meV depending on the hexagonality of the polytype. The evolution of the doping with the slab thickness reveals that several tens of SiC bilayers are required to effectively remove the depolarization field and recover the macroscopic regime whereby the graphene doping should equal the SP.

I. INTRODUCTION

Obtaining quasi-freestanding graphene (QFG) from epitaxial graphene (EG) on the SiC(111)/(0001)-face of silicon carbide (SiC) via intercalation of a H layer¹⁻⁴ has recently become a promising route to fabricate large area graphene of high-quality. Due to the reduced graphene-substrate interaction, QFG presents improved carrier mobilities as compared to graphene on the buffer layer (2000-3000 vs 700-900 cm²/Vs) together with a weak dependence on temperature^{5,6}. Excellent performance of QFG-based transistors has been already reported, for instance, by Robinson *et al.*⁷. Furthermore, as observed in scanning tunneling microscope (STM) experiments⁸ QFG is hardly corrugated and almost defect-free, which makes it an interesting system in the context of many-body theories in "2+1" dimensions. The electronic structure of QFG has been intensively studied during the last few years under different experimental techniques¹⁻¹² and a general consensus has been reached regarding the preservation of the linear Dirac cones. The most intriguing property, however, is the *p*-type doping consistently found in QFG, which is at striking contrast with the large *n*-type doping values ($\sim e \times 10^{13} \text{cm}^{-2}$) generally measured for EG^{3,5}. In Table I we present a summary of the doping charges, $\delta\sigma$, or alternatively the Dirac point (DP) shifts with respect to the chemical potential, ΔDP , reported in some representative works. Indeed, an ample

range of doping levels has been measured for similarly prepared QFG samples²⁻¹¹, attaining values larger than 300 meV¹³ or even small *n*-type doping¹. Furthermore, the values presented in the table hint certain correlation between the doping level and the hexagonality of the underlying SiC polytype; while cubic 3C-SiC(111) samples show relatively small *n*-type doping, all 6H- and 4H-SiC(0001) samples are *p*-doped. Very recently Mamadov *et al.*¹⁴ performed a systematic study of this correlation to find that the graphene doping was around 1.5 times larger in 4H than in 6H samples (see Table I), regardless of the substrate's doping level. Notably, similar doping levels are found for bilayer¹⁴ and even trilayer¹⁵ graphene, since in such multilayer systems the spacing between the occupied π bands is sufficiently large so that only the uppermost one becomes doped¹⁴.

Although the possibility of tuning the doping of the graphene layer across such a wide energy range (equivalent to hole concentrations of up to $2 e \times 10^{13} \text{cm}^{-2}$) is a key issue for the fabrication of QFG-based elements,¹⁶ the origin of the doping has remained controversial in many recent works^{13,15,17-20}. The main sources of graphene doping are recognized to be: (i) self-doping induced by intrinsic defects²¹, (ii) the substrate bulk doping¹⁴ and, (iii) the spontaneous polarization (SP) associated to the particular SiC polytype employed as substrate. The former stems from charge accumulation in the vicinity of a defect (vacancy or adsorbate); its electronic and magnetic properties have been characterized

in detail from the theoretical side for both free-standing graphene (FG)^{22–24} and QFG²⁴. The second arises from the details of the band bending at the surface and will in general depend on the nature and concentration of the bulk dopants which determine the location of the chemical potential within the gap (such mechanism is thought to be the cause of the mild *n*-type doping found for QFG on 3C-SiC(111) samples¹⁴). Last, the influence of the SP on the doping was first proposed by Ristein, Mammadov and Seyller (RMS) based on macroscopic dielectric theory²⁵ (a similar analysis was later presented in Ref. [26]) and next corroborated experimentally¹⁴ (Table I). This so called spontaneous polarization doping model assumes that the SP creates a *pseudo-charge* at the surface equivalent to an acceptor layer which should induce considerable doping charges of the order of $6\text{--}9\ e \times 10^{12}/\text{cm}^2$ for the most common 6H/4H-SiC(0001) substrates. Furthermore, since the SP along the (0001) direction remains negative for all hexagonal SiC polytypes, only *p*-doping should be induced at the Si terminated QFG systems, in accordance with the experimental observations listed in Table I.

Generally, the SP occurs in dielectric crystals with a distribution of dipoles along the surface normal such as those created at planar stacking defects (SDs); that is, when a stacking sequence is altered with respect to that in an ideal cubic crystal^{25,27,28}. In the bulk phase periodic boundary conditions impose a vanishing net electric field across the unit cell. However, at surfaces translation symmetry is broken and the dipoles may add up generating an uncompensated polarization field. As a consequence, the electrostatic (Hartree) potential, V_H , will raise or lower leading to an electrostatically unstable surface unless a source of hole or electron trapping is attached to it –the QFG layer, in our case, whose Dirac cones will end up *p*- or *n*-type doped, respectively. The SP is an intrinsic property of the dielectric characterized by its density of dipoles and their sign and magnitude, but the final value of the band bending at the surface will be also determined by the density of states (DOS) of the compensating charges at the 2D surface bands –for QFG, ideally linear in energy– as well as by the screening capabilities of the free carriers present in the dielectric which, in turn, depend on the temperature and the nature and concentration of impurities (bulk dopants)¹⁴.

Although macroscopic theory predicts a direct relationship between the SP and the doping charge in the QFG layer²⁵, it is not obvious if it still holds at the nanoscale. From the theoretical side, this represents a challenging task; despite several groups have reported *ab initio* SP estimates for the most common 2H-, 4H- and 6H-SiC(0001) polytypes following different approaches^{27,28,30,31}, no equivalent calculation has been attempted to date addressing its impact on the QFG doping. The difficulties associated to the slab geometries typically employed in *ab initio* studies of surfaces are various. First, one needs to reconcile a surface property such as the graphene doping with a bulk property such as the SP.

TABLE I. Summary of experimental doping values reported for graphene on hydrogenated SiC(111)/(0001) substrates employing different techniques. ΔDP expressed in meV and $\delta\sigma$ in $e \times 10^{12}\text{cm}^{-2}$.

Second, the polar character of the SiC(0001) slab³² leads to an uncompensated *compositional* polarization which will affect the calculated doping levels. Last, a reference chemical potential in the slab independent of the selected polytype is required to render any differences in the graphene doping meaningful. The aim of this study is precisely to develop a framework which circumvents these drawbacks allowing a precise determination of the QFG doping induced by the SP and, ultimately, establish their relationship.

In the spirit of Fu *et al.*³³ (FYRR) and Shi and Ramprasad³⁴ (SR) our scheme involves two dimensional slabs which can be solved by standard approaches such as density functional theory (DFT). We first generalize the SR slab formalism in order to estimate the bulk SP of the different SiC polytypes including the appropriate corrections required by the polar character of the SiC(0001). In doing so, we arrive at a general and simple, yet self-contained, expression relating the slab's dipole moment to the dielectric's macroscopic properties. Next, we address the problem of an adequate boundary condition at the bottom of the slab which could pin the chemical potential within the SiC gap regardless of the specific polytype. To this end we test various bottom terminations, including a H capping layer with and without an additional graphene layer as well as an ultrathin gold film of different thicknesses, to find that the latter solves satisfactorily the chemical potential problem. Semi-infinite QFG surfaces are next constructed and solved via Green's function methods in order to attain an accurate descrip-

tion of the Dirac cones and allow a precise estimation of their doping for each SiC polytype. Our scheme also provides a detailed picture of the development of the SP as a function of the slab thickness which should be relevant in the context of QFG on thin SiC films. We will assume throughout a perfect defect-free graphene layer thus restricting the study to SP induced dopings. The combined effect of SP and self-doping, on the other hand, is even more challenging and will be presented in a separate work³⁵.

The paper is organized as follows: in Section II the theoretical details of the DFT calculations are summarized. In Section III we present the slab formalism employed to study the bulk SiC dielectric properties together with the derived values for the relative permittivities and the SPs. The central findings of the paper are given in Section IV, where (i) different boundary conditions at the bottom are addressed, (ii) the QFG's doping due to the substrate's SP is calculated as a function of the slab thickness and, (iii) a simple electrostatic model based on macroscopic averages of the DFT results is analyzed in order to account for the calculated dopings. The last section is devoted to a final discussion and the conclusions.

II. THEORETICAL DETAILS

All DFT calculations have been performed with the pseudopotential SIESTA formalism³⁶ (as implemented within the GREEN package³⁷) and under the generalized gradient approximation (GGA).³⁸ We generated the atomic orbital basis set according to the double- ζ polarized (DZP) scheme employing confinement energies of 200 meV for all elements. Real space meshes with a resolution of $\sim 0.06 \text{ \AA}^3$ (mesh cut-off set to 700 Ryd) were defined for performing the 3-center integrals. Unless otherwise stated, the temperature used in the Fermi-Dirac distribution was $k_B T = 10 \text{ meV}$ while dipole-dipole interactions among neighbor supercells were suppressed via the usual dipole-dipole corrections.³⁹ Figure 1 shows the geometries of all considered polytypes, cubic 3C-SiC(111) as well as hexagonal 2H-, 4H- and 6H-SiC(0001) in a slab geometry. The density of SDs increases with the hexagonality of the polytype, presenting a SD every four, three and two bilayers (BLs) in the 6H, 4H and 2H structures, respectively. The corresponding lattice constant along the surface normal, c , contains two SDs and therefore, is six, four and two times longer than that of the cubic 3C (vertical solid lines in the figure). In all calculations the in-plane lattice constant was always fixed to the experimental value of $a^{\text{exp}} = 3.08 \text{ \AA}$ (our GGA optimized value is 3.10 \AA), while c was optimized for each polytype leading to the values given in Table II. The SDs only cause marginal expansions (below 0.5 %) of the inter-BL spacings.

Two types of 2D slabs have been considered. First, and in order to address the SiC dielectric properties, we defined (1×1) slabs, $\text{H}/(\text{SiC})_n/\text{H}$, oriented along the (111)

(or (0001) for polytypes) direction of different thicknesses n , with both the top (Si) and bottom (C) layers fully hydrogenated. A k -sampling of (30×30) for all these (1×1) slabs was found enough to achieve well converged values of the SP.

For the second set of slab calculations we added a graphene layer on top of the upper H capping layer, $\text{G}/\text{H}/(\text{SiC})_n/\text{X}$, and assumed a simplified $(2 \times 2)/(\sqrt{3} \times \sqrt{3})R30^\circ$ commensurability between the $\text{G}/\text{SiC}(111)$ lattices with the lattice constant of the slab set to that of the SiC, thus forcing an 8% expansion of the C-C bonds in the graphene with respect to that in the $(13 \times 13)/(6\sqrt{3} \times 6\sqrt{3})R30^\circ$ Moiré pattern experimentally observed⁸ (this should, nevertheless, have a minor impact on the calculated doping values). As detailed in section IV.A, different terminations X at the bottom of the slab were considered. We included van der Waals dispersion forces for a proper description of the graphene-substrate interactions following the semiempirical scheme of Ortman and Bechstedt.^{24,40} In the total energy optimizations we relaxed the first upper and lower surface layers in the slabs until forces were smaller than 0.02 eV/\AA while the geometry of the most internal SiC BLs was set to that optimized for the corresponding bulk polytype.

We highlight the fact that, in order to obtain well converged results for the (2×2) slabs, specially regarding the QFG doping charges, we required unusually fine reciprocal space k -meshes as large as (100×100) in the self-consistent Hamiltonian's calculations thus increasing considerably the computational effort. In Figure 2(a) and (b) we plot the graphene projected density of states (PDOS) and its associated charge, respectively. For a broadening of 5 meV the PDOS presents a spiky structure but, fortunately, the e and hole charges are well converged and can be accurately fitted by a quadratic energy dependence with a Fermi velocity of $v_F = 0.7 \text{ m/s}$ (for an isolated graphene layer we obtain $v_F = 0.9 \text{ m/s}$, which is about 20% smaller than the experimental value).

Once self-consistent Hamiltonians were obtained for the QFG slabs, we constructed true semi-infinite surfaces after replacing the bottom layers of the slabs by a semi-infinite bulk following the Green's functions based prescription detailed elsewhere.⁴¹ Band structures in the form of k -resolved density of states, $\text{PDOS}(k, E)$, projected on the QFG, H and uppermost SiC BLs were evaluated employing a broadening (imaginary part of energy) of 5 meV.

III. BULK SiC DIELECTRIC PROPERTIES

In this section we address the bulk dielectric properties of different SiC polytypes, namely: 3C-SiC(111) and 2H-, 4H- and 6H-SiC(0001). Although different schemes have been proposed to study these properties, most of them relying on 3D unit cell calculations^{27,30,42,43}, here we will adopt an alternative approach based on 2D slabs of different thicknesses^{33,34} given its simplicity and because the

FIG. 1. Geometries of the 9 BLs thick G/H/(SiC)₉/Au₂ slabs employed to model the QFG for different SiC polytypes. The two planes at the bottom correspond to the capping Au layer (see Section IV.A). The out of plane lattice parameter c , is indicated by vertical solid lines while dashed horizontal lines are drawn at the location of the SDs. The subindexes in 6H₁ and 4H₁ indicate that the first SD is the closest possible to the surface.

FIG. 2. (a) DOS projected on the graphene layer. Results for the G/H/(SiC)_n/Au₂ slabs with $n = 8 - 12$ and all polytypes are superimposed in different colors (see Fig. 4). The energy origin for each case is located at its DP while the broadening was set to 5 meV. (b) Charge doping of the graphene layer as a function of the chemical potential μ with respect to the DP and for the same cases as in (a). Thick dashed lines in (a) and (b) show the best linear fit to the DOS (obtained for a reduced Fermi velocity of $v_F = 0.7$ m/s) and the associated quadratic surface charge density, respectively.

impact of the SP at surfaces will be studied under this model geometry. We will revisit below the slab formalism in terms of the slab's dipole moment and its relationship to the *macroscopic* bulk polarization. Despite the derivation of such expression being based on standard electrostatic theory, we find it appropriate to present the entire formalism in detail since, after inspecting a vast number of works in the field, we were not able to find a general and explicit equation analogous to the one derived below. In appendix A we present a parallel study based on the bulk formalism of Qteish *et al*²⁷, which we find less precise.

Throughout this section we consider (1×1) H/(SiC)_n/H slabs with $n = 6 - 12$ the number of

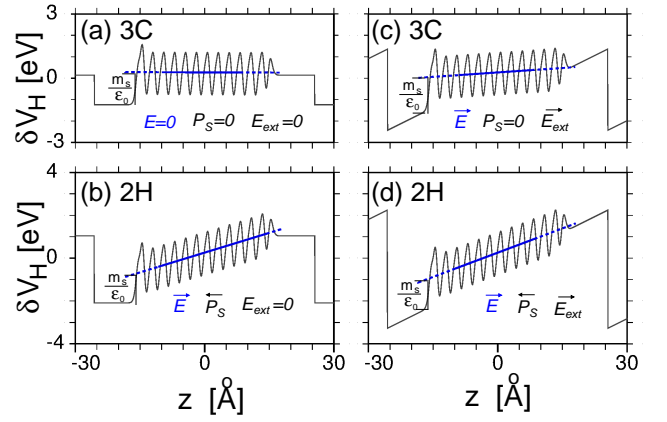

FIG. 3. $\delta V_H(z)$ profiles after averaging over the 2D unit cell for H/(SiC)₁₂/H slabs calculated under DDCs boundary conditions assuming a (a) 3C-SiC(111) and (b) 2H-SiC(0001) substrate. (c) and (d) are the same as (a) and (b), respectively, after applying an external field $E_{ext} = 0.1$ eV/Å. In each graph thick blue lines in the inner region of the dielectric correspond to macroscopic averages, $\overline{\delta V_H}(z)$, obtained via gaussian smearing employing a width of 5 Å. The potential discontinuity at the vacuum region, ΔV , appears at the right and left of each plot. The DDCs leave a localized dipole at the left surface (H-C termination) responsible for the m_s/ϵ_0 potential drop at the vacuum-surface interface, indicated in each plot after extrapolating $\overline{\delta V_H}(z)$ (thick dashed blue lines). On the other hand, the dipole and potential drop at the right surface (H-Si termination) is almost negligible.

SiC bilayers (BLs) while hydrogen capping layers are adsorbed both at the top (Si terminated) and bottom (C terminated) surfaces in order to saturate the dangling bonds and reduce the slab's dipole moment arising from the polar character of the SiC(0001) surface. As pointed out in Section II, all calculations include the usual dipole-dipole corrections (DDC) among image slabs so that the electric field in the vacuum arising from the slab's dipole is suppressed³⁹. In Figure 3 we present the planar averaged Hartree potential⁴⁴ profile along the slab's normal, $\delta V_H(z)$, for the 12 BLs thick 3C and 2H slabs without and with an applied external field ($E_{ext} = 0.1$ eV/Å). The corresponding macroscopic average $\overline{\delta V_H}(z)$ within the dielectric is superimposed as a thick blue line, from which the local electric field may be extracted via $\overline{E} = -\partial \overline{\delta V_H}(z)/\partial z$ (recall $\delta V_H(z)$ is given in $-|e|V$ units).

In order to establish the connection between the macroscopic bulk dielectric properties we are seeking and the quantities that may be extracted from the DFT calculations we express the slab's dipole moment per unit area, m , in terms of the polarization P in the dielectric and its thickness t as:

$$m(t) = m_s + P t \quad (1)$$

where, under DDC boundary conditions, the m_s constant is a surface localized contribution that accounts

for the polar character of the SiC slab and, as will be shown below, is only slightly dependent on the actual SiC polytype. In the absence of polarization m_s determines the potential drop at the vacuum region: $\Delta V = m_s/\epsilon_0$ (Fig. 3(a)), while for the general $P \neq 0$ case, ΔV has additional contributions from the external field and/or the SP (Figs. 3(b-d)).

In the above equation P represents the macroscopically averaged dipole moment density in the dielectric assuming it is homogeneous –that is, does not depend on z . In general, P may be split into two terms:

$$P = P_S + P_E = P_S + \epsilon_0 \chi_e \bar{E} \quad (2)$$

where P_S corresponds to the SP strictly defined as the polarization present in the slab at zero local field ($\bar{E} = 0$) while P_E is the polarization induced by the presence of a finite local field ($\bar{E} \neq 0$) –for the last equality we have further assumed that the dielectric is linear with a susceptibility $\chi_e = \epsilon_r - 1$.

Applying the continuity equation for the displacement field across any of the two vacuum-dielectric interfaces we arrive at:

$$\epsilon_0 \epsilon_r \bar{E} + P_S = \epsilon_0 E_{ext} \quad (3)$$

Thus, even if $E_{ext} = 0$, a finite value of P_S will be associated to a non-vanishing local field \bar{E} inside the slab (see Fig. 3(b)).

Combining eqs. (2-3) we arrive at a general expression for the total polarization which does not depend on the macroscopically averaged field \bar{E} :

$$P = \frac{P_S}{\epsilon_r} + \frac{\chi_e}{\epsilon_r} \epsilon_0 E_{ext} \quad (4)$$

Comparison of eq. (2) versus (4) clearly establishes that the SP defined at zero local field and that defined at zero external field differ by a $1/\epsilon_r$ factor³³. It also follows that if $P_S \neq 0$, the E_{ext} contribution in the second term above should not be identified with the induced polarization $P_E = \epsilon_0 \chi_e \bar{E}$.

Finally, inserting eq. (4) in (1) we arrive at our desired expression for $m(t)$ valid under DDCs boundary conditions:

$$m = m_s + (P_S + \chi_e \epsilon_0 E_{ext}) \frac{t}{\epsilon_r} \quad (5)$$

To our knowledge, and despite its simplicity, eq. (5) has not been explicitly reported before. For instance, in Ref.[33], where the SP for BaTiO₃ was studied also employing slab geometries, the $1/\epsilon_r$ factor was included via somewhat heuristic arguments.

In the spirit of SR, the unknowns in eq. (5), namely ϵ_r , P_S and m_s , may be extracted after fits of $m(t)$ curves calculated for different slab thicknesses and/or external fields. This is already an advantage versus bulk approaches where ϵ_r and P_S are typically obtained from independent calculations, or even the experimental value

of ϵ_r is employed²⁷. Below, we will derive first ϵ_r and next P_S from eq. (5) following a two stage linear fitting scheme –we found this approach more accurate than performing a simultaneous non-linear fit for both unknowns.

A. Relative Permittivities

The calculation of the relative permittivities, ϵ_r , for the various SiC polytypes is straightforward and may be regarded as a benchmark to test the accuracy of the calculation parameters described in the previous section. Taking the partial derivative with respect to t in eq. (5), we have:

$$\epsilon_r = \frac{\epsilon_0 E_{ext} - P_S}{\epsilon_0 E_{ext} - \partial m / \partial t} \quad (6)$$

The existence of a finite SP ($P_S \neq 0$), however, requires eq. (5) to be fitted with certain care. Here, we perform two sets of calculations for each polytype, one under a positive external field, $E_{ext} = 0.1$ eV/Å and a second one under a negative field, $E_{ext} = -0.1$ eV/Å. Denoting by m^\pm the dipole moment under $\pm E_{ext}$, we may subtract them to eliminate the P_S and m_s contributions in eq. (5) to obtain $\delta m = \frac{1}{2}(m^+ - m^-) = \frac{\chi_e}{\epsilon_r} \epsilon_0 E_{ext} t$, so that the relative permittivity may be directly calculated from the $\partial \delta m / \partial t$ slope via:

$$\epsilon_r = \frac{\epsilon_0 E_{ext}}{\epsilon_0 E_{ext} - \partial \delta m / \partial t} \quad (7)$$

If the atoms are relaxed under the presence of the electric field eq. (7) provides the static permittivity $\epsilon_r(0)$, while if they are fixed to their zero field equilibrium positions it gives the high-frequency permittivity, $\epsilon_r(\infty)$ ³⁴.

In Fig. 4(a) we show the $m(t)$ dependence for (1×1) H/(SiC)_n/H slabs with $n = 6 - 12$ and for all polytypes under $E_{ext} = \pm 0.1$ V/Å keeping fixed the geometry. The correct performance of the approach can be judged by the almost perfect linear behavior in all plots and the resulting high frequency permittivities $\epsilon_r(\infty) = 7.0 - 7.3$ (see Table II), only slightly larger than the reported experimental values for SiC at room temperature of $\epsilon_r(\infty) = 6.5$ ⁴⁵. Similar linear plots are obtained if the slabs' geometries are relaxed (not shown), yielding increased static permittivities of $\epsilon_r(0) = 10.3 - 10.9$ (Table II) which are again in good agreement with the experimental value of $\epsilon_r(0) = 9.7$ ⁴⁵. The small differences among polytypes arise from the fact that P_S and ϵ_r are coupled in eq. (5). On the other hand, we find the expected trend that as the hexagonality of the dielectric increases, the asymmetry between the $\partial m^\pm / \partial t$ slopes also increases due to the larger SP; that is, the response of the dielectric to an external field will be different if it already shows a finite polarization at zero field.

Finally, the intercept of $m(t)$ with the ordinate axis provides the DDC dipole moment m_s arising from the polar character of the SiC slabs (which is substantially

FIG. 4. DFT derived bulk dielectric properties for SiC. (a) Dependence of the dipole moment per unit area, m , with the $\text{H}/(\text{SiC})_n/\text{H}$ slab thickness, t , for 3C-, 6H₁-, 4H₁- and 2H-SiC polytypes. The slabs thickness ranges between 6 and 12 BLs. Positive and negative curves calculated under external fields of $+0.1 \text{ eV}/\text{\AA}$ and $-0.1 \text{ eV}/\text{\AA}$, respectively. Open circles correspond to the calculated dipole moments with fixed geometry while the straight lines are best fits to the data points. (b) Same as (a) but in the absence of an external electric field. Solid lines link the fitted values using approximation (9) for P_S in eq. (5). Blue, red, green and dark lines correspond to the 2H, 4H_{1/2}, 6H_{1/2/3} and 3C cases, respectively (see text for further explanations).

TABLE II. Calculated lattice parameter c in Å, dynamic and static relative permittivities, $\epsilon_r(\infty)$ and $\epsilon_r(0)$, respectively, and the spontaneous polarization values, P_S , in $\text{C} \times 10^{-2}/\text{m}^2$ ($e \times 10^{12}/\text{cm}^2$), for the different SiC polytypes considered in this work.

	c	$\epsilon_r(\infty)$	$\epsilon_r(0)$	P_S
3C	2.53	6.96	10.3	+0.1 (+0.4)
6H	15.22	7.26	10.8	-1.2 (-7.5)
4H	10.14	7.32	10.5	-2.0 (-12.5)
2H	5.08	7.35	10.9	-4.0 (-25.0)

reduced, but not fully removed, by the capping H layers). In our case, m_s attains essentially the same negative value for the 3C, 4H and 6H polytypes, while the 2H slightly deviates towards a smaller absolute value since the SP partially counteracts m_s .

B. Spontaneous Polarizations

Once ϵ_r is known, eq. (5) may be applied to the same set of $\pm E_{ext}$ slab calculations in order to estimate the SP of each SiC polytype via:

$$P_S = \epsilon_r \frac{1}{2} \frac{\partial(m^+ + m^-)}{\partial t} \quad (8)$$

Instead, we present below the SP analysis based on similar slab calculations but in the absence of an external field ($E_{ext} = 0$) in which case P_S takes the even simpler form $P_S = \epsilon_r \frac{\partial m}{\partial t}$. Hereafter we also pay attention to

the location of the first SD relative to the top Si layer and arrange the 6H (4H) slabs into three (two) subsets, 6H₁₋₃ (4H₁₋₂), where the subindex increases as the first SD is located further away from the uppermost BL.

In Fig. 4(b) we plot the dipole moment per unit area for all $\text{H}/(\text{SiC})_n/\text{H}$ systems with $n=6-12$. For the SD free SiC(111)-3C slab (black line) no SP exists and, according to eq. (5), the dipole moment (per unit area) should remain fixed to m_s independent of n , as it is indeed the case (the slope yields a negligible SP of $P_S^{3C} = 7 \text{ C} \times 10^{-4}/\text{m}^2$). On the other hand, the dipole moment for the 2H slabs (blue line) presents an almost perfect linear dependence with t due to the absence of crystalline regions, yielding a value of $P_S^{2H} = -4.0 \text{ C} \times 10^{-2}/\text{m}^2$ which is in reasonable agreement with previous works given the large scatter among the reported values ($P_S^{2H} = -1.1$ to $-4.3 \text{ C} \times 10^{-2}/\text{m}^2$)^{27,30,46}.

The 4H and 6H cases (red and green lines, respectively) show a somewhat different behavior and vary in a non-linear way with n . They present rather flat slopes with sudden drops whenever an additional SD is incorporated in the slab. The drops always attain similar values regardless of the slab thickness, the location of the first SD or the actual polytype (see below). Hence, they may be identified with the dipole moment per unit area associated to a single SD, m_{SD} , while the horizontal sections correspond to the SP in the crystalline regions of the slab, $P_{S,c}$. In fact, they are not strictly flat, but present negative slopes with associated SP values that decrease in absolute value with the hexagonality, $P_{S,c}^{4H_{1/2}} = -0.7 \text{ C} \times 10^{-2}/\text{m}^2$ and $P_{S,c}^{6H_{1/2/3}} = -0.4 \text{ C} \times 10^{-2}/\text{m}^2$, implying that the wider the crystalline region, the more efficiently is m_{SD} screened. Notably, and as indicated by the lines in the figure, within each subset the dipole moments can be very accurately fitted by setting:

$$P_S(t) = P_{S,c} + \epsilon_r m_{SD} N_{SD}(t)/t \quad (9)$$

in eq. (5), where $N_{SD}(t)$ is the number of SDs in the slab. The bulk SP for a given polytype is then simply given by:

$$P_S \approx \frac{\partial(P_S(t) t)}{\partial t} = P_{S,c} + 2\epsilon_r m_{SD}/c \quad (10)$$

where c is the length of the bulk repeat vector along the slab's normal (specific of each polytype and given in Table II) and the factor two accounts for the fact that there are two SDs per repeat unit (see Fig. 1). The fits employing eq. (10) yield a dipole moment per SD of $m_{SD} = 5.5 \times 10^{-4} \text{ e}/\text{\AA}$ and SP values of $P_S^{4H_{1/2}} = -2.0 \text{ C} \times 10^{-2}/\text{m}^2$ and $P_S^{6H_{1/2/3}} = -1.2 \text{ C} \times 10^{-2}/\text{m}^2$, again, in close agreement with previous estimates based on bulk calculations^{27,30,31,46} (see also Appendix A).

It also follows from eq. (9) and Fig. 4(b) that if within each subset of slabs we only consider in the fits those whose thicknesses differ by $c/2$ (that is, $\delta n = 2m$ for the 4H and $\delta n = 3m$ for the 6H cases, with m integer) then P_S becomes independent of t and may be directly obtained from the resulting linear slopes.

FIG. 5. Evolution of (a) the SP and (b) the electron/hole concentration as a function of the *electronic* (or Fermi-Dirac) temperature, T , for all polytypes (same color scheme as in Fig. 4). In (b) we only show results for the 12 BLs thick slabs.

1. SP dependence with e /hole concentration

Last, we explore the robustness of the SP versus the e /hole concentration in the *intrinsic* dielectric. To this end, we have recalculated the electronic structure of all $\text{H}/(\text{SiC})_n/\text{H}$ slabs self-consistently at different temperatures, T . More precisely, and since T only enters our calculations when computing the occupation of states via the Fermi-Dirac distribution function, we estimate the evolution of P_S with the density of bulk *free* charges or, equivalently, with the hole/electron concentration at the valence/conduction bands (we disregard, however, the dependence of ϵ_r with T). The results are displayed in Fig. 5 where we find the expected decrease of the SP in (a) as the electron/hole concentration shown in (b) increases. At typical SiC doping concentrations ($\sim 10^{18} \text{e}/\text{cm}^3$) all P_S values remain constant while beyond threshold concentrations of $\sim 10^{19} \text{e}/\text{cm}^3$ (or $k_B T > 120 \text{ meV}$) they start to decrease rapidly due to the screening of the internal dipole moments by the *bulk free* charges. Obviously, the threshold free charge concentration increases as the SP of the polytype does. Since the equivalent *electronic* temperature threshold is far above RT ($T > 1000 \text{ K}$), the SP in SiC(0001) samples may thus be considered as highly robust versus temperature or bulk dopings.

IV. RELATIONSHIP BETWEEN THE DOPING OF GRAPHENE AND THE SP

We now focus on the main point in this work, which is the estimation, from first principles calculations, of the doping of the Dirac cones in the QFG surface system due to the SP.

A. Slab models for QFG

Let us first address in detail the drawbacks of the slab geometry when modeling polar surfaces. To this end, we consider the QFG system $\text{G}/\text{H}/(\text{SiC}-3\text{C})_6/\text{X}$ already described in Section II, and examine different terminations X at the bottom of the slab in order to reduce the surface dipole and obtain a boundary condition at the bottom of the slab which could reasonably mimic that expected from a semi-infinite SiC(111) surface. Essentially, we look for electronic states within the gap and localized at the bottom of the slab which could lead to a well defined chemical potential, μ , in a similar manner as dopant impurities determine the chemical potential in a real dielectric. Although the discussion below is restricted to six BLs thick slabs, we have checked in all cases that increasing the slab thickness up to twelve BLs does not alter our conclusions.

We start with the most common practice of saturating the C dangling bonds at the bottom of the slab with H atoms. In Fig. 6(a) we plot the Hartree potential profile, $V_H(z)$, before (green line) and after (dark) adding the H capping layer. A reversal of sign and a substantial decrease of the surface dipole, m_s , is immediately obvious from the reduction of the potential step between the vacuum regions at both sides of the slab. In the same figure we present the graphene and BL resolved DOS for both cases. For the slab without H atoms at the bottom no trace of the graphene bands is seen in the energy window due to the huge doping induced by the unsaturated C atoms. Under the presence of the H-capping layer, on the other hand, the chemical potential (or Fermi level) remains fixed at the DP and within the gap. The surface dipole may be reduced by expanding the C-H bond lengths at the bottom of the slab thus generating a local dipole that may counterbalance the former. The resulting potential after an outwards 0.45 \AA displacement of the saturating Hs is shown by the blue lines in Fig. 6(b). Although the potential step is essentially removed, the position of the DP remains pinned at μ . This is a consequence of the absence of gap states at the bottom of the slab, so that charge neutrality forces the bands of graphene to follow any band bending (BB) and pins μ at the DP. Indeed, as long as the BB does not cross into the conduction or valence bands this picture will remain regardless of the presence of any internal dipoles in the slab. Therefore, slab models with a H capping layer at the bottom are not suitable for the estimation of any SP-derived doping.

A natural way of introducing gap states could be to add another graphene layer at the bottom leading to a more symmetric $\text{G}/\text{H}/(\text{SiC})_n/\text{H}/\text{G}$ geometry. The Hartree potential and DOS for such case are given by the dark lines in Fig. 6(c). We now find an enhanced BB which leads to the pinning of μ at the valence band edge of the lower SiC BL together with large n - and p -type dopings at the bottom and top graphene layers, respectively, that compensate each other. Expanding the bond lengths at the

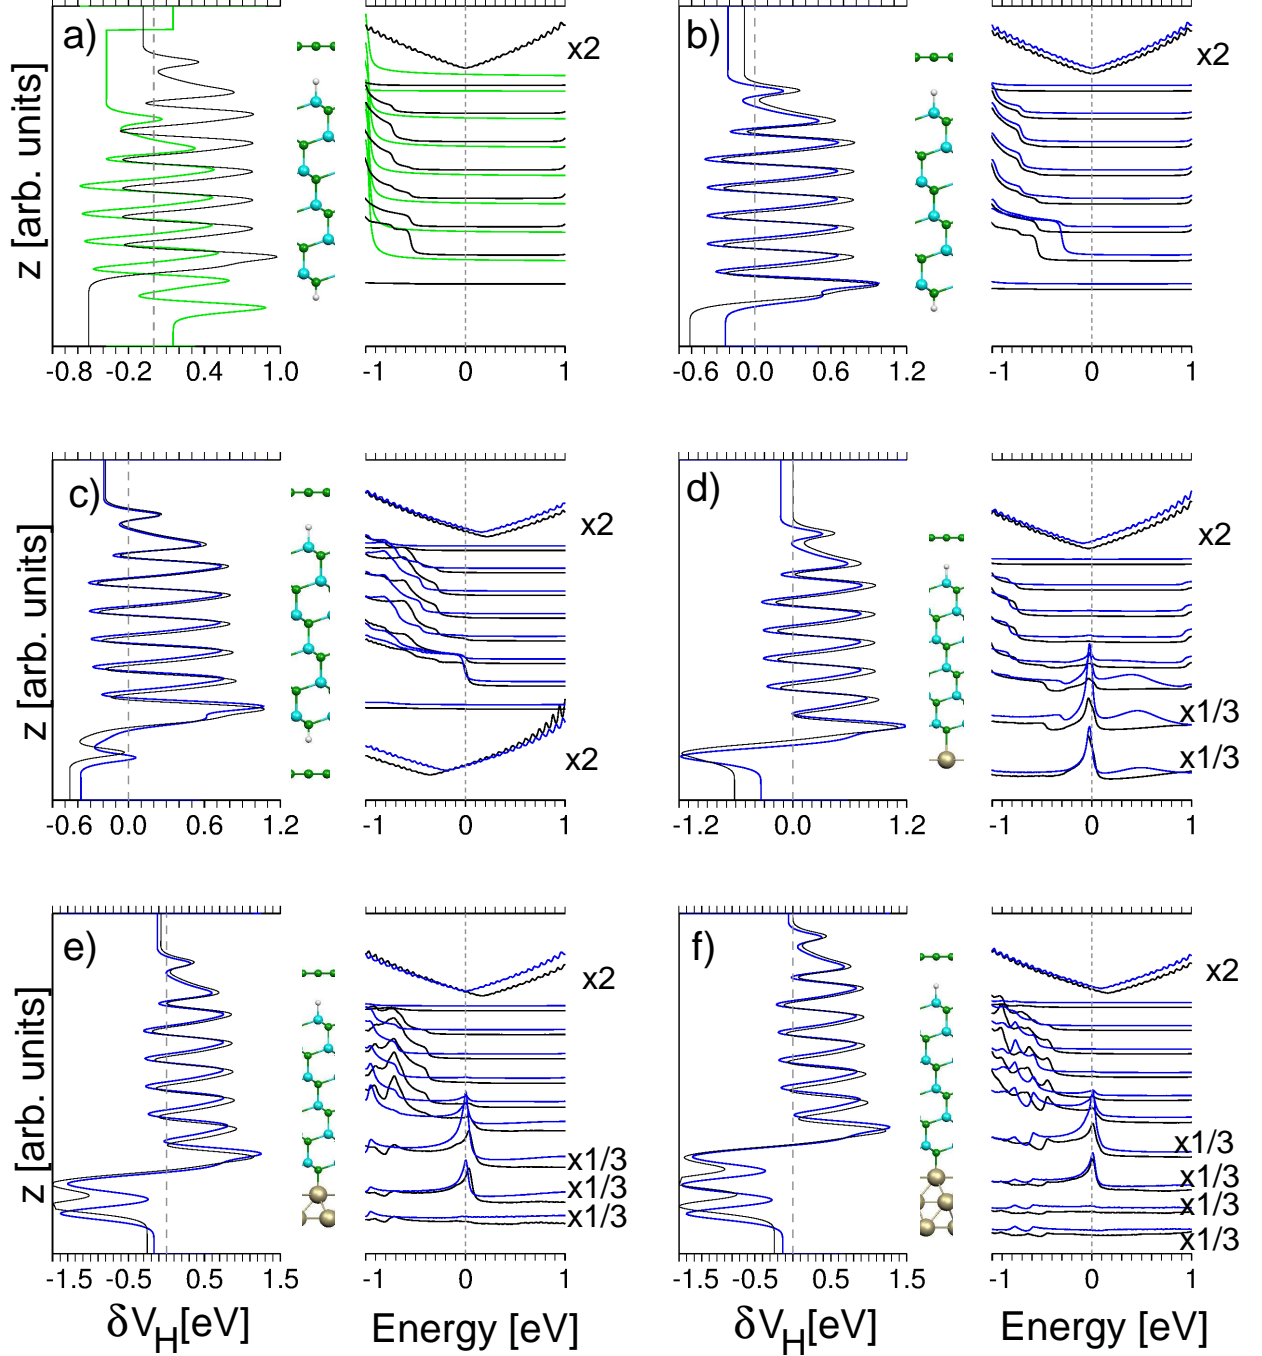

FIG. 6. (a) left: $\delta V_H(z)$ profile along a $G/H/(\text{SiC})_6/H$ slab depicted at the center and, right: the corresponding DOS projected, in ascending order, on the bottom H layer, the six SiC BLs, the intercalated H layer and the graphene; green (dark) lines correspond to a slab calculation without (with) the H capping layer at the bottom. (b) Dark lines same as in (a) while blue lines correspond to the same H-saturated slab after elongating the C-H bonds at the bottom by 0.45 \AA . (c) Same as (b) but for a $G/H/(\text{SiC})_6/H/G$ slab; dark lines correspond to the relaxed geometry and blue after elongating the C-H bonds by 0.4 \AA and shifting the bottom graphene layer by another 0.4 \AA . (d) Same as (c) but for a $G/H/(\text{SiC})_6/\text{Au}$ slab; dark lines for the relaxed geometry and blue after expanding the Au-C bonds by 0.5 \AA . (e) Same as (d) but for a $G/H/(\text{SiC})_6/\text{Au}_2$ slab; blue lines correspond to expansion of the Au-C bonds and the Au interlayer distances by 0.5 \AA and 0.65 \AA , respectively, with respect to the relaxed geometry (dark). (f) Same as (e) but for a $G/H/(\text{SiC})_6/\text{Au}_3$ slab after applying 0.4 \AA elongations to the C-Au and both Au-Au interlayer spacings (blue) with respect to the relaxed geometry (dark).

bottom of the slab by considerable amounts (blue lines) hardly changes the doping level at the top graphene and hence, this model can also be ruled out for the estimation of any influence of SPs.

Our next trial model consists of replacing the H capping layer by a metallic one with the hope that the creation of a metal-induced gap states (MIGS) could effectively pin μ within the gap. As shown in Fig. 6(d)-(f), this is indeed the case when one, two or three Au layers, respectively, are used to passivate the C dangling bonds. We found energetically more favorable to place the Au layer in contact with the C atoms at top positions while additional Au layers are stacked following an *fcc* sequence. For the 1 ML case, dark line in (d), the MIGS appears as a large peak in the middle of the gap which penetrates up to three bilayers into the dielectric. The top graphene is now only slightly *n*-doped and although the dipole is still considerable it may be again suppressed by expanding the Au-C spacings (blue lines). The expansion leads to an enhancement of the MIGS's DOS and a slightly larger doping. Adding a second Au layer changes the doping to *p*-type with the MIGS still pinning the chemical potential within the gap although this time slightly closer to the valence band (dark lines in (e)). In order to compensate the surface dipole we now require Au-C and Au-Au expansions as large as 0.50 and 0.65 Å, respectively, but with the fortunate outcome of removing the doping and leaving the DP aligned with μ . For the sake of completeness, we present in (f) the case of three Au layers, where a moderate *p*-doping is now obtained even after elongating the interlayer spacings.

In summary, we find that μ can be pinned at the bottom of the slab and within the gap after capping the C atoms with an Au layer via the appearance of a MIGS. Furthermore, the surface dipole can be removed by expanding the Au-C and Au-Au interlayer distances by large amounts (~ 0.5 Å) while the actual doping in the graphene layer can be tuned by choosing the thickness of the metallic layer, obtaining *n*-doping for one atomic plane, no doping for two and *p*-doping for three. The pinning of μ occurs due to the much larger DOS of the MIGS compared to that of the QFG, and we stress that it is an essential prerequisite to make meaningful any differences in the graphene doping among different polytypes. Also note that our model slabs may be as well employed to quantify any doping in the graphene arising from defects³⁵.

B. Doping of graphene due to the substrate's SP

Once we have proven that both the SP and the QFG doping can be evaluated under the same slab-based framework we may explore their interplay as a function of the SiC polytype and the slab thickness. We choose the G/H/(SiC)_{*n*}/Au₂ slab with elongated bonds at the bottom shown in Fig. 1 as our model system for all calculations presented in this section since in the absence

of SDs it yields hardly any doping (see Fig. 6(e)). Alternatively one may use the Au₁ termination if a small *n*-type doping is desired for the 3C case (as often found experimentally –see Table I) or the Au₃ termination for a mild initial *p*-type doping. Both terminations should anyhow yield similar dopings if the DP location for the 3C case is used as the reference when comparing against the rest of polytypes.

In order to achieve a more accurate picture of the surface electronic structure we calculated the graphene and SiC projected density of states (PDOS) under a semi-infinite geometry after replacing the Hamiltonian matrix elements involving the lower layers in the 12 BL thick slab by those corresponding to an ideal bulk termination as outlined in Section II⁴¹. Figure 7 shows *k*-resolved PDOS on graphene, the intercalated H layer and the first three SiC BLs for the 3C, 6H₁, 4H₁ and 2H slabs for the maximum thickness considered, *n*=12. The semi-infinite geometry provides a continuum of states for the valence band while the Dirac cones across the gap are clearly visible in all plots. In accordance with the experimental trend, the DP shift with respect to the chemical potential, ΔDP , increases with the hexagonality of the polytype; starting from a marginal value of 14 meV for the SD free surface (a), we obtain a value as large as $\Delta DP=320$ meV for the 2H case (d), that is, equivalent to a *p*-type doping surface charge density of $\delta\sigma = 17 e \times 10^{12}/\text{cm}^2$. The 6H₁ and 4H₁ surfaces (b)-(c), also show substantial shifts of 183 and 240 meV, respectively, corresponding to charges in the $5-10 e \times 10^{12}/\text{cm}^2$ range.

It is important to note, however, that despite the model system being semi-infinite, the doping calculated for each polytype depends on the particular slab employed to perform the matching with the bulk. This is because the Fermi level and the Hamiltonian matrix elements employed for the surfacemost layers in the semi-infinite are extracted from the slab calculation and, hence, they implicitly contain the DP shift, whereas those employed for the bulk like layers are extracted from a separate bulk calculation in which no band bending can occur due to the periodic boundary conditions (in fact, the ΔDP values differ by less than 5 meV when deduced from equivalent PDOS plots extracted directly from the slab calculation).

Fig. 8 shows the calculated graphene doping for all surface systems as a function of the number of BLs, *n*, included in the slab. For the 6H and 4H stackings we again take care of the location of the uppermost SD and group the results accordingly (see III.B). For the 3C case the DP remains close to μ for all thicknesses, thus corroborating the general validity of our slab model as no doping is expected in the absence of SP. On the other hand, the correlation between $\delta\sigma$ and the SP becomes patent after noting the stairlike behavior of the doping for the 4H and 6H polytypes, highly reminiscent of that appearing in Fig. 4(b). The dopings depend on the number of SDs in the slab, with positive jumps whenever a new SD is incorporated while if the added BL follows the

FIG. 7. DOS(k, E) projected on graphene, H and first three SiC BLs of a G/H/SiC semi-infinite surface calculated after matching the Green's function of a G/H/(SiC)₁₂/Au₂ slab with that of the corresponding bulk (see Sec. II for further details). Four different SiC polytype surfaces are shown: (a) 3C, (b) 6H₁, (c) 4H₁ and (d) 2H. The DP shift, ΔDP , is indicated in each plot in meV.

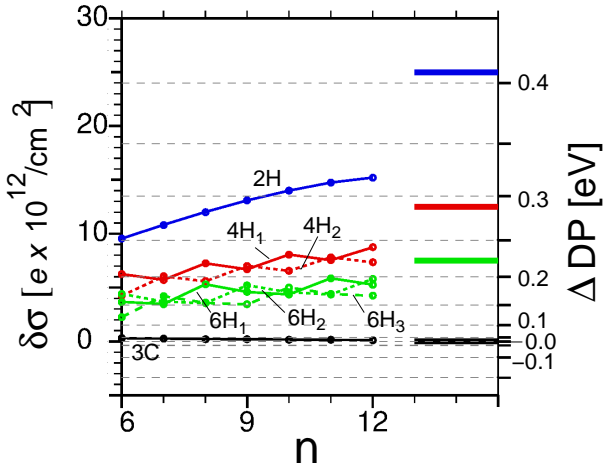

FIG. 8. Doping of the graphene layer for all G/(SiC)_n/Au₂ slabs considered in this work as a function of n , the SiC polytype and the location of the SD closest to the surface (same color scheme as in Fig. 4); left axis gives the surface charge density and right axis (quadratic scale) the Dirac point shift, $\Delta DP = DP - \mu$. Horizontal lines at the right give the bulk SP associated to each polytype (see Table II).

cubic stacking the doping decreases only slightly. Overall, the surface charge densities, $\delta\sigma$, increase almost linearly with n and approach the SP value of each polytype (given in Table II and indicated in the plot by thick horizontal lines at the right). At the largest thicknesses considered, $n=12$, the dopings amount to around 60-70% of their respective P_S limits (see next subsection). For the 2H surface the plot shows certain curvature for $n > 10$ suggesting that the doping may saturate at a value well below P_S . Indeed, Fig 7 shows that μ approaches the valence band maximum (VBM) as the hexagonality of the polytype increases due to a larger BB at the surface. For the 12 BLs thick 2H slab, μ is already pinned at the VBM (Fig. 7(d)) and, therefore, the substrate bands become an additional source of hole doping which competes with the graphene.

C. Macroscopic model

We end this section by presenting a *macroscopic* analysis of our results in order to rationalize the $\delta\sigma(t)$ behavior shown in Fig. 8 as well as to establish its connection with the expected $P_S = -\delta\sigma$ macroscopic relationship²⁵. To this end, we display in Fig. 9 with thick dark lines macroscopic averages⁴⁴ of the charge redistribution profile, $\overline{\delta\rho}(z)$, and its Hartree potential, $\overline{\delta V_H}(z)$, for a G/H/(SiC)₁₂/Au₂ slab considering a 3C (a)-(c) and 2H (b)-(d) stacking –the original profiles are also shown as thin lines in each plot. Both slabs present a region at the center of the dielectric where charge neutrality is preserved ($\overline{\delta\rho}(z)=0$) and the local field remains constant ($\overline{E} = -\partial\overline{\delta V_H}(z)/\partial z$). Thus the entire system may be split into four sections, namely: a central (neutral) dielectric region (I), the left and right edges (L and R) which will be metallic due to the G at R and the Au layers at L , and the vacuum region V where both $\overline{\delta\rho}(z)$ and the electric field vanish. The widths of each region, $d_{I/L/R}$, are determined by requiring $\sigma_I=0$ and $\sigma_L = -\sigma_R$, where σ_i is the total charge per unit area in region i . The model satisfies Gauss' law $\sigma_{R/L} = \mp\epsilon_0 E_I$, with $E_I = ((\overline{\delta V_H}(R) - \overline{\delta V_H}(L))/d_I)$ being the local electric field in the dielectric (see Figs. 9(a) and (b)) generally denoted as the depolarization field in the context of ferroelectricity^{32,47}. Its origin is the incomplete compensation of the SP by the graphene doping charge so that net charges of opposite signs reside at each surface of the slab (in Fig. 9(d) we have a net negative charge at R and positive at L).

Finite positive depolarization fields consistently appear for the rest of slabs and polytypes, as shown in Fig. 10(a) where we plot the E_I dependence on d_I . For the 2H case we obtain an almost linear behavior indicating that the depolarization field should vanish at large n (after linear extrapolation this should occur at $d_I \gtrsim 50$ Å or 30 BLs). The 4H slabs also show an overall decrease as d_I increases with upwards jumps when the added BL follows a cubic stacking while the 6H cases do not show such clear trends

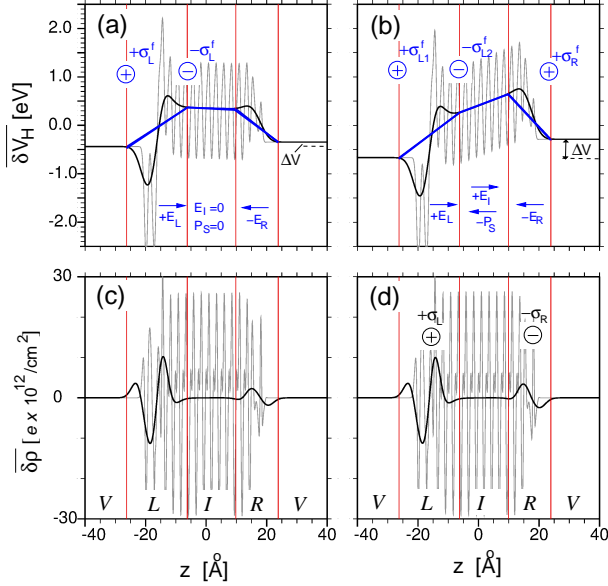

FIG. 9. (a) and (c) Macroscopically averaged potential and charge density profiles, $\overline{\delta V_H}(z)$ and $\overline{\delta \rho}(z)$, respectively, for a G/H/(3C-SiC)₁₂/Au₂ slab. (b) and (d) same as (a) and (c) but for a G/H/(2H-SiC)₁₂/Au₂ slab. The macroscopic averaging has been performed via gaussian smearing employing a width of 3 Å. Thin lines in all plots show the original profiles averaged over the 2D unit cell but before macroscopic averaging. The V/L/I/R/V regions into which the system is split are delimited by the vertical lines, while in (a) and (b) thick blue lines depict the model potential profile used to analyze the data together with the location of the free charge sheets (only in (b)). In (d) total net charges in L and R are also sketched.

specially at small thicknesses mainly due to inaccuracies in the determination of E_I . After comparison against Fig. 8, a clear anticorrelation is again found between the depolarization field E_I and the doping charge $\delta\sigma$. Indeed, applying the continuity of the displacement field across region R, both quantities are related via the SP:

$$\delta\sigma = -\epsilon_0 \epsilon_I E_I + P_S \quad (11)$$

Therefore, using the data shown in Figs. 8 and 10(a) for $\delta\sigma$ and E_I , respectively, and assuming ϵ_I attains, for each polytype, the bulk high frequency permittivity given in Table II, one may estimate P_S as a function of d_I . The resulting SPs, shown in Fig. 10(b), remain essentially constant and very close to the bulk SPs derived in the previous section (indicated by thick horizontal lines at the right of the plot). Only the 6H slabs at the smallest thicknesses present substantial deviations due to the accuracy problems mentioned above. We thus conclude that the SP has basically fully developed in all our model slabs so that, according to eq. (11), it is the depolarization field alone which reduces the graphene doping charge to values below the bulk SP.

In order to gain further insight into the origin of E_I , we follow a similar approach to that employed by Daw-

FIG. 10. (a) Macroscopic depolarization field E_I as a function of the width of the dielectric region, d_I , for the 2H, 4H_{1/2} and 6H_{1/2/3} G/H/(SiC)_n/Au₂ slabs. Color scheme same as in Fig. 4. Solid circles correspond to the values derived after macroscopic averaging and lines to the fitted values employing eq. (12). (b) SP value for each polytype and slab thickness deduced from fits to eq. (11). (c) Calculated $\epsilon_0 \Delta V$ potentials and (d) fitted $\epsilon_0 \Delta V_{L2}$ potentials using eq. (12) for the same cases as in (a) and (b). Note that, by convention, both P_S and ΔV_{L2} are defined as positive quantities in this subsection.

ber *et al*⁴⁷ to study the effect of the electrode's thickness on the depolarization field in ferroelectric slabs. However, at contrast with their model for the potential profile where two thin sheets of *free* charge are placed at the edges of the slab, our slab geometries are less symmetric and require at least three such sheets, as indicated in Fig. 9(b) where the model profile is superimposed by thick blue lines. One sheet is placed at the right edge of region R ($+\sigma_R^f = \delta\sigma$) simulating the doped graphene layer and another two ($+\sigma_{L1}^f$ and $-\sigma_{L2}^f$), located at the left and right edges of region L, in order to model the double gold layer. The model grasps the main peculiarity of the slabs' macroscopic profiles (dark thick lines) which is the large dipole at the gold region L –already evident from the $\overline{\delta \rho}(z)$ profiles in Fig. 9(c-d). Obviously, the sum of these charges should yield no net free charge in the system. Effective constant fields $E_{L/I/R}$ may then be defined within each region, while the potential drop in the vacuum region due to the DDC boundary conditions may be written as: $\Delta V = E_L d_L + E_I d_I - E_R d_R$. Throughout this subsection we follow the convention that all variables take positive values while the \pm signs take care of the direction of the fields. Employing the above relation and applying the continuity equation for the dis-

placement field at the V/L and L/I interfaces we obtain:

$$\epsilon_0 E_I = \frac{P_S d_m + \epsilon_0(\Delta V - \Delta V_{L2})}{d_I + \epsilon_I d_m} \quad (12)$$

where $d_m = d_L/\epsilon_L + d_R/\epsilon_R$ is a distance that only depends on the width and nature of the left and right electrodes and $\Delta V_{L2} = \sigma_{L2}^f d_L/\epsilon_L$ represents the potential drop for a capacitor of charged $\pm\sigma_{L2}^f$ sheets with a dielectric of width d_L and relative permittivity ϵ_L inserted between them. Eq. (12) recovers the correct $E_I \approx 0$ limit as d_I increases with the slab thickness. It is essentially the same as that deduced by Dawber *et al* except for the extra $-\epsilon_0\Delta V_{L2}$ term in the numerator. We note, however, that reasonable fits for E_I using eq. (12) cannot be achieved if this extra term is ignored.

Unfortunately, the ΔV_{L2} potential drop introduces too many unknowns at the L electrode (namely, ϵ_L and $\sigma_{L1/2}$), which cannot be all determined from the available computed data. Instead, we set a large value for the relative permittivity in this region, $\epsilon_L = 10^3$ and use eq. (12) to estimate ΔV_{L2} (the conclusions are hardly affected by the precise permittivity value as long as it attains reasonably large values $\epsilon_L > 20$, as expected for a metallic electrode). In Figs. 10(c) and (d) we present the computed $\epsilon_0\Delta V$ and optimized $\epsilon_0\Delta V_{L2}$ values, respectively, as a function of n for all polytypes. In the absence of SP, the condition for a vanishing depolarization field becomes $\Delta V_{L2} = \Delta V$. Indeed, in the previous subsection we showed that by elongating the Au-Au and Au-C spacings at the bottom of the 3C slab the graphene doping was removed (Fig. 6e). Within our simple model this is equivalent to increasing ΔV_{L2} at the cost of ΔV until both quantities equal. As shown in Figs. 10(c-d), when the same geometrical boundary conditions at the bottom of the slab are applied to a polytype with a finite SP, both potential values increase in magnitude with the hexagonality of the SiC and n but, interestingly, $\epsilon_0\Delta V_{L2}$ attains values three to four times larger than $\epsilon_0\Delta V$, that is, of the same order as the $P_S d_m$ term in eq. (12) ($d_m \approx 5 \text{ \AA}$). Therefore, and at least for the considered thicknesses, the depolarization field E_I derives from a delicate balance between the left electrode's dipole contribution, $\epsilon_0\Delta V_{L2}$, and the sum of the SP and $\epsilon_0\Delta V$ terms.

V. FINAL DISCUSSION AND CONCLUSIONS

We have quantitatively studied, at the DFT level, the impact of the bulk spontaneous polarization of the SiC substrate on the graphene's electronic properties. First, we have presented a self-consistent scheme to calculate the SP for polar surfaces based on standard DFT slab calculations under DDC boundary conditions. The scheme relies on the slab's dipole moment and its dependence on the slab thickness, requires no macroscopic averaging and represents a generalization of previous works^{33,34} as it allows to determine the dielectric properties ϵ_r and

P_S under the same eq. (5). The derived values are in good correspondence with previous works, while we estimate their accuracy to be around 20-30% which, given the well recognized difficulties associated to such calculations, seems satisfactory enough. A first source of error is the accuracy of the calculated relative permittivities (up to around 10% after comparison with the experimental ϵ_r values), while a second more subtle source is related to the slab's geometry optimization. Here only the two upper and lower BLs of the slab were allowed to relax while test calculations including all atoms in the relaxations lead to P_S values 10-20% smaller. However, it is doubtful that unconstrained relaxations provide more realistic values due to anomalous dynamical contributions⁴⁸. In this sense, the approach of Meyer *et al*⁴⁹ proposing as appropriate boundary condition for atomic relaxations a vanishing internal electric field ($\bar{E} = 0$) by applying a finite external field could improve the accuracy although at the expense of longer computation times in the self-consistent process.

Next, we examined different terminations X for G/H/SiC/X slab models which is a crucial prerequisite to correctly account for the influence of the SP. We have chosen a slab terminated with a double Au capping layer which (i) pins the chemical potential at the bottom of the slab (instead of at the DP), hence it reasonably mimics a semi-infinite SiC substrate, (ii) presents a reduced slab dipole after expanding the Au-Au bonds and, (iii) leads to a vanishing doping of the graphene for the SD free 3C-SiC(111) substrate. Based on this slab model we have calculated the DP shifts and graphene doping charges for 2H-, 4H- and 6H-SiC(0001) substrates as a function of the slab thickness. Our results indeed confirm the experimentally observed p -doping in the graphene layer and reveal that it increases with the slab thickness and the hexagonality of the polytype, although remaining below the bulk SP value which, for each polytype, represents the upper limit to the SP-derived doping (as dictated by macroscopic electrostatics). At the largest thickness considered of $n = 12$, the graphene doping charge reaches 60-70% of the total SP, while a 100% is expected at thicknesses beyond 20 BLs; that is, far beyond the usual slab sizes considered in DFT calculations, with the added disadvantage of requiring a hyperfine k -sampling to correctly account for the graphene DOS. Interestingly, for the most common 4H- and 6H-SiC polytypes, we find certain dependence of the doping on the precise location of the SD closest to the surface; for a given thickness the doping decreases by around $2 e \times 10^{12}/\text{cm}^2$ the deeper it is buried due to the depolarization effect of the crystalline layers at the surface.

After analyzing the macroscopic averages of the charge densities and the electrostatic potentials we ascribe this slow convergence to the presence of a depolarization field arising from incomplete charge compensation of the SP by the graphene doping. To understand the electrostatics in our slabs we find necessary to explicitly consider the dipole moment of the gold capping double layer, yield-

ing a potential drop at the left electrode, ΔV_{L2} , which varies dynamically as the charge distribution across the slab changes (that is, with n and P_S) and is the main responsible for the drastic reduction of E_I . Although in the current work we employed the same geometry at the bottom of the slab for all polytypes, eq. (12) suggests that an alternative approach could be to tune ΔV_{L2} for each polytype by further increasing the Au-Au spacings so as to achieve a vanishing field within the dielectric and, hence, a 100% compensation of the SP by the graphene doping charge.

In summary, we have studied the relationship between the graphene doping and the SiC substrate's SP in QFG surfaces from first principles calculations. Our findings suggest the possibility to tune the level of the graphene's

doping almost in a continuous way by manipulating the number and location of the SDs closest to the surface. The results should naturally apply as well to ultrathin SiC films.

- ⁴⁴ Throughout this work we will refer to $\delta\rho$ as the total charge density minus that of the isolated atoms while δV_H to its associated electrostatic potential. We show these quantities rather than the total ones, ρ and V_H , since the formers provide a better visual resolution. On the other hand, macroscopic averages of their profiles across the slab are obtained via gaussian smearing employing widths of 2-6 Å.

Appendix A: Spontaneous Polarizations deduced from 3D unit cells

For the sake of completeness we present an alternative estimate of the bulk SPs based on the more traditional formalism proposed by Posternak *et al* in Ref.[50] and Qteish *et al* in Ref.[27], which is probably the simplest one since it only requires a bulk-type (3D) calculation. Due to the imposed periodic boundary conditions the electric field generated by the internal dipoles at the SDs is compensated by a (local) depolarization field across the rest of the unit cell, $-E_{SD}$. If the internal dipole is sufficiently localized to leave a substantial region of the unit cell free of dipoles, one may obtain $-E_{SD}$ from the slope $\partial V_H/\partial z$ across this region once the electrostatic potential has been macroscopically averaged.⁵⁰ The associated spontaneous polarization is then obtained via:

$$P_S = -\epsilon_r \epsilon_0 \frac{\partial V_H}{\partial z} \quad (\text{A1})$$

As shown in Ref. [50], eq. (A2) may still be used in geometries where the dipoles are too close among them by constructing a larger supercell after adding extra SD

free layers. In Fig. 11(c) we plot the macroscopically averaged^{43,50} Hartree potential, $\delta V_H(z)$, and the associated charge densities, $\delta\rho(z)$, for the 6H-, 4H- and 2H-SiC(0001) bulk phases. For the latter, and since the dipole density is large, we generated several 3D supercells 6 to 9 BLs thick comprising two or four 2H BLs plus four or five 3C crystalline BLs (see notation in the figure). We quote in the plots the slopes of the depolarization potentials obtained after linear fits of $\delta V_H(z)$ in the crystalline regions. While for the 6H and 4H cases the SP values are in reasonable agreement with those obtained from the slab calculations described in the main text, for the 2H supercells we obtain a range of values $P_S^{2H}=1.8\text{-}2.3 \text{ C} \times 10^{-2}/\text{m}^2$ significantly smaller. However, we recall certain ambiguity on the particular choice of z at which $\partial(V_H)/\partial z$ is obtained. For instance, values obtained using the local value of the partial derivative at the center of the ramp, or including in the fits either the positive or negative sections of the ramp may lead to deviations larger than a factor of 2 from those given in the figure.

FIG. 11. Macroscopically averaged charge density profiles (solid lines and right axis) and their associated Hartree potentials (dashed lines and left axis) for bulk calculations of different SiC polytypes. Green, red and blue lines correspond to 6H, 4H and mixed 2H-3C SiC bulk phases, respectively. For the latter we have considered several different supercells after varying the number of 2H and 3C units included (indicated in each plot). Thick straight lines overlaid on the Hartree potential ramps (depolarization regions) correspond to linear fits whose slopes provide the P_S values indicated for each plot in $\text{C} \times 10^{-2}/\text{m}^2$ units.

A simple improvement of eq. (A2) is to explicitly consider the widths of the crystalline and non-crystalline regions in the unit cell, d_c and d_{nc} respectively. The former (latter) may be identified with the regions where $\delta V_H(z)$ has a negative (positive) slope. Applying the continuity equation for the displacement vector across both regions we obtain:

$$\epsilon_0(\epsilon_c E_c + \epsilon_{nc} E_{nc}) = P_S \quad (\text{A2})$$

with $\epsilon_{c/nc}$ being the relative permittivities in each region and P_S the SP only present within the nc section. Since the potential drop within the cell is $\Delta\delta V_H = -E_c d_c =$

FIG. 12. 2D-averaged $\epsilon_r(z)$ profile across different 15 BL thick SiC slabs after applying ± 0.1 eV/Å external fields. Solid and dotted lines correspond to the high frequency and static relative permittivities, respectively. The profiles have been obtained after a gaussian smearing for $p(z)$ employing widths of 2.5 Å.

$E_{nc} d_{nc}$, the SP may be written as:

$$P_S = \epsilon_0 \left(\frac{\epsilon_c}{d_c} + \frac{\epsilon_{nc}}{d_{nc}} \right) \Delta \delta V_H \quad (\text{A3})$$

Notice that, as opposed to eq. (4), the above expression depends on macroscopically averaged quantities (δV_H and implicitly $d_{c/nc}$). Applying eq. (A3) to the slabs shown in Fig. 11 and employing the theoretically derived relative permittivities for each polytype given in Table II, we obtain: $P_S^{6H/4H/2H} = 1.4/2.0/2.7\text{-}2.9$ C $\times 10^{-2}/\text{m}^2$. Although the agreement with the slab calculations is clearly improved for the 2H case, the SP for the 6H and 4H polytypes is now overestimated, suggesting that further crystalline BLs should be included in the unit cells.

Appendix B: Permittivity profiles

We have additionally calculated local permittivity profiles across the dielectric slabs, $\epsilon_r(z)$ ^{51,52}:

$$\epsilon_r(z) = \frac{2E_{ext}}{2E_{ext} - p(z)} \quad (\text{B1})$$

where $p(z)$ gives the microscopic polarization averaged over the 2D unit cell which is obtained from the 2D averaged induced charge density, $\rho^{ind}(z)$ ⁵¹:

$$p(z) = -\epsilon_0 \int_{-\infty}^z dz' \rho^{ind}(z') \quad (\text{B2})$$

The induced charge is approximated by $\rho^{ind}(z) = \rho^+(z) - \rho^-(z)$, where $\rho^\pm(z)$ is the charge density profile under an $\pm E_{ext}$ external field (after averaging over the 2D unit cell). In practice, large oscillations at the atomic scale in $\epsilon_r(z)$ need to be removed either by taking macroscopic averages⁵⁰ for $\rho^{ind}(z)$ or employing other kind of smoothing. In Figure 12 we present $\epsilon_r(z)$ profiles of the high frequency (solid lines) and static (dashed) relative permittivities for a H/(SiC)₁₅/H slab, respectively. The profiles remain fairly constant in the inner region of the slabs attaining values in good correspondance with those deduced above and listed in Table II. Notice, however, certain asymmetric features particularly in the static profiles probably related to anomalous dynamical contributions^{32,48}. In fact, these features change with the slab thickness or the precise location of the first SD in each polytype.
