Abstract

Derivatives, mostly in the form of gradients and Hessians, are ubiquitous in machine learning. Automatic differentiation (AD), also called algorithmic differentiation or simply “autodiff”, is a family of techniques similar to but more general than backpropagation for efficiently and accurately evaluating derivatives of numeric functions expressed as computer programs. AD is a small but established field with applications in areas including computational fluid dynamics, atmospheric sciences, and engineering design optimization. Until very recently, the fields of machine learning and AD have largely been unaware of each other and, in some cases, have independently discovered each other’s results. Despite its relevance, general-purpose AD has been missing from the machine learning toolbox, a situation slowly changing with its ongoing adoption under the names “dynamic computational graphs” and “differentiable programming”. We survey the intersection of AD and machine learning, cover applications where AD has direct relevance, and address the main implementation techniques. By precisely defining the main differentiation techniques and their interrelationships, we aim to bring clarity to the usage of the terms “autodiff”, “automatic differentiation”, and “symbolic differentiation” as these are encountered more and more in machine learning settings.

Keywords: Backpropagation, Differentiable Programming
1. Introduction

Methods for the computation of derivatives in computer programs can be classified into four categories: (1) manually working out derivatives and coding them; (2) numerical differentiation using finite difference approximations; (3) symbolic differentiation using expression manipulation in computer algebra systems such as Mathematica, Maxima, and Maple; and (4) automatic differentiation, also called algorithmic differentiation, which is the subject matter of this paper.

Conventionally, many methods in machine learning have required the evaluation of derivatives and most of the traditional learning algorithms have relied on the computation of gradients and Hessians of an objective function (Sra et al., 2011). When introducing new models, machine learning researchers have spent considerable effort on the manual derivation of analytical derivatives to subsequently plug these into standard optimization procedures such as L-BFGS (Zhu et al., 1997) or stochastic gradient descent (Bottou, 1998). Manual differentiation is time consuming and prone to error. Of the other alternatives, numerical differentiation is simple to implement but can be highly inaccurate due to round-off and truncation errors (Jerrell, 1997); more importantly, it scales poorly for gradients, rendering it inappropriate for machine learning where gradients with respect to millions of parameters are commonly needed. Symbolic differentiation addresses the weaknesses of both the manual and numerical methods, but often results in complex and cryptic expressions plagued with the problem of “expression swell” (Corliss, 1988). Furthermore, manual and symbolic methods require models to be defined as closed-form expressions, ruling out or severely limiting algorithmic control flow and expressivity.

We are concerned with the powerful fourth technique, automatic differentiation (AD). AD performs a non-standard interpretation of a given computer program by replacing the domain of the variables to incorporate derivative values and redefining the semantics of the operators to propagate derivatives per the chain rule of differential calculus. Despite its widespread use in other fields, general-purpose AD has been underused by the machine learning community until very recently.1 Following the emergence of deep learning (LeCun et al., 2015; Goodfellow et al., 2016) as the state-of-the-art in many machine learning tasks and the modern workflow based on rapid prototyping and code reuse in frameworks such as Theano (Bastien et al., 2012), Torch (Collobert et al., 2011), and TensorFlow (Abadi et al., 2016), the situation is slowly changing where projects such as autograd2 (Maclaurin, 2016), Chainer3 (Tokui et al., 2015), and PyTorch4 (Paszke et al., 2017) are leading the way in bringing general-purpose AD to the mainstream.

The term “automatic” in AD can be a source of confusion, causing machine learning practitioners to put the label “automatic differentiation”, or just “autodiff”, on any method or tool that does not involve manual differentiation, without giving due attention to the underlying mechanism. We would like to stress that AD as a technical term refers to a specific family of techniques that compute derivatives through accumulation of values during code execution to generate numerical derivative evaluations rather than derivative expressions. This allows accurate evaluation of derivatives at machine precision with only

---

2. https://github.com/HIPS/autograd
3. https://chainer.org/
a small constant factor of overhead and ideal asymptotic efficiency. In contrast with the
effort involved in arranging code as closed-form expressions under the syntactic and semantic
constraints of symbolic differentiation, AD can be applied to regular code with minimal change,
allowing branching, loops, and recursion. Because of this generality, AD has been applied
to computer simulations in industry and academia and found applications in fields
including engineering design optimization (Forth and Evans, 2002; Casanova et al., 2002),
computational fluid dynamics (Müller and Cusdin, 2005; Thomas et al., 2006; Bischof et al.,
2006), physical modeling (Ekström et al., 2010), optimal control (Walther, 2007), structural
mechanics (Haase et al., 2002), atmospheric sciences (Carmichael and Sandu, 1997;
Charpentier and Ghemires, 2000), and computational finance (Bischof et al., 2002; Capriotti,
2011).

In machine learning, a specialized counterpart of AD known as the backpropagation algo-
rithm has been the mainstay for training neural networks, with a colorful history of having
been reinvented at various times by independent researchers (Griewank, 2012; Schmidhuber,
2015). It has been one of the most studied and used training algorithms since the day it
became popular mainly through the work of Rumelhart et al. (1986). In simplest terms,
backpropagation models learning as gradient descent in neural network weight space, looking
for the minima of an objective function. The required gradient is obtained by the
backward propagation of the sensitivity of the objective value at the output (Figure 1),
utilizing the chain rule to compute partial derivatives of the objective with respect to each
weight. The resulting algorithm is essentially equivalent to transforming the network evaluation
function composed with the objective function under reverse mode AD, which, as we
shall see, actually generalizes the backpropagation idea. Thus, a modest understanding of
the mathematics underlying backpropagation provides one with sufficient background for
grasping AD techniques.

In this paper we review AD from a machine learning perspective, covering its origins,
applications in machine learning, and methods of implementation. Along the way, we also
aim to dispel some misconceptions that we believe have impeded wider recognition of AD by
the machine learning community. In Section 2 we start by explicating how AD differs from
numerical and symbolic differentiation. Section 3 gives an introduction to the AD technique
and its forward and reverse accumulation modes. Section 4 discusses the role of derivatives
in machine learning and examines cases where AD has relevance. Section 5 covers various
implementation approaches and general-purpose AD tools, followed by Section 6 where we
discuss future directions.

2. What AD Is Not

Without proper introduction, one might assume that AD is either a type of numerical or
symbolic differentiation. Confusion can arise because AD does in fact provide numerical
values of derivatives (as opposed to derivative expressions) and it does so by using symbolic
rules of differentiation (but keeping track of derivative values as opposed to the resulting
expressions), giving it a two-sided nature that is partly symbolic and partly numerical
(Griewank, 2003). We start by emphasizing how AD is different from, and in several aspects
superior to, these two commonly encountered techniques of computing derivatives.
Figure 1: Overview of backpropagation. (a) Training inputs $x_i$ are fed forward, generating corresponding activations $y_i$. An error $E$ between the actual output $y_3$ and the target output $t$ is computed. (b) The error adjoint is propagated backward, giving the gradient with respect to the weights $\nabla_w E = \left(\frac{\partial E}{\partial w_1}, \ldots, \frac{\partial E}{\partial w_6}\right)$, which is subsequently used in a gradient-descent procedure. The gradient with respect to inputs $\nabla_x E$ can be also computed in the same backward pass.

2.1 AD Is Not Numerical Differentiation

Numerical differentiation is the finite difference approximation of derivatives using values of the original function evaluated at some sample points (Burden and Faires, 2001) (Figure 2, lower right). In its simplest form, it is based on the limit definition of a derivative. For example, for a multivariate function $f : \mathbb{R}^n \rightarrow \mathbb{R}$, one can approximate the gradient $\nabla f = \left(\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}\right)$ using

$$\frac{\partial f(x)}{\partial x_i} \approx \frac{f(x + h e_i) - f(x)}{h},$$

where $e_i$ is the $i$-th unit vector and $h > 0$ is a small step size. This has the advantage of being uncomplicated to implement, but the disadvantages of performing $O(n)$ evaluations of $f$ for a gradient in $n$ dimensions and requiring careful consideration in selecting the step size $h$.

Numerical approximations of derivatives are inherently ill-conditioned and unstable.\(^5\) with the exception of complex variable methods that are applicable to a limited set of holomorphic functions (Fornberg, 1981). This is due to the introduction of truncation\(^6\) and

---

\(^5\) Using the limit definition of the derivative for finite difference approximation commits both cardinal sins of numerical analysis: “thou shalt not add small numbers to big numbers”, and “thou shalt not subtract numbers which are approximately equal”.

\(^6\) Truncation error is the error of approximation, or inaccuracy, one gets from $h$ not actually being zero. It is proportional to a power of $h$. 

4
Figure 2: The range of approaches for differentiating mathematical expressions and computer code, looking at the example of a truncated logistic map (upper left). Symbolic differentiation (center right) gives exact results but requires closed-form input and suffers from expression swell; numerical differentiation (lower right) has problems of accuracy due to round-off and truncation errors; automatic differentiation (lower left) is as accurate as symbolic differentiation with only a constant factor of overhead and support for control flow.
Figure 3: Error in the forward (Eq. 1) and center difference (Eq. 2) approximations as a function of step size $h$, for the derivative of the truncated logistic map $f(x) = 64x(1-x)(1-2x)^2(1-8x+8x^2)^2$. Plotted errors are computed using $E_{\text{forward}}(h, x_0) = \left| \frac{f(x_0+h)-f(x_0)-d}{d} f(x) \right|_{x_0}$ and $E_{\text{center}}(h, x_0) = \left| \frac{f(x_0+h)-f(x_0-h)}{2h} - d f(x) \right|_{x_0}$ at $x_0 = 0.2$.

round-off\textsuperscript{7} errors inflicted by the limited precision of computations and the chosen value of the step size $h$. Truncation error tends to zero as $h \to 0$. However, as $h$ is decreased, round-off error increases and becomes dominant (Figure 3).

Various techniques have been developed to mitigate approximation errors in numerical differentiation, such as using a center difference approximation

$$\frac{\partial f(x)}{\partial x_i} = \frac{f(x + h e_i) - f(x - h e_i)}{2h} + O(h^2), \tag{2}$$

where the first-order errors cancel and one effectively moves the truncation error from first-order to second-order in $h$.\textsuperscript{8} For the one-dimensional case, it is just as costly to compute the forward difference (Eq. 1) and the center difference (Eq. 2), requiring only two evaluations of $f$. However, with increasing dimensionality, a trade-off between accuracy and performance is faced, where computing a Jacobian matrix of a function $f : \mathbb{R}^n \to \mathbb{R}^m$ requires $2mn$ evaluations.

\textsuperscript{7} Round-off error is the inaccuracy one gets from valuable low-order bits of the final answer having to compete for machine-word space with high-order bits of $\left| f(x_0+h) - f(x_0) \right|$ and $f(x)$ (Eq. 1), which the computer has to store just until they cancel in the subtraction at the end. Round-off error is inversely proportional to a power of $h$.

\textsuperscript{8} This does not avoid either of the cardinal sins, and is still highly inaccurate due to truncation.
Other techniques for improving numerical differentiation, including higher-order finite differences, Richardson extrapolation to the limit (Brezinski and Zaglia, 1991), and differential quadrature methods using weighted sums (Bert and Malik, 1996), have increased computational complexity, do not completely eliminate approximation errors, and remain highly susceptible to floating point truncation.

The $O(n)$ complexity of numerical differentiation for a gradient in $n$ dimensions is the main obstacle to its usefulness in machine learning, where $n$ can be as large as millions or billions in state-of-the-art deep learning models (Shazeer et al., 2017). In contrast, approximation errors would be tolerated in a deep learning setting thanks to the well-documented error resiliency of neural network architectures (Gupta et al., 2015).

2.2 AD Is Not Symbolic Differentiation

Symbolic differentiation is the automatic manipulation of expressions for obtaining derivative expressions (Grabmeier and Kaltofen, 2003) (Figure 2, center right), carried out by applying transformations representing rules of differentiation such as

$$
\frac{d}{dx}(f(x) + g(x)) \sim \frac{d}{dx}f(x) + \frac{d}{dx}g(x)
$$

$$
\frac{d}{dx}(f(x)g(x)) \sim \left(\frac{d}{dx}f(x)\right)g(x) + f(x)\left(\frac{d}{dx}g(x)\right).
$$

When formulae are represented as data structures, symbolically differentiating an expression tree is a perfectly mechanistic process, considered subject to mechanical automation even at the very inception of calculus (Leibniz, 1685). This is realized in modern computer algebra systems such as Mathematica, Maxima, and Maple and machine learning frameworks such as Theano.

In optimization, symbolic derivatives can give valuable insight into the structure of the problem domain and, in some cases, produce analytical solutions of extrema (e.g., solving for $\frac{d}{dx}f(x) = 0$) that can eliminate the need for derivative calculation altogether. On the other hand, symbolic derivatives do not lend themselves to efficient runtime calculation of derivative values, as they can get exponentially larger than the expression whose derivative they represent.

Consider a function $h(x) = f(x)g(x)$ and the multiplication rule in Eq. 3. Since $h$ is a product, $h(x)$ and $\frac{d}{dx}h(x)$ have some common components, namely $f(x)$ and $g(x)$. Note also that on the right hand side, $f(x)$ and $\frac{d}{dx}f(x)$ appear separately. If we just proceeded to symbolically differentiate $f(x)$ and plugged its derivative into the appropriate place, we would have nested duplications of any computation that appears in common between $f(x)$ and $\frac{d}{dx}f(x)$. Hence, careless symbolic differentiation can easily produce exponentially large symbolic expressions which take correspondingly long to evaluate. This problem is known as expression swell (Table 1).

When we are concerned with the accurate numerical evaluation of derivatives and not so much with their actual symbolic form, it is in principle possible to significantly simplify computations by storing only the values of intermediate sub-expressions in memory. Moreover, for further efficiency, we can interleave as much as possible the differentiation and simplification steps. This interleaving idea forms the basis of AD and provides an account
Table 1: Iterations of the logistic map \( l_{n+1} = 4l_n(1 - l_n) \), \( l_1 = x \) and the corresponding derivatives of \( l_n \) with respect to \( x \), illustrating expression swell.

</table>

of its simplest form: apply symbolic differentiation at the elementary operation level and keep intermediate numerical results, in lockstep with the evaluation of the main function. This is AD in the forward accumulation mode, which we shall introduce in the following section.

3. AD and Its Main Modes

AD can be thought of as performing a non-standard interpretation of a computer program where this interpretation involves augmenting the standard computation with the calculation of various derivatives. All numerical computations are ultimately compositions of a finite set of elementary operations for which derivatives are known (Verma, 2000; Griewank and Walther, 2008), and combining the derivatives of the constituent operations through the chain rule gives the derivative of the overall composition. Usually these elementary operations include the binary arithmetic operations, the unary sign switch, and transcendental functions such as the exponential, the logarithm, and the trigonometric functions.

On the left hand side of Table 2 we see the representation of the computation \( y = f(x_1, x_2) = \ln(x_1) + x_1x_2 - \sin(x_2) \) as an evaluation trace of elementary operations—also called a Wengert list (Wengert, 1964). We adopt the three-part notation used by Griewank and Walther (2008), where a function \( f : \mathbb{R}^n \to \mathbb{R}^m \) is constructed using intermediate variables \( v_i \) such that

- variables \( v_{i-n} = x_i, \ i = 1, \ldots, n \) are the input variables,
- variables \( v_i, \ i = 1, \ldots, l \) are the working (intermediate) variables, and
- variables \( y_{m-i} = v_{l-i}, \ i = m-1, \ldots, 0 \) are the output variables.

Figure 4 shows the given trace of elementary operations represented as a computational graph (Bauer, 1974), useful in visualizing dependency relations between intermediate variables.

Evaluation traces form the basis of the AD techniques. An important point to note here is that AD can differentiate not only closed-form expressions in the classical sense, but also
algorithms making use of control flow such as branching, loops, recursion, and procedure calls, giving it an important advantage over symbolic differentiation which severely limits such expressivity. This is thanks to the fact that any numeric code will eventually result in a numeric evaluation trace with particular values of the input, intermediate, and output variables, which are the only things one needs to know for computing derivatives using chain rule composition, regardless of the specific control flow path that was taken during execution. Another way of expressing this is that AD is blind with respect to any operation, including control flow statements, which do not directly alter numeric values.

3.1 Forward Mode

AD in forward accumulation mode is the conceptually most simple type. Consider the evaluation trace of the function \( f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2) \) given on the left-hand side in Table 2 and in graph form in Figure 4. For computing the derivative of \( f \) with respect to \( x_1 \), we start by associating with each intermediate variable \( v_i \) a derivative \( \dot{v}_i = \frac{\partial v_i}{\partial x_1} \).

Applying the chain rule to each elementary operation in the forward primal trace, we generate the corresponding tangent (derivative) trace, given on the right-hand side in Table 2. Evaluating the primals \( v_i \) in lockstep with their corresponding tangents \( \dot{v}_i \) gives us the required derivative in the final variable \( \dot{v}_5 = \frac{\partial y}{\partial x_1} \).

This generalizes naturally to computing the Jacobian of a function \( f : \mathbb{R}^n \to \mathbb{R}^m \) with \( n \) independent (input) variables \( x_i \) and \( m \) dependent (output) variables \( y_j \). In this case, each forward pass of AD is initialized by setting only one of the variables \( \dot{x}_i = 1 \) and setting the rest to zero (in other words, setting \( \dot{x} = e_i \), where \( e_i \) is the \( i \)-th unit vector). A run of the code with specific input values \( x = a \) then computes

\[
\dot{y}_j = \left. \frac{\partial y_j}{\partial x_i} \right|_{x=a}, \quad j = 1, \ldots, m,
\]

9. Also called \textit{tangent linear mode}.
Table 2: Forward mode AD example, with \( y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2) \) evaluated at \((x_1, x_2) = (2, 5)\) and setting \( \dot{x}_1 = 1 \) to compute \( \frac{\partial y}{\partial x_1} \). The original forward evaluation of the primals on the left is augmented by the tangent operations on the right, where each line complements the original directly to its left.

</tbody>
</table>

- Giving us one column of the Jacobian matrix
- \( J_f = \) evaluated at point \( a \). Thus, the full Jacobian can be computed in \( n \) evaluations.

Furthermore, forward mode AD provides a very efficient and matrix-free way of computing Jacobian–vector products

\[
J_f r = \begin{bmatrix}
\frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_1}{\partial x_n} \\
\vdots & \ddots & \vdots \\
\frac{\partial y_m}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_n}
\end{bmatrix}
\begin{bmatrix}
r_1 \\
\vdots \\
r_n
\end{bmatrix},
\]

simply by initializing with \( \dot{x} = r \). Thus, we can compute the Jacobian–vector product in just one forward pass. As a special case, when \( f : \mathbb{R}^n \rightarrow \mathbb{R} \), we can obtain the directional derivative along a given vector \( r \) as a linear combination of the partial derivatives

\[
\nabla f \cdot r
\]

by starting the AD computation with the values \( \dot{x} = r \).

Forward mode AD is efficient and straightforward for functions \( f : \mathbb{R} \rightarrow \mathbb{R}^m \), as all the derivatives \( \frac{\partial y}{\partial x} \) can be computed with just one forward pass. Conversely, in the other extreme of \( f : \mathbb{R}^n \rightarrow \mathbb{R} \), forward mode AD requires \( n \) evaluations to compute the gradient

\[
\nabla f = \left( \frac{\partial y}{\partial x_1}, \ldots, \frac{\partial y}{\partial x_n} \right),
\]

which also corresponds to a \( 1 \times n \) Jacobian matrix that is built one column at a time with the forward mode in \( n \) evaluations.

In general, for cases \( f : \mathbb{R}^n \rightarrow \mathbb{R}^m \) where \( n \gg m \), a different technique is often preferred. We will describe AD in reverse accumulation mode in Section 3.2.
3.1.1 Dual Numbers

Mathematically, forward mode AD (represented by the left- and right-hand sides in Table 2) can be viewed as evaluating a function using dual numbers, which can be defined as truncated Taylor series of the form

\[ v + \dot{v} \epsilon, \]

where \( v, \dot{v} \in \mathbb{R} \) and \( \epsilon \) is a nilpotent number such that \( \epsilon^2 = 0 \) and \( \epsilon \neq 0 \). Observe, for example, that

\[
(v + \dot{v} \epsilon) + (u + \dot{u} \epsilon) = (v + u) + (\dot{v} + \dot{u}) \epsilon
\]
\[
(v + \dot{v} \epsilon)(u + \dot{u} \epsilon) = (vu) + (v\dot{u} + \dot{v}u) \epsilon,
\]

in which the coefficients of \( \epsilon \) conveniently mirror symbolic differentiation rules (e.g., Eq. 3). We can utilize this by setting up a regime where

\[ f(v + \dot{v} \epsilon) = f(v) + f'(v) \dot{v} \epsilon \tag{5} \]

and using dual numbers as data structures for carrying the tangent value together with the primal. The chain rule works as expected on this representation: two applications of Eq. 5 give

\[
f(g(v + \dot{v} \epsilon)) = f(g(v)) + f'(g(v))g'(v) \dot{v} \epsilon.
\]

The coefficient of \( \epsilon \) on the right-hand side is exactly the derivative of the composition of \( f \) and \( g \). This means that since we implement elementary operations to respect the invariant Eq. 5, all compositions of them will also do so. This, in turn, means that we can extract the derivative of a function by interpreting any non-dual number \( v \) as \( v + 0 \epsilon \) and evaluating the function in this non-standard way on an initial input with a coefficient 1 for \( \epsilon \):

\[
\left. \frac{df(x)}{dx} \right|_{x=v} = \text{epsilon-coefficient(dual-version}(f)(v + 1 \epsilon)) .
\]

This also extends to arbitrary program constructs, since dual numbers, as data types, can be contained in any data structure. As long as a dual number remains in a data structure with no arithmetic operations being performed on it, it will just remain a dual number; and if it is taken out of the data structure and operated on again, then the differentiation will continue.

In practice, a function \( f \) coded in a programming language of choice would be fed into an AD tool, which would then augment it with corresponding extra code to handle the dual operations so that the function and its derivative are simultaneously computed. This can be implemented through calls to a specific library, in the form of source code transformation where a given source code will be automatically modified, or through operator overloading, making the process transparent to the user. We discuss these implementation techniques in Section 5.

---

10. First introduced by Clifford (1873), with important uses in linear algebra and physics.
11. Just as the complex number written \( x + yi \) is represented in the computer as a pair in memory \((x, y)\) whose two slots are reals, the dual number written \( x + \dot{x} \epsilon \) is represented as the pair \((x, \dot{x})\). Such pairs are sometimes called Argand pairs (Hamilton, 1837, p107 Eqs. (157) and (158)).
3.2 Reverse Mode

AD in the reverse accumulation mode\textsuperscript{12} corresponds to a generalized backpropagation algorithm, in that it propagates derivatives backward from a given output. This is done by complementing each intermediate variable $v_i$ with an adjoint

$$\bar{v}_i = \frac{\partial y_j}{\partial v_i},$$

which represents the sensitivity of a considered output $y_j$ with respect to changes in $v_i$. In the case of backpropagation, $y$ would be a scalar corresponding to the error $E$ (Figure 1).

In reverse mode AD, derivatives are computed in the second phase of a two-phase process. In the first phase, the original function code is run forward, populating intermediate variables $v_i$ and recording the dependencies in the computational graph through a bookkeeping procedure. In the second phase, derivatives are calculated by propagating adjoints $\bar{v}_i$ in reverse, from the outputs to the inputs.

Returning to the example $y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2)$, in Table 3 we see the adjoint statements on the right-hand side, corresponding to each original elementary operation on the left-hand side. In simple terms, we are interested in computing the contribution $\bar{v}_0 = \frac{\partial y}{\partial v_0}$ of the change in each variable $v_i$ to the change in the output $y$. Taking the variable $v_0$ as an example, we see in Figure 4 that the only way it can affect $y$ is through affecting $v_2$ and $v_3$, so its contribution to the change in $y$ is given by

$$\frac{\partial y}{\partial v_0} = \frac{\partial y}{\partial v_2} \frac{\partial v_2}{\partial v_0} + \frac{\partial y}{\partial v_3} \frac{\partial v_3}{\partial v_0} \quad \text{or} \quad \bar{v}_0 = \bar{v}_2 \frac{\partial v_2}{\partial v_0} + \bar{v}_3 \frac{\partial v_3}{\partial v_0}. $$

In Table 3, this contribution is computed in two incremental steps

$$\bar{v}_0 = \bar{v}_3 \frac{\partial v_3}{\partial v_0}, \quad \text{and} \quad \bar{v}_0 = \bar{v}_0 + \bar{v}_2 \frac{\partial v_2}{\partial v_0},$$

lined up with the lines in the forward trace from which these expressions originate.

After the forward pass on the left-hand side, we run the reverse pass of the adjoints on the right-hand side, starting with $\bar{v}_5 = \bar{y} = \frac{\partial y}{\partial y} = 1$. In the end we get the derivatives $\frac{\partial y}{\partial x_1} = \bar{x}_1$ and $\frac{\partial y}{\partial x_2} = \bar{x}_2$ in just one reverse pass.

Compared with the straightforwardness of forward accumulation mode, reverse mode AD can, at first, appear somewhat “mysterious” (Dennis and Schnabel, 1996). Griewank and Walther (2008) argue that this is in part because of the common acquaintance with the chain rule as a mechanistic procedure propagating derivatives forward.

An important advantage of the reverse mode is that it is significantly less costly to evaluate (in terms of operation count) than the forward mode for functions with a large number of inputs. In the extreme case of $f : \mathbb{R}^n \rightarrow \mathbb{R}$, only one application of the reverse mode is sufficient to compute the full gradient $\nabla f = \left( \frac{\partial y}{\partial x_1}, \ldots, \frac{\partial y}{\partial x_n} \right)$, compared with the $n$ passes of the forward mode needed for populating the same. Because machine learning practice principally involves the gradient of a scalar-valued objective with respect to a large number of parameters, this establishes the reverse mode, as opposed to the forward mode, as the mainstay technique in the form of the backpropagation algorithm.

\textsuperscript{12} Also called adjoint or cotangent linear mode.
Table 3: Reverse mode AD example, with \( y = f(x_1, x_2) = \ln(x_1) + x_1 x_2 - \sin(x_2) \) evaluated at \((x_1, x_2) = (2, 5)\). After the forward evaluation of the primals on the left, the adjoint operations on the right are evaluated in reverse (cf. Figure 1). Note that both \( \frac{\partial y}{\partial x_1} \) and \( \frac{\partial y}{\partial x_2} \) are computed in the same reverse pass, starting from the adjoint \( \bar{v}_5 = \bar{y} = \frac{\partial y}{\partial y} = 1 \).

In general, for a function \( f : \mathbb{R}^n \rightarrow \mathbb{R}^m \), if we denote the operation count to evaluate the original function by \( \text{ops}(f) \), the time it takes to calculate the \( m \times n \) Jacobian by the forward mode is \( n c \ \text{ops}(f) \), whereas the same computation can be done via reverse mode in \( m c \ \text{ops}(f) \), where \( c \) is a constant guaranteed to be \( c < 6 \) and typically \( c \sim [2, 3] \) (Griewank and Walther, 2008). That is to say, reverse mode AD performs better when \( m \ll n \).

Similar to the matrix-free computation of Jacobian–vector products with forward mode (Eq. 4), reverse mode can be used for computing the transposed Jacobian–vector product

\[
J^T_{\bar{r}} = \begin{bmatrix}
\frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_1} \\
\vdots & \ddots & \vdots \\
\frac{\partial y_1}{\partial x_n} & \cdots & \frac{\partial y_m}{\partial x_n}
\end{bmatrix}
\begin{bmatrix}
r_1 \\
\vdots \\
r_m
\end{bmatrix},
\]

by initializing the reverse phase with \( \bar{y} = r \).

The advantages of reverse mode AD, however, come with the cost of increased storage requirements growing (in the worst case) in proportion to the number of operations in the evaluated function. It is an active area of research to improve storage requirements in implementations by using advanced methods such as checkpointing strategies and data-flow analysis (Dauvergne and Hascoët, 2006; Siskind and Pearlmutter, 2017).
3.3 Origins of AD and Backpropagation

Ideas underlying AD date back to the 1950s (Nolan, 1953; Beda et al., 1959). Forward mode AD as a general method for evaluating partial derivatives was essentially discovered by Wengert (1964). It was followed by a period of relatively low activity, until interest in the field was revived in the 1980s mostly through the work of Griewank (1989), also supported by improvements in modern programming languages and the feasibility of an efficient reverse mode AD.

Reverse mode AD and backpropagation have an intertwined history. The essence of the reverse mode, cast in a continuous-time formalism, is the Pontryagin maximum principle (Rozonoer, 1959; Boltvanskii et al., 1960). This method was understood in the control theory community (Bryson and Denham, 1962; Bryson and Ho, 1969) and cast in more formal terms with discrete-time variables topologically sorted in terms of dependency by Werbos (1974). Prior to Werbos, the work by Linnainmaa (1970, 1976) is often cited as the first published description of the reverse mode. Speelpenning (1980) subsequently introduced reverse mode AD as we know it, in the sense that he gave the first implementation that was actually automatic, accepting a specification of a computational process written in a general-purpose programming language and automatically performing the reverse mode transformation.

Incidentally, Hecht-Nielsen (1989) cites the work of Bryson and Ho (1969) and Werbos (1974) as the two earliest known instances of backpropagation. Within the machine learning community, the method has been reinvented several times, such as by Parker (1985), until it was eventually brought to fame by Rumelhart et al. (1986) and the Parallel Distributed Processing (PDP) group. The PDP group became aware of Parker’s work only after their own discovery; similarly, Werbos’ work was not appreciated until it was found by Parker (Hecht-Nielsen, 1989). This tells us an interesting story of two highly interconnected research communities that have somehow also managed to stay detached during this foundational period.

For a thorough review of the development of AD, we advise readers to refer to Rall (2006). Interested readers are highly recommended to read Griewank (2012) for an investigation of the origins of the reverse mode and Schmidhuber (2015) for the same for backpropagation.

4. AD and Machine Learning

In the following, we examine the main uses of derivatives in machine learning and report on a selection of works where general-purpose AD, as opposed to just backpropagation, has been successfully applied in a machine learning context. Areas where AD has seen use include optimization, neural networks, computer vision, natural language processing, and probabilistic inference.

4.1 Gradient-Based Optimization

Gradient-based optimization is one of the pillars of machine learning (Bottou et al., 2016). Given an objective function $f: \mathbb{R}^n \to \mathbb{R}$, classical gradient descent has the goal of finding (local) minima $w^* = \arg \min_w f(w)$ via updates of the form $\Delta w = -\eta \nabla f$, where $\eta > 0$ is a step size. Gradient-based methods make use of the fact that $f$ decreases steepest if
Table 4: Evaluation times of the Helmholtz free energy function and its gradient (Figure 5). Times are given relative to that of the original function with both (1) $n = 1$ and (2) $n$ corresponding to each column. (For instance, reverse mode AD with $n = 43$ takes approximately twice the time to evaluate relative to the original function with $n = 43$.) Times are measured by averaging a thousand runs on a machine with Intel Core i7-4785T 2.20 GHz CPU and 16 GB RAM, using DiffSharp 0.5.7. The evaluation time for the original function with $n = 1$ is 0.0023 ms.

one goes in the direction of the negative gradient. The convergence rate of gradient-based methods is usually improved by adaptive step-size techniques that adjust the step size $\eta$ on every iteration (Duchi et al., 2011; Schaul et al., 2013; Kingma and Ba, 2015).

As we have seen, for large $n$, reverse mode AD provides a highly efficient method for computing gradients.\(^\text{13}\) Figure 5 and Table 4 demonstrate how gradient computation scales differently for forward and reverse mode AD and numerical differentiation, looking at the Helmholtz free energy function that has been used in AD literature for benchmarking gradient calculations (Griewank, 1989; Griewank and Walther, 2008; Griewank et al., 2012).

Second-order methods based on Newton’s method make use of both the gradient $\nabla f$ and the Hessian $H_f$, working via updates of the form $\Delta w = -\eta H_f^{-1}\nabla f$ and providing significantly faster convergence (Press et al., 2007). AD provides a way of automatically computing the exact Hessian, enabling succinct and convenient general-purpose implementations.\(^\text{14}\) Newton’s method converges in fewer iterations, but this comes at the cost of having to compute $H_f$ in each iteration. In large-scale problems, the Hessian is usually replaced by a numerical approximation using first-order updates from gradient evaluations,

Figure 5: Evaluation time of the Helmholtz free energy function of a mixed fluid, based on the Peng-Robinson equation of state (Peng and Robinson, 1976),
\[
f(x) = RT \sum_{i=0}^{n} \log \frac{x_i}{1-b_i^T x} - \frac{x^T Ax}{\sqrt{8b^T x}} \log \frac{1+(1+\sqrt{2})b^T x}{1+(1-\sqrt{2})b^T x},
\]
where \( R \) is the universal gas constant, \( T \) is the absolute temperature, \( b \in \mathbb{R}^n \) is a vector of constants, \( A \in \mathbb{R}^{n \times n} \) is a symmetric matrix of constants, and \( x \in \mathbb{R}^n \) is the vector of independent variables describing the system. The plots show the evaluation time of \( f \) and the gradient \( \nabla f \) with numerical differentiation (central difference), forward mode AD, and reverse mode AD, as a function of the number of variables \( n \). Reported times are relative to the evaluation time of \( f \) with \( n = 1 \). The lower plot uses logarithmic scale for illustrating the behavior for small \( n \). Numerical results are given in Table 4. (Code: http://DiffSharp.github.io/DiffSharp/misc/Benchmarks-h-grad-v0.5.7.fsx)
Automatic Differentiation in Machine Learning: a Survey

giving rise to quasi-Newton methods. A highly popular such method is the BFGS\textsuperscript{15} algorithm, together with its limited-memory variant L-BFGS (Dennis and Schnabel, 1996). On the other hand, Hessians arising in large-scale applications are typically sparse. This sparsity along with symmetry can be readily exploited by AD techniques such as computational graph elimination (Dixon, 1991), partial separability (Gay, 1996), and matrix coloring and compression (Gebremedhin et al., 2009).

In many cases one does not need the full Hessian but only a Hessian–vector product $\mathbf{Hv}$, which can be computed efficiently using a reverse-on-forward configuration of AD by applying the reverse mode to take the gradient of code produced by the forward mode.\textsuperscript{16} Given the function $f : \mathbb{R}^n \to \mathbb{R}$, the evaluation point $\mathbf{x}$, and the vector $\mathbf{v}$, one can accomplish this by first computing the directional derivative $\nabla f \cdot \mathbf{v}$ through the forward mode via setting $\dot{\mathbf{x}} = \mathbf{v}$ and then applying the reverse mode on this result to get $\nabla^2 f \cdot \mathbf{v} = \mathbf{H}_f \mathbf{v}$ (Pearlmutter, 1994). This computes $\mathbf{Hv}$ with $O(n)$ complexity, even though $\mathbf{H}$ is a $n \times n$ matrix. Availability of robust AD tools may make more sophisticated optimization methods applicable to large-scale machine-learning problems. For instance, when fast stochastic Hessian–vector products are available, these can be used as the basis of stochastic Newton’s methods (Agarwal et al., 2016), which have the potential to endow stochastic optimization with quadratic convergence.

Another approach for improving the rate of convergence of gradient-based methods is to use gain adaptation methods such as stochastic meta-descent (SMD) (Schraudolph, 1999), where stochastic sampling is introduced to avoid local minima and reduce the computational expense. An example using SMD with AD Hessian–vector products is given by Vishwanathan et al. (2006) on conditional random fields (CRF). Similarly, Schraudolph and Graepel (2003) use Hessian–vector products in their model combining conjugate gradient techniques with stochastic gradient descent.

4.2 Neural Networks, Deep Learning, Differentiable Programming

Training of a neural network is an optimization problem with respect to its set of weights, which can in principle be addressed by using any method ranging from evolutionary algorithms (Such et al., 2017) to gradient-based methods such as BFGS (Apostolopoulou et al., 2009) or the mainstay stochastic gradient descent (Bottou, 2010) and its many variants (Kingma and Ba, 2015; Tieleman and Hinton, 2012; Duchi et al., 2011). As we have seen, the backpropagation algorithm is only a special case of AD: by applying reverse mode AD to an objective function evaluating a network’s error as a function of its weights, we can readily compute the partial derivatives needed for performing weight updates.\textsuperscript{17}

The LUSH system (Bottou and LeCun, 2002), and its predecessor SN (Bottou and LeCun, 1988), were the first production systems that targeted efficient neural network simulation while incorporating both a general-purpose programming language and AD. Modern deep learning frameworks provide differentiation capability in one way or another, but the un-

\textsuperscript{15} After Broyden–Fletcher–Goldfarb–Shanno, who independently discovered the method in the 1970s.

\textsuperscript{16} Christianson (2012) demonstrates that the second derivative can be computed with the same arithmetic operation sequence using forward-on-reverse, reverse-on-forward, and reverse-on-reverse. The taping overheads of these methods may differ in implementation-dependent ways.

\textsuperscript{17} See \url{http://DiffSharp.github.io/DiffSharp/examples-neuralnetworks.html} for an implementation of backpropagation with reverse mode AD.
derlying mechanism is not always made clear and confusion abounds regarding the use of the terms “autodiff”, “automatic differentiation”, and “symbolic differentiation”, which are sometimes even used interchangeably. In mainstream frameworks including Theano\(^{18}\) (Bastien et al., 2012), TensorFlow (Abadi et al., 2016), Caffe (Jia et al., 2014), and CNTK (Seide and Azarwal, 2016) the user first constructs a model as a computational graph using a domain-specific mini language, which then gets interpreted by the framework during execution. This approach has the advantage of enabling optimizations of the computational graph structure (e.g., as in Theano), but the disadvantages of having limited and unintuitive control flow and being difficult to debug. In contrast, the lineage of recent frameworks led by autograd (Maclaurin, 2016), Chainer (Tokui et al., 2015), and PyTorch (Paszke et al., 2017) provide truly general-purpose reverse mode AD of the type we outline in Section 3, where the user directly uses the host programming language to define the model as a regular program of the forward computation. This eliminates the need for an interpreter, allows arbitrary control flow statements, and makes debugging simple and intuitive.

Simultaneously with the ongoing adoption of general-purpose AD in machine learning, we are witnessing a modeling-centric terminology emerge within the deep learning community. The terms define-and-run and static computational graph refer to Theano-like systems where a model is constructed, before execution, as a computational graph structure, which later gets executed with different inputs while remaining fixed. In contrast, the terms define-by-run and dynamic computational graph refer to the general-purpose AD capability available in newer PyTorch-like systems where a model is a regular program in the host programming language, whose execution dynamically constructs a computational graph on-the-fly that can freely change in each iteration.\(^{19}\)

Differentiable programming\(^{20}\) is another emerging term referring to the realization that deep learning practice essentially amounts to writing program templates of potential solutions to a problem, which are constructed as differentiable directed graphs assembled from functional blocks whose parameters are learned from examples using gradient-based optimization. Expressed in this paradigm, neural networks are just a class of parameterized differentiable programs composed of building blocks such as feed-forward, convolutional, and recurrent elements. We are increasingly seeing these traditional building blocks freely composed in arbitrary algorithmic structures using control flow, as well as the introduction of novel differentiable architectures such as the neural Turing machine (Graves et al., 2014), a range of controller–interface abstractions (Graves et al., 2016; Zaremba et al., 2016; Joulin and Mikolov, 2015; Sukhbaatar et al., 2015), and differentiable versions of data structures such as stacks, queues, deques (Grefenstette et al., 2015). Availability of general-

---

18. Theano is a computational graph optimizer and compiler with GPU support and it currently handles derivatives in a highly optimized form of symbolic differentiation. The result can be interpreted as a hybrid of symbolic differentiation and reverse mode AD, but Theano does not use the general-purpose reverse accumulation as we describe in this paper. (Personal communication with the authors.)

19. Note that the terms “static” and “dynamic” here are used in the sense of having a fixed versus non-fixed computational graph topology and not in the sense of data flow architectures.

purpose AD greatly simplifies the implementation of such architectures by enabling their expression as regular programs that rely on the differentiation infrastructure. Although the differentiable programming perspective on deep learning is new, we note that programming with differentiable functions and having differentiation as a language infrastructure has been the main research subject of the AD community for many decades and realized in a wide range of systems and languages as we shall see in Section 5.

There are instances in neural network literature—albeit few—where explicit reference has been made to AD for computing error gradients, such as Eriksson et al. (1998) using AD for large-scale feed-forward networks, and the work by Yang et al. (2008), where the authors use AD to train a neural-network-based proportional-integral-derivative (PID) controller. Similarly, Rollins (2009) uses reverse mode AD in conjunction with neural networks for the problem of optimal feedback control. Another example is given for continuous time recurrent neural networks (CTRNN) by Al Seyab and Cao (2008), where the authors apply AD for the training of CTRNNs predicting dynamic behavior of nonlinear processes in real time and report significantly reduced training time compared with other methods.

4.3 Computer Vision

Since the influential work by Krizhevsky et al. (2012), computer vision has been dominated by deep learning, specifically, variations of convolutional neural networks (LeCun et al., 1998). These models are trained end-to-end, meaning that a mapping from raw input data to corresponding outputs is learned, automatically discovering the representations needed for feature detection in a process called representation learning (Bengio et al., 2013).

Besides deep learning, an interesting area where AD can be applied to computer vision problems is inverse graphics (Horn, 1977; Hinton and Ghahramani, 1997)—or analysis-by-synthesis (Yildirim et al., 2015)—where vision is seen as the inference of parameters for a generative model of a scene. Using gradient-based optimization in inverse graphics requires propagating derivatives through whole image synthesis pipelines including the renderer. Eslami et al. (2016) use numerical differentiation for this purpose. Loper and Black (2014) implement the Open Differentiable Renderer (OpenDR), which is a scene renderer that also supplies derivatives of the image pixels with respect to scene parameters, and demonstrate it in the task of fitting an articulated and deformable 3D model of the human body to image and range data from a Kinect device. Similarly, Kulkarni et al. (2015) implement a differentiable approximate renderer for the task of inference in probabilistic programs describing scenes.

Srajer et al. (2016) investigate the use of AD for three tasks in computer vision and machine learning, namely bundle adjustment (Triggs et al., 1999), Gaussian mixture model fitting, and hand tracking (Taylor et al., 2014), and provide a comprehensive benchmark of various AD tools for the computation of derivatives in these tasks.

Pock et al. (2007) make use of AD in addressing the problems of denoising, segmentation, and recovery of information from stereoscopic image pairs, and note the usefulness of AD in identifying sparsity patterns in large Jacobian and Hessian matrices. In another study, Grabner et al. (2008) use reverse mode AD for GPU-accelerated medical 2D/3D registration, a task involving the alignment of data from different sources such as X-ray images or computed tomography. The authors report a six-fold increase in speed compared with
Baydin, Pearlmutter, Radul, and Siskind

numerical differentiation using center difference (cf. our benchmark with the Helmholtz function, Figure 5 and Table 4).

Barrett and Siskind (2013) present a use of general-purpose AD for the task of video event detection using hidden Markov models (HMMs) and Dalal and Triggs (2005) object detectors, performing training on a corpus of pre-tracked video using an adaptive step size gradient descent with reverse mode AD. Initially implemented with the R6RS-AD package which provides forward and reverse mode AD in Scheme, the resulting gradient code was later ported to C and highly optimized.

4.4 Natural Language Processing

Natural language processing (NLP) constitutes one of the areas where rapid progress is being made by applying deep learning techniques (Goldberg, 2016), with applications in tasks including machine translation (Bahdanau et al., 2014), language modeling (Mikolov et al., 2010), dependency parsing (Chen and Manning, 2014), and question answering (Kumar et al., 2016). Besides deep learning approaches, statistical models in NLP are commonly trained using general purpose or specialized gradient-based methods and mostly remain expensive to train. Improvements in training time can be realized by using online or distributed training algorithms (Gimpel et al., 2010). An example using stochastic gradient descent for NLP is given by Finkel et al. (2008) optimizing conditional random field parsers through an objective function. Related with the work on video event detection in the previous section, Yu and Siskind (2013) report their work on sentence tracking, representing an instance of grounded language learning paired with computer vision, where the system learns word meanings from short video clips paired with descriptive sentences. The method uses HMMs to represent changes in video frames and meanings of different parts of speech. This work is implemented in C and computes the required gradients using AD through the ADOL-C tool.

4.5 Probabilistic Modeling and Inference

Inference in probabilistic models can be static, such as compiling a given model to Bayesian networks and using algorithms such as belief propagation for inference; or they can be dynamic, executing a model forward many times and computing statistics on observed values to infer posterior distributions. Markov chain Monte Carlo (MCMC) (Neal, 1993) methods are often used for dynamic inference, such as the Metropolis–Hastings algorithm based on random sampling (Chib and Greenberg, 1995). Meyer et al. (2003) give an example of how AD can be used to speed up Bayesian posterior inference in MCMC, with an application in stochastic volatility. Amortized inference (Gershman and Goodman, 2014; Stuhlmüller et al., 2013) techniques based on deep learning (Le et al., 2017; Ritchie et al., 2016) work by training neural networks for performing approximate inference in generative models defined as probabilistic programs (Gordon et al., 2014).

22. Personal communication.
23. An implementation of the sentence tracker applied to video search using sentence-based queries can be accessed online: http://upplysingaoflun.ecn.purdue.edu/~qobi/cccp/sentence-tracker-video-retrieval.html
When model parameters are continuous, the Hamiltonian—or, hybrid—Monte Carlo (HMC) algorithm provides improved convergence characteristics avoiding the slow exploration of random sampling, by simulating Hamiltonian dynamics through auxiliary “momentum variables” (Duane et al., 1987). The advantages of HMC come at the cost of requiring gradient evaluations of complicated probability models. AD is highly suitable here for complementing probabilistic modeling, because it relieves the user from the manual derivation of gradients for each model. For instance, the probabilistic programming language Stan (Carpenter et al., 2016) implements automatic Bayesian inference based on HMC and the No-U-Turn sampler (NUTS) (Hoffman and Gelman, 2014) and uses reverse mode AD for the calculation of gradients for both HMC and NUTS (Carpenter et al., 2015). Similarly, Wingate et al. (2011) demonstrate the use of AD as a non-standard interpretation of probabilistic programs enabling efficient inference algorithms. Kucukelbir et al. (2017) present an AD-based method for deriving variational inference (VI) algorithms.

PyMC3 (Salvatier et al., 2016) allows fitting of Bayesian models using MCMC and VI, for which it uses gradients supplied by Theano. Edward (Tran et al., 2016) is a library for deep probabilistic modeling, inference, and criticism (Tran et al., 2017) that supports VI using TensorFlow. Availability of general-purpose AD in this area has enabled new libraries such as Pyro and ProbTorch (Siddharth et al., 2017) for deep universal probabilistic programming with support for recursion and control flow, relying, in both instances, on VI using gradients supplied by PyTorch’s reverse mode AD infrastructure.

When working with probabilistic models, one often needs to backpropagate derivatives through sampling operations of random variables in order to achieve stochastic optimization of model parameters. The score-function estimator, or REINFORCE (Williams, 1992), method provides a generally applicable unbiased gradient estimate, albeit with high variance. When working with continuous random variables, one can substitute a random variable by a deterministic and differentiable transformation of a simpler random variable, a method known as the “reparameterization trick” (Williams, 1992; Kingma and Welling, 2014; Rezende et al., 2014). For discrete variables, the REBAR (Tucker et al., 2017) method provides a lower-variance unbiased gradient estimator by using continuous relaxation. A generalization of REBAR called RELAX (Grathwohl et al., 2017) works by learning a free-form control variate parameterized by a neural network and is applicable in both discrete and continuous settings.

5. Implementations

It is useful to have an understanding of the different ways in which AD can be implemented. Here we cover major implementation strategies and provide a survey of existing tools.

A principal consideration in any AD implementation is the performance overhead introduced by the AD arithmetic and bookkeeping. In terms of computational complexity, AD guarantees that the amount of arithmetic goes up by no more than a small constant factor (Griewank and Walther, 2008). On the other hand, managing this arithmetic can introduce a significant overhead if done carelessly. For instance, naively allocating data structures for

---

24. See http://diffsharp.github.io/DiffSharp/examples-hamiltonianmontecarlo.html for an implementation of HMC with reverse mode AD.
holding dual numbers will involve memory access and allocation for every arithmetic operation, which are usually more expensive than arithmetic operations on modern computers.\textsuperscript{26} Likewise, using operator overloading may introduce method dispatches with attendant costs, which, compared to raw numerical computation of the original function, can easily amount to a slowdown of an order of magnitude.\textsuperscript{27}

Another major issue is the risk of hitting a class of bugs called “perturbation confusion” (Siskind and Pearlmutter, 2005; Manzvuk et al., 2012). This essentially means that if two ongoing differentiations affect the same piece of code, the two formal epsilons they introduce (Section 3.1.1) need to be kept distinct. It is very easy to have bugs—particularly in performance-oriented AD implementations—that confuse these in various ways. Such situations can also arise when AD is nested, that is, derivatives are computed for functions that internally compute derivatives.

Translation of mathematics into computer code often requires attention to numeric issues. For instance, the mathematical expressions \( \log(1+x) \) or \( \sqrt{x^2 + y^2 + z^2} \) or \( \tan^{-1}(y/x) \) should not be na"ively translated, but rather expressed as \( \log1p(x) \), \( \text{hypot}(x,\text{hypot}(y,z)) \), and \( \text{atan2}(y,x) \). In machine learning, the most prominent example of this is probably the so-called log-sum-exp trick to improve the numerics of calculations of the form \( \log \sum_i \exp x_i \). AD is not immune to such numeric considerations. For example, code calculating \( E = \sum_i E_i \), processed by AD, will calculate \( \nabla_w E = \sum_i \nabla_w E_i \). If the system is seeking a local minimum of \( E \) then \( \nabla_w E = \sum_i \nabla_w E_i \to 0 \), and na"ively adding a set of large numbers whose sum is near zero is numerically fraught. This is to say that AD is not immune to the perils of floating point arithmetic, and can sometimes introduce numeric issues which were not present in the primal calculation. Issues of numeric analysis are outside our present scope, but there is a robust literature on the numerics of AD (e.g., Griewank et al. (2012)) involving using subgradients to allow optimization to proceed despite non-differentiability of the objective, appropriate subgradients and approximations for functions like \( |\cdot| \) and \( \|\cdot\|_2 \) and \( \sqrt{\cdot} \) near zero, and a spate of related issues.

One should also be cautious about approximated functions and AD (Sirkes and Tziperman, 1997). In this case, if one has a procedure approximating an ideal function, AD always gives the derivative of the procedure that was actually programmed, which may not be a good approximation of the derivative of the ideal function that the procedure was approximating. For instance, consider \( e^x \) computed by a piecewise-rational approximation routine. Using AD on this routine would produce an approximated derivative in which each piece of the piecewise formula will get differentiated. Even if this would remain an approximation of the derivative of \( e^x \), we know that \( \frac{d}{dx} e^x = e^x \) and the original approximation itself was already a better approximation for the derivative of \( e^x \).\textsuperscript{28} Users of AD implementations must be therefore cautious to approximate the derivative, not differentiate the approximation. This would

\textsuperscript{26} The implementation of forward mode in Julia (Revels et al., 2016b) attempts to avoid this, and some current compilers can avoid this expense by unboxing dual numbers (Leroy, 1997; Jones et al., 1993b; Jones and Launchbury, 1991; Siskind and Pearlmutter, 2016). This method is also used to reduce the memory-access overhead in the implementations of forward mode in Stalingrad and the Haskell \textit{ad} library.

\textsuperscript{27} Flow analysis (Shivers, 1991) and/or partial evaluation (Jones et al., 1993a), together with tag stripping (Appel, 1989; Peterson, 1989), can remove this method dispatch. These, together with unboxing, can often make it possible to completely eliminate the memory access, memory allocation, memory reclamation, and method dispatch overhead of dual numbers (Siskind and Pearlmutter, 2016).

\textsuperscript{28} In modern systems this is not an issue, because \( e^x \) is a primitive implemented in hardware.
require explicitly approximating a known derivative, in cases where a mathematical function can only be computed approximately but has a well-defined mathematical derivative.

We note that there are similarities as well as differences between machine learning workloads and those studied in the traditional AD literature (Baydin et al., 2016b). Deep learning systems are generally compute-bound and spend a considerable amount of computation time in highly-optimized numerical kernels for matrix operations (Hadjis et al., 2015; Chetlur et al., 2014). This is a situation which is arguably amenable to operator-overloading-based AD implementations on high-level operations, as is commonly found in current machine learning frameworks. In contrast, numerical simulation workloads in traditional AD applications can be bandwidth-bound, making source code transformation and compiler optimization approaches more relevant. Another difference worth noting is that whereas high numerical precision is desirable in traditional application domains of AD such as computational fluid dynamics (Cohen and Molemaker, 2009), in deep learning lower-precision is sufficient and even desirable in improving computational efficiency, thanks to the error resiliency of neural networks (Gupta et al., 2015; Courbariaux et al., 2015).

There are instances in recent literature where implementation-related experience from the AD field has been put to use in machine learning settings. One particular area of recent interest is implicit and iterative AD techniques (Griewank and Walther, 2008), which has found use in work incorporating constrained optimization within deep learning (Amos and Kolter, 2017) and probabilistic graphical models and neural networks (Johnson et al., 2016). Another example is checkpointing strategies (Dauvergne and Hascoët, 2006; Siskind and Pearlmutter, 2017), which allow balancing of application-specific trade-offs between time and space complexities of reverse mode AD by not storing the full tape of intermediate variables in memory and reconstructing these as needed by re-running parts of the forward computation from intermediate checkpoints. This is highly relevant in deep learning workloads running on GPUs with limited memory budgets. A recent example in this area is the work by Gruslys et al. (2016), where the authors construct a checkpointing variety of the backpropagation through time (BPTT) algorithm for recurrent neural networks and demonstrate it saving up to 95% memory usage at the cost of a 33% increase in computation time in one instance.

In Table 5 we present a review of notable general-purpose AD implementations 29 A thorough taxonomy of implementation techniques was introduced by Juedes (1991), which was later revisited by Bischof et al. (2008) and simplified into elemental, operator overloading, compiler-based, and hybrid methods. We adopt a similar classification for the following part of this section.

5.1 Elemental Libraries

These implementations form the most basic category and work by replacing mathematical operations with calls to an AD-enabled library. Methods exposed by the library are then used in function definitions, meaning that the decomposition of any function into elementary operations is done manually when writing the code.

The approach has been utilized since the early days of AD, with prototypical examples being the WCOMP and UCOMP packages of Lawson (1971), the APL package of Neidinger

Elemental libraries still constitute the simplest strategy to implement AD for languages without operator overloading.

5.2 Compilers and Source Code Transformation

These implementations provide extensions to programming languages that automate the decomposition of algorithms into AD-enabled elementary operations. They are typically executed as preprocessors\(^{30}\) to transform the input in the extended language into the original language.

Classical instances of source code transformation include the Fortran preprocessors GRESS (Horwedel et al., 1988) and PADRE2 (Kubo and Iri, 1990), which transform AD-enabled variants of Fortran into standard Fortran 77 before compiling. Similarly, the ADIFOR tool (Bischof et al., 1996), given a Fortran source code, generates an augmented code in which all specified partial derivatives are computed in addition to the original result. For procedures coded in ANSI C, the ADIC tool (Bischof et al., 1997) implements AD as a source code transformation after the specification of dependent and independent variables. A recent and popular tool also utilizing this approach is Tapenade (Pascual and Hascoët, 2008; Hascoët and Pascual, 2013), implementing forward and reverse mode AD for Fortran and C programs. Tapenade itself is implemented in Java and can be run locally or as an online service.\(^{31}\)

In addition to language extensions through source code transformation, there are implementations introducing new languages with tightly integrated AD capabilities through special-purpose compilers or interpreters. Some of the earliest AD tools such as SLANG (Adamson and Winant, 1969) and PROSE (Pfeiffer, 1987) belong to this category. The NAGWare Fortran 95 compiler (Naumann and Riehme, 2005) is a more recent example, where the use of AD-related extensions triggers automatic generation of derivative code at compile time.

As an example of interpreter-based implementation, the algebraic modeling language AMPL (Fourer et al., 2002) enables objectives and constraints to be expressed in mathematical notation, from which the system deduces active variables and arranges the necessary AD computations. Other examples in this category include the FM/FAD package (Mazourik, 1991), based on the Algol-like DIFALG language, and the object-oriented COSY language (Berz et al., 1996) similar to Pascal.

The Stalingrad compiler (Pearlmutter and Siskind, 2008; Siskind and Pearlmutter, 2008a), working on the Scheme-based AD-aware VLAD language, also falls under this category. The newer DVL compiler\(^{32}\) is based on Stalingrad and uses a reimplementation of portions of the VLAD language.

Motivated by machine learning applications, the Tangent library (van Merriënboer et al., 2017) implements AD using source code transformation, and accepts numeric functions written in a syntactic subset of Python and Numpy.

---

\(^{30}\) Preprocessors transform program source code before it is given as an input to a compiler.

\(^{32}\) [https://github.com/axch/dysvunctional-language](https://github.com/axch/dysvunctional-language)
5.3 Operator Overloading

In modern programming languages with polymorphic features, operator overloading provides the most straightforward way of implementing AD, exploiting the capability of redefining elementary operation semantics.

A popular tool implemented with operator overloading in C++ is ADOL-C (Walther and Griewank, 2012). ADOL-C requires the use of AD-enabled types for variables, and records arithmetic operations on variables in tape data structures, which can subsequently be “played back” during reverse mode AD computations. The Mxyzptlk package (Michelotti, 1990) is another example for C++ capable of computing arbitrary-order partial derivatives via forward propagation. The FADBAD++ library (Bendtsen and Stauning, 1996) implements AD for C++ using templates and operator overloading. For Python, the ad package uses operator overloading to compute first- and second-order derivatives, while the newer autograd package provides forward and reverse mode AD with support for higher-order derivatives.

For functional languages, examples include R6RS-AD and the AD routines within the Scmutils library for Scheme, the ad library for Haskell, and DiffSharp for F# and C#.

6. Conclusions

Backpropagation and gradient-based optimization are behind virtually all recent successes in machine learning, yielding state-of-the-art results in computer vision, speech recognition and synthesis, and machine translation. We expect these techniques to remain at the core of machine learning for the foreseeable future. Research in the field involves a rapid prototyping and development cycle for testing new models and ideas, using a collection of increasingly higher-quality machine learning frameworks. These frameworks are in the process of transition from coarse-grained (module level) backpropagation towards fine-grained, general-purpose AD, allowing models to be implemented as regular programs in general-purpose programming languages with differentiation as an integral part of the infrastructure. We strongly believe that general-purpose AD is the future of gradient-based machine learning and we expect it to become an indispensable tool in the machine learning toolbox.

It is an exciting time for working at the intersection of AD and machine learning, and there are many opportunities for bringing advanced techniques and expertise from AD literature to bear on machine learning problems. Techniques that have been developed by the AD community such as tape reduction and elimination (Naumann, 2004), fixed-point iterations (Christianson, 1994), utilizing sparsity by matrix coloring (Gebremedhin et al., 2009, 2013), and reverse AD checkpointing (Dauvergne and Hascoët, 2006) are just a few examples that can find potential use in machine learning for increasing performance, improving convergence of optimization, using hardware more efficiently, and even enabling new types of machine learning models to be implemented. Similarly, exciting new AD modes like

33. http://pythonhosted.org/ad/
34. https://github.com/HIPS/autograd
35. https://github.com/NUIM-BCL/R6RS-AD
Direct propagation of the inverse Jacobian (Srinivasan and Todorov, 2015) have emerged from the machine learning community, but have yet to be examined and formalized by the AD community.

An important direction for future work is to make use of nested AD techniques in machine learning, allowing differentiation to be nested arbitrarily deep with referential transparency (Siskind and Pearlmutter, 2008b; Pearlmutter and Siskind, 2008). Nested AD is highly relevant in hyperparameter optimization as it can effortlessly provide exact hypergradients, that is, derivatives of a training objective with respect to the hyperparameters of an optimization routine (Maclaurin et al., 2015; Baydin et al., 2018). Potential applications include Bayesian model selection (Rasmussen and Williams, 2006) and gradient-based tuning of Hamiltonian Monte Carlo step sizes and mass matrices (Salimans et al., 2015). Besides hyperparameters, models internally using higher-order derivatives constitute a straightforward usage case for nested AD. The Riemannian manifold Langevin and Hamiltonian Monte Carlo methods (Girolami and Calderhead, 2011) use higher-order derivative information to more closely track the information geometry of the sampled distribution for faster convergence and exploration. In neural networks, it is very natural to use nested derivatives in defining objective functions that take input transformations into account, such as the Tangent Prop method (Simard et al., 1998) for imposing invariance under a set of chosen transformations.
