

Pulsar interpretation of lepton spectra measured by AMS-02

Jie Feng and Hong-Hao Zhang¹

School of Physics and Engineering, Sun Yat-Sen University, Guangzhou 510275, China

Abstract

AMS-02 recently published its lepton spectra measurement. The results show that the positron fraction no longer increases above ~ 200 GeV. The aim of this work is to investigate the possibility that the excess of positron fraction is due to pulsars. Nearby known pulsars from ATNF catalogue are considered as a possible primary positron source of the high energy positrons. We find that the pulsars with age $T \simeq (0.45 \sim 4.5) \times 10^5$ yr and distance $d < 0.5$ kpc can explain the behavior of positron fraction of AMS-02 in the range of high energy. We show that each of the four pulsars — Geminga, J1741-2054, Monogem and J0942-5552 — is able to be a single source satisfying all considered physical requirements. We also discuss the possibility that these high energy e^\pm are from multiple pulsars. The multiple pulsars contribution predicts a positron fraction with some structures at higher energies.

1 Introduction

The positron fraction spectrum $e^+/(e^++e^-)$ in the cosmic ray (CR) contains two components: secondary e^\pm produced by nuclei collision and primary e^- . It is currently believed that these two components, each of which will produce a diffused power low spectrum, predict a positron fraction which goes down with energy. However, the latest results measured by the Alpha Magnetic Spectrometer (AMS-02) with high accuracy indicate that the positron fraction increases with energy above ~ 8 GeV and does not increase with energy above ~ 200 GeV [1, 2]. This “increasing” behavior, which is also observed by the payload for antimatter matter exploration and light-nuclei astrophysics (PAMELA) [4–6] and the Fermi Large Area Telescope (Fermi-LAT) [10, 11], is not compatible with only diffused power low components. The “cutoff” behavior above 200 GeV, which can be well described by a common source term with an exponential cutoff parameter in the Eq.(1) of [1], indicates that potential sources produce the exceed of electron and positron pairs.

AMS-02 [1, 2] is a state-of-the-art astroparticle detector installed on the International Space Station (ISS). It carries a Transition Radiation Detector (TRD) and a Electromagnetic Calorimeter (ECAL). These two sub-detectors provide independent proton/lepton identification, which will achieve a much larger proton rejection power of AMS-02 compared with PAMELA which has only one Electromagnetic Calorimeter for proton/lepton identification using the 3D shower shape

and Energy-Momentum match (E/P). Compared with Fermi-LAT, AMS-02 has a large magnet which can identify charge sign of the particle. Thus, the contamination of electrons (also called “charge confusion” in [1]) in the positron sample of AMS-02 is much smaller than that of Fermi-LAT. For the reasons given above, there is much less proton or charge confusion contamination in AMS-02 measurement than that in PAMELA or Fermi-LAT. Here, we only interpret AMS-02 result due to the lack of knowledge of the contamination control in PAMELA and Fermi-LAT measurements.

The AMS-02’s recent measurements of positron fraction [1], e^+ flux, e^- flux [2] and (e^-+e^+) flux [12] were published. The e^- flux contains three components: primary e^- , secondary e^- and e^- from unknown sources. The e^+ flux contains only two components: e^+ from secondary production and primary e^+ from sources to be identified. To avoid the unnecessary uncertainty of primary e^- , the e^+ flux seems to be an ideal spectrum to study extra sources. However, there is an acceptance uncertainty from the detector itself in the e^+ and e^- fluxes. This uncertainty in e^+ flux is strongly correlated with that in e^- flux [2], especially at high energies. The positron fraction can avoid this systematic uncertainty [1]. For example, one can clearly see a drop at the last point (350 GeV \sim 500 GeV) in the positron fraction but cannot tell a drop at the last point (370 GeV \sim 500 GeV) in the e^+ flux due to its larger error bars. Therefore, positron fraction is used to study extra sources while e^- flux is used to estimate the primary e^- which will affect the denominator of $e^+/(e^++e^-)$.

Recent studies have proposed some interpretations, such as dark matter annihilation or decay [13–21], supernova remnants (SNRs) [22–27], secondary production in the interstellar medium (ISM) [28] and pulsars [20, 21, 29–43]. Cosmic ray flux data can also be together with other observations (like the dark matter relic density and the direct detection experimental results etc.) to give a combined constraint on dark matter models [44, 45]. Besides dark matter scenario, the others can provide astrophysical explanations which do not require the existence of new particles. SNRs model, for instance in [26] and [46], introduce some new mechanisms for the propagation model or special distributions of the primary sources. The “model-independent” approach from [28], sets an upper limit of the positron fraction by neglecting radiative losses of electrons and positron but does not indicate any obvious cutoff in the spectrum. Among them, the pulsar interpretation is one of the scenarios which predict a cutoff at a few hundred GeV in the positron fraction spectrum and do not contradict other cosmic ray spectrums (eg. boron-to-carbon). The pioneering works on pulsar interpretation of positron fraction have been performed by [33, 35, 42] a few years ago. Combined analyses of the recent AMS-02 lepton data have been performed by [27] and [20], with a global fit on positron fraction [1], e^+ flux, e^- flux and (e^-+e^+) flux. To avoid the over-estimation of the χ^2 , however,

only two out of four spectrums should be used in the fit. As the reasons given by the previous paragraph, we only study positron fraction and e^- flux in this paper.

A pulsar is widely regarded as a rotating neutron star with a strong magnetosphere, which can accelerate electrons, which will induce an electromagnetic cascade through the emission of curvature radiation [47–50]. This leads to the production of high energy photons which eventually induces e^+e^- pair production. This process produces the same amount of high energy e^+ and e^- , which can escape from the magnetosphere and propagate to the earth. There is a cutoff energy of the photons produced in a pulsar, which leads to a cutoff in the positron fraction.

In this paper, DRAGON [51–55] is used as a numerical tool to model the propagation environment, to tune the related parameters and to estimate the e^\pm background. The authors of [53–56] did a very complete work on three-dimensional cosmic-ray modeling. In the 3-D models, they pointed out the spiral arms have an effect on the propagation parameters. A 2-D model is used in this paper because we focus on the lepton spectra implication. Due to the energy loss of leptons, the effect of spiral arms on the high energy leptons is less important than that of the additional nearby sources contribution. ROOT is used to minimize χ^2 to get the best fit results. We consider six nearby pulsars from ATNF catalogue [57, 58] as the possible extra single sources of the high energy positrons. We find only four, which are Geminga, J1741-2054, Monogem and J0942-5552, can survive from all considered physical requirements. We then discuss the possibility that these high energy e^\pm are from multiple pulsars. The multiple pulsars contribution predicts a positron fraction with some structures at higher energies.

The paper is organized as follows. Section 2 shows the way where e^\pm background is estimated. In Section 3, the properties of pulsars are described and the profile of e^\pm fluxes produced by a pulsar is derived. The interpretation of positron fraction with one single pulsar is discussed in Section 4 and the hypothesis about multiple pulsars interpretation is tested in Section 5. The conclusions are drawn in Section 6. In Appendix A, the diffusion energy-loss equation for a burst-like source is solved with the spherically symmetric approximation.

2 Propagation parameters and e^\pm background

The Galactic background of the lepton fluxes are considered as three main components, which are primary electrons from CR sources, secondary electrons and positrons from the interactions between the CR and the interstellar medium (ISM). The propagation of e^\pm in the Galaxy obeys the following Ginzburg and Syrovatskii's

equation [59], also in [52, 60]

$$\begin{aligned} & \frac{\partial f_i}{\partial t} - \nabla \cdot [(D\nabla - \vec{v}_c)f_i] - \frac{\partial}{\partial p} p^2 D_{pp} \frac{\partial f_i}{\partial p} + \frac{\partial}{\partial p} \left[\left(\dot{p} - \frac{p}{3} \nabla \cdot \vec{v}_c \right) f_i \right] \\ & = Q_i(\vec{x}, t, p) + \sum_{j>i} c\beta n_{\text{gas}} \sigma_{ji} f_j - c\beta n_{\text{gas}} \sigma_{\text{in}} f_i \end{aligned} \quad (1)$$

where $p \equiv |\vec{p}|$ is the particle momentum; $f_i(\vec{x}, t, p)$ is the particle number density of a species i per unit momentum interval; \vec{v}_c is the convection velocity, $\beta \equiv v/c$ is the ratio of velocity to the speed of light; σ_{in} is the total inelastic cross section onto the ISM gas, whose density is n_{gas} ; σ_{ji} is the production cross section of the species i by the fragmentation of the species j (with $j > i$); and $Q_i(\vec{x}, t, p)$ is the source term of species i , which can be thought to be steady $Q_i = Q_i(\vec{x}, p)$ for background CR particles.

The spatial diffusion coefficient D in the cylindrical coordinate system (r, z) may be parameterized as [52, 60, 61]

$$\begin{cases} D(\rho, r, z) = D(\rho, r) e^{-|z|/z_t} & \text{or} & D(\rho, r, z) = D(\rho, r) (-L < z < L) \\ D(\rho, r) = D_0 f(r) \beta \left(\frac{\rho}{\rho_0} \right)^\delta \end{cases} \quad (2)$$

where $\rho \equiv pc/(Ze)$ is defined as the particle magnetic rigidity, z_t is the scale height of the diffusion coefficient, L is the halo size, and δ is the index of the power-law dependence of the diffusion coefficient on the rigidity. D_0 is the normalization of the diffusion coefficient at the reference rigidity $\rho_0 = 4$ GV. Previous DRAGON papers [53–55] tested a few models with the exponential profile, i.e., the left formula in (2), which is more physical than the constant one, i.e., the right one. The effect of choosing different profiles on the electron and positron background is small if the parameters are properly set. In this paper, the constant profile is used in order to compute the pulsar profile in an analytical way, i.e., eq. (17) in Section 3. The function $f(r)$ describes a possible radial dependence of D , and it can be taken to be unity for simplicity.

The diffusion coefficient in momentum space D_{pp} is related to the spatial diffusion coefficient D by [18, 61, 62, 65]

$$D_{pp} D = \frac{4p^2 v_A^2}{3\delta(4 - \delta^2)(4 - \delta)w} \quad (3)$$

where v_A is the Alfvén velocity, and δ is the power-law index as given in (2). w is the ratio of magnetohydrodynamic wave energy density to the magnetic field energy density, and it is usually taken to be 1.

DRAGON [51–53] is used to tune the propagation parameters according to the B/C ratio, which is sensitive to the parameters. The Markov Chain Monte Carlo

algorithm (MCMC, [67]) is used to determine D_0 and δ . The priors are shown in Table. 1. The posterior distributions can be shown in a contour in the D_0 and δ plane in Fig. 1.

Table 1: The priors of D_0 and δ

	start value	minimum value	maximum value
$D_0(\times 10^{28} \text{ cm}^2 \text{ s}^{-1})$	3	2.5	7.5
δ	0.40	0.20	0.65

Figure 1: Contour in the D_0 and δ plane. The cross shows the best fit value while the three closed curves from inside to outside show the 68.3% C.L., 95.4% C.L. and 99.7% C.L. respectively.

The parameters with their 68% C.L. uncertainties from the fit are as follows:

$$\left\{ \begin{array}{l} D_0|_{\rho_0=4 \text{ GV}} = (6.20 \pm 0.31) \times 10^{28} \text{ cm}^2\text{s}^{-1} \\ \delta = 0.31 \pm 0.03 \\ L = 4 \text{ kpc} \\ v_A = 40 \text{ km/s} \end{array} \right. \quad (4)$$

where the halo size L is taken from the MED model of [63], and the v_A is fixed. These parameters are consistent with what the authors of Ref.[20] has got in the reacceleration propagation model.

To avoid the uncertainty of solar modulation, AMS-02 proton flux [3] above 45 GV is fitted to get the injection spectra using MCMC [67]. Three breaks, which are 6.7 GV, 11 GV and 316(± 148) GV, are introduced in the injection spectrum of nuclei. The proton spectral indice below and above the breaks are 2.25, 2.35, 2.501(± 0.010) and 2.501-0.084(± 0.050), respectively. The high energy spectral indices of helium, carbon and oxygen are shifted by -0.1 w.r.t those of proton according to proton-to-helium ratio [5]. The Ferriere model [64] is used as the source distribution for the primary components, e.g. SNRs for SNe type II. To assure that the propagation parameters are correct, we need to compare the model prediction with the boron-to-carbon ratio [6–9] and the proton flux [3]. As shown in Fig. 2, the set of parameters used can reproduce the boron-to-carbon ratio and the proton flux well. According to this set of parameters, we can obtain the fluxes of the secondary positrons and electrons. A power-law spectrum with two breaks is introduced to parameterize the injection spectrum of the primary electrons as a function of rigidity,

$$Q(\rho) \propto \left\{ \begin{array}{ll} (\rho/\rho_{\text{br1}}^e)^{-\gamma_1} & (\rho < \rho_{\text{br1}}^e) \\ (\rho/\rho_{\text{br1}}^e)^{-\gamma_2} & (\rho_{\text{br1}}^e \leq \rho \leq \rho_{\text{br2}}^e) \\ (\rho_{\text{br2}}^e/\rho_{\text{br1}}^e)^{-\gamma_2} \cdot (\rho/\rho_{\text{br2}}^e)^{-\gamma_3} & (\rho > \rho_{\text{br2}}^e) \end{array} \right. \quad (5)$$

The parameters are adjusted according to the electron flux from AMS-02 [2]. The agreement between the model and the data is shown in Section 5. These spectral indices are $\gamma_1 = 1.95$, $\gamma_2 = 2.75$ and $\gamma_3 = 2.5$ respectively. The breaks are $\rho_{\text{br1}}^e = 8.6$ GV and $\rho_{\text{br2}}^e = 110$ GV. Since the high energy breaks of primary particles, such as protons and helium, are found by PAMELA [5] and recently confirmed by AMS-02 [3], it is reasonable to assume that there is also a high energy break in primary electron flux. More detailed discussion on the necessity of the high energy break ρ_{br2}^e can be found in [20] and [68], where the high energy break hypothesizes are in favor compared to the no-break ones. Ref. [68] gave us an estimation by taking the primary electron flux as $\Phi_{e-} - \Phi_{e+}$ and could roughly determine the break.

Figure 2: (a) model prediction of B/C ratio compared with measurements from PAMELA [6], ATIC02 [7], CREAM-I [8] and TRACER06 [9]. (b) model prediction of proton flux compared with measurements from AMS-02 [3]. The solar modulation is taken as 500 MeV here. The red band in (a) shows the variation of the propagation parameters D_0 and δ within 95% C.L.

3 e^\pm from a single pulsar

The pulsars are potential sources which could produce primary e^\pm at high energy [33–36, 42]. Electrons can be accelerated by the strong magnetosphere of the pulsars, and this acceleration produces photons. When those photons annihilate with each other, they can produce e^\pm pairs. Thus, the e^\pm energies are related to the pulsar magnetosphere. Assuming the pulsar magnetosphere as a magnetic dipole, this magnetic dipole radiation energy is proportional to the spin down luminosity. Due to this spin down (*i.e.* slowing of rotation), the rotational frequency of a pulsar $\Omega \equiv 2\pi/P$ (with P being the period) is a function of time as follows [33, 35, 42]

$$\Omega(t) = \frac{\Omega_0}{\sqrt{1 + t/\tau_0}}, \quad (6)$$

where Ω_0 is the initial spin frequency of the pulsar and τ_0 is a time scale which describes the spin-down luminosity decays. τ_0 cannot be directly obtained from pulsar timing observations, and it is assumed to be [35, 42]

$$\tau_0 \simeq 10^4 \text{ yr} \quad (7)$$

The rotational energy of the pulsar is $E(t) = (1/2)I\Omega^2(t)$. Here I is the moment of inertia, which is related to the mass and the radius of the pulsar and can be regarded as a time independent value. The magnetic dipole radiation energy is equal to the

energy loss rate,

$$|\dot{E}(t)| = I\Omega(t)|\dot{\Omega}(t)| = \frac{I\Omega_0^2}{2} \frac{1}{\tau_0(1+t/\tau_0)^2} \quad (8)$$

The total energy loss of a pulsar is [35, 36, 42]

$$E_{\text{tot}}(t) = \int_0^t dt' |\dot{E}(t')| = \frac{I\Omega_0^2}{2} \frac{t/\tau_0}{1+t/\tau_0} = |\dot{E}(t)|t \left(1 + \frac{t}{\tau_0}\right) \quad (9)$$

The total energy injection of e^\pm out of a pulsar should be proportional to the total energy loss

$$E_{\text{out}}(t) = \eta E_{\text{tot}}(t) = \eta |\dot{E}(t)|t \left(1 + \frac{t}{\tau_0}\right) \quad (10)$$

where η is the efficiency of the injected e^\pm energy converted from the magnetic dipole radiation energy.

The pulsar characteristic age is defined as [58]

$$T \equiv \frac{P}{2\dot{P}} = \frac{\Omega}{2|\dot{\Omega}|} = t + \tau_0 \quad (11)$$

For a mature pulsar with $t \gg \tau_0$, we have $T \simeq t$. In this condition, eqs. (8), (9) and (10) become

$$|\dot{E}(T)| \simeq \frac{I\Omega_0^2}{2} \frac{\tau_0}{T^2} \quad (12)$$

$$E_{\text{tot}}(T) \simeq |\dot{E}(T)| \frac{T^2}{\tau_0} \quad (13)$$

$$E_{\text{out}}(T) \simeq \eta |\dot{E}(T)| \frac{T^2}{\tau_0} \quad (14)$$

The propagation equation for the e^\pm can be described as [33, 42]

$$\frac{\partial f}{\partial t} = D(E)\nabla^2 f + \frac{\partial}{\partial E}[b(E)f] + Q(\vec{x}, t, E), \quad (15)$$

where $f(\vec{x}, t, E)$ is the number density per unit energy interval of e^\pm ; $D(E) = (v/c)D_0(E/4 \text{ GeV})^\delta$ is the diffusion coefficient with the velocity v of the particle, the speed c of light, D_0 and δ the same as the parameters used to calculate the background in Section 2; and $b(E) \equiv -dE/dt = b_0 E^2$ with $b_0 = 1.4 \times 10^{-16} \text{ GeV}^{-1}\text{s}^{-1}$ is the rate of energy loss due to inverse Compton scattering and synchrotron [10, 35, 42].

The source term $Q(\vec{x}, t, E)$ of a pulsar can be described by a burst-like source with a power-law energy spectrum and an exponential cutoff

$$Q(\vec{x}, t, E) = Q_0 E^{-\alpha} \exp\left(-\frac{E}{E_{\text{cut}}}\right) \delta^3(\vec{x} - \vec{x}_0) \delta(t - t_0), \quad (16)$$

where Q_0 is the normalization factor related to the total injected energy E_{out} , α is the spectral index, and E_{cut} is the cutoff energy.

In Appendix A, we briefly review how to solve the equation (15) with the source (16). The method is equivalent to many previous works (for example, Refs. [30, 42]). Using the results, *i.e.* eqs. (56) and (60), in Appendix A, we obtain the electron or positron flux observed at the earth as follows:

$$\Phi_e(r, t_{\text{dif}}, E) = \frac{c}{4\pi} f = \frac{c}{4\pi} \frac{Q_0 E^{-\alpha}}{\pi^{\frac{3}{2}} r_{\text{dif}}^3} \left(1 - \frac{E}{E_{\text{max}}}\right)^{\alpha-2} \exp \left[-\frac{E/E_{\text{cut}}}{(1 - E/E_{\text{max}})} - \frac{d^2}{r_{\text{dif}}^2} \right], \quad (17)$$

where d is the distance between the earth and the source, the diffusion distance r_{dif} is given by

$$r_{\text{dif}}(t_{\text{dif}}, E) = 2 \sqrt{\frac{D(E) t_{\text{dif}}}{(1 - \delta)} \frac{E_{\text{max}}}{E} \left[1 - \left(1 - \frac{E}{E_{\text{max}}}\right)^{1-\delta} \right]} \quad (18)$$

and the diffusion time t_{dif} is the time a charged particle travels in the ISM before it reaches the earth. The electrons and positrons may be trapped in the pulsar wind nebula (PWN) for some time before they escape. The age of a pulsar is $T = t_{\text{escape}} + t_{\text{dif}}$, where t_{escape} is the time before the leptons escape from the PWN. In some case, t_{escape} and t_{dif} can be of the same order of magnitude, and then the discussion will be complicated. In some other case, t_{escape} could be negligible. For instance, when the SNR is evolving into the "Sedov-Taylor" phase, the leptons in it are trapped (See Ref. [69] and references there in). In that case, the time t_{escape} , during which the SNR reverse shock collides with the PWN forward shock, is typically a few 10^3 yr [69], which is small comparing to the ages of the pulsars we studied here, which are around 10^5 yr. In this work, we consider the latter case and neglect t_{escape} for simplicity. We leave the case of large t_{escape} to a further specific study. Thus, we assume that $t_{\text{dif}} \simeq T$. The maximum energy E_{max} is defined as

$$E_{\text{max}} = 1/(b_0 T). \quad (19)$$

The positron fraction from AMS-02 implies a primary positron source with a cut-off energy $1/E_s = 1.84 \pm 0.58 \text{ TeV}^{-1}$ in their "minimal" model [1], which corresponds to $E_s \in [490, 790]$. Due to the limitation of statistics of high energy e- and e+ measured by AMS-02, the upper bound 790 GeV is not a strict limit. Thus, we consider a primary e+ and e- source contribution with a cut-off energy $E_{\text{cut-off}} \simeq (500 \sim 5000) \text{ GeV}$, which corresponds to a pulsar with an age $T \simeq (0.45 \sim 4.5) \times 10^5$ yr according to (19). The term $\exp \left[-\frac{d^2}{r_{\text{dif}}^2} \right]$ in (17) tells us that a pulsar with $d > r_{\text{dif}}$ requires a larger normalization Q_0 , which hints a larger E_{out} , a larger η in (10), or

both. $r_{\text{dif}} > d$ is required in our study, whose physical interpretation is that the distance a particle travels in the ISM should be larger than the distance between the earth and the source. Eq. (18) tells us that r_{dif} is as a function of diffusion time t_{dif} and lepton energy E , as is shown by Fig. 3 where the color scale indicates r_{dif} . For $T \simeq (0.45 \sim 4.5) \times 10^5$ yr and the lepton energy $E = 1000$ GeV, r_{dif} is always greater than 0.5 kpc. Selecting pulsars with $d < 0.5$ kpc and $T \simeq (0.45 \sim 4.5) \times 10^5$ yr, high energy leptons they produced can reach the earth.

Figure 3: r_{dif} as a function of t_{dif} and E , which is from eq. (18). The lepton energy E is the e^+ (or e^-) energy detected at location away from the pulsar with the diffusion distance r_{dif} . r_{dif} increases with E .

Thus, the pulsars with ages $T \simeq (0.45 \sim 4.5) \times 10^5$ yr and distance $d < 0.5$ kpc can explain the behavior of positron fraction of AMS-02 at high energy range.

4 Single pulsar interpretation

A few simple examples using a single pulsar are given to explain high energy positron fraction of AMS-02 [1]. The background electrons and positrons are described in Section 2. The primary electron flux is scaled by a normalization factor A_{prim,e^-}

since it is not possible to constrain the electron flux contribution from SNRs. The age T and the distance d are taken from the ATNF catalogue and the positron fraction is fitted to obtain the free parameters in (17), the spectral index α , and the normalization Q_0 . Q_0 is fixed by the relation [27, 36, 41] $E_{\text{out}} = \int_{E_{\text{min}}}^{E_{\text{max}}} dE E Q(E) \simeq \int_0^\infty dE E Q(E)$, which approximately yields $Q_0 \simeq E_{\text{out}}$ for $\alpha \simeq 2$. The cutoff energy E_{cut} is set to be 5000 GeV, which is large enough, as it does not change the shape of pulsar contribution. Since we are interested in the positron excess at high energies, the fit is started from 10 GeV where the effect of solar modulation is negligible.

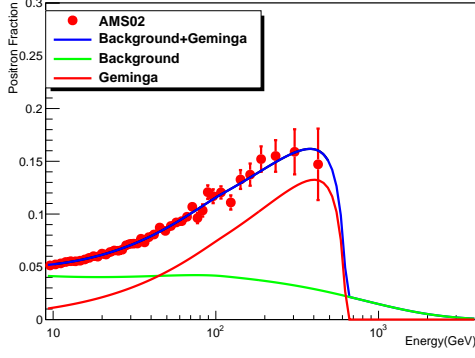

Six nearby single pulsars, whose ages $T \simeq (0.45 \sim 4.5) \times 10^5$ yr and distance $d < 0.5$ kpc, are used to fit the positron fraction. Minuit package in ROOT is used to determine the parameters to minimize χ^2 . The best results of the single pulsars are listed in Table 2. The results are also shown in Fig. 4. Using the parameters

Pulsar name	$d(\text{kpc})$	$T(10^5 \text{ yr})$	$\log_{10}(\frac{Q_0}{\text{GeV}})$	α	A_{prim,e^-}	χ^2/ndf
Geminga	0.25	3.42	50.5	2.04	0.50	26.8/40
J1741-2054	0.25	3.86	50.6	2.03	0.50	26.8/40
Monogem	0.28	1.11	50.1	2.15	0.50	27.3/40
J0942-5552	0.30	4.61	50.6	2.01	0.49	27.7/40
J1001-5507	0.30	4.43	50.1	2.34	0.47	27.6/40
J1825-0935	0.30	2.32	50.5	2.61	0.44	28.8/40

Table 2: Parameters of six nearby single pulsars from the best fit results. The χ^2/ndf from the fits of Geminga, J1741-2054, Monogem, J0942-5552 and J1001-5507 are smaller than 1, which show a good agreement between those single pulsar models and the experiment.

of the best fit results, the positron fraction can be well reproduced by these single pulsar's contributions. Table 2 tells us that the normalization A_{prim,e^-} are around 0.5 and the spectral indices α of different pulsars are around 2.

We can estimate the injection efficiency η from the pulsar. Take Geminga as an example, the spin-down energy loss rate of Geminga $|\dot{E}(T)| = 3.2 \times 10^{34}$ erg/s. The total radiation energy of the magnetic dipole can be derived from eq. (13) as $E_{\text{tot}}(T) \simeq |\dot{E}(T)|T^2/\tau_0 = 1.2 \times 10^{49}$ erg. From the fit, we get the injection energy $E_{\text{out}}/2 = 10^{50.5}$ GeV $\simeq 5.19 \times 10^{47}$ erg. From (14), we get $\eta \sim 8.7\%$. This efficiency is consistent with the previous studies by [33] and [42]. We can perform similar studies on the other five pulsars, whose results are listed in Table 3. A smaller η means it is easier for this pulsar to produce the same amount of positrons and electrons. The efficiency required by J1001-5507 or J1825-0935 is too large to satisfy the physics condition for single pulsar interpretation. Geminga, J1741-2054, Monogem and J0942-5552 are the only candidates which survive from our selection

J1001-5507	0.68	0.043	1.89	88
J1825-0935	4.6	0.082	5.09	120

Table 3: Electron injection efficiency η of the six nearby pulsars. For single pulsar interpretation of positron fraction, the results of Geminga, J1741-2054, Monogem and J0942-5552 are thought to be reasonable while the possibilities of J1001-5507 and J1825-0935 as the high energy positron sources can be excluded.

so far.²

5 Multiple pulsars interpretation

The extra high energy positrons may come from several pulsars. We perform similar study for multiple pulsars as we do for a single pulsar. Benefiting from the study in Section 4, we can assume that the spectral indices α of all the pulsars are the same. Considering the physical models of the pulsars are similar, we make another assumption that the electron injection efficiencies η are the same. These two assumptions help us reduce the number of free parameters. The discussion on η from single pulsar in Section 4 tells us that Geminga, J1741-2054 and Monogem will give a much larger contribution to the high energy positron than J0942-5552. In other words, the η of J0942-5552 in Table 3 is much larger than that of Geminga, which implies that the contribution from J0942-5552 in the multiple pulsars interpretation can be negligible compared with that from Geminga.

We choose three from the four “surviving” pulsars in the multiple pulsars discussion. The input parameters are the age T , the distance d and the energy loss rate \dot{E} of each pulsar while the parameters we get from the fit is the normalization factor of primary electron A_{prim,e^-} , the spectral index α and the electron injection efficiency η . As shown in Fig. 5 (a), we obtain a good result from the multiple pulsar fit where $\chi^2/\text{ndf} = 26.9/40$. The parameters we get are $A_{\text{prim},e^-} = 0.50$, $\alpha = 2.07$ and $\eta = 2.58\%$. The multiple pulsars interpretation predicts a positron fraction with

²Considering that the uncertainty of $\log_{10}(\frac{Q_0}{\text{GeV}})$ from the fit is ± 0.1 , the E_{out} for J1001-5507 is $1.89^{+0.44}_{-0.36} \times 10^{47} \text{ erg}$. Thus, $\eta = 88^{+21}_{-17} \%$ for J1001-5507. There is no enough strong evidence that this η is smaller than 1. One should also note that $\eta = 67^{+14}_{-12} \%$ for J0942-5552, which is 2σ smaller than 1.

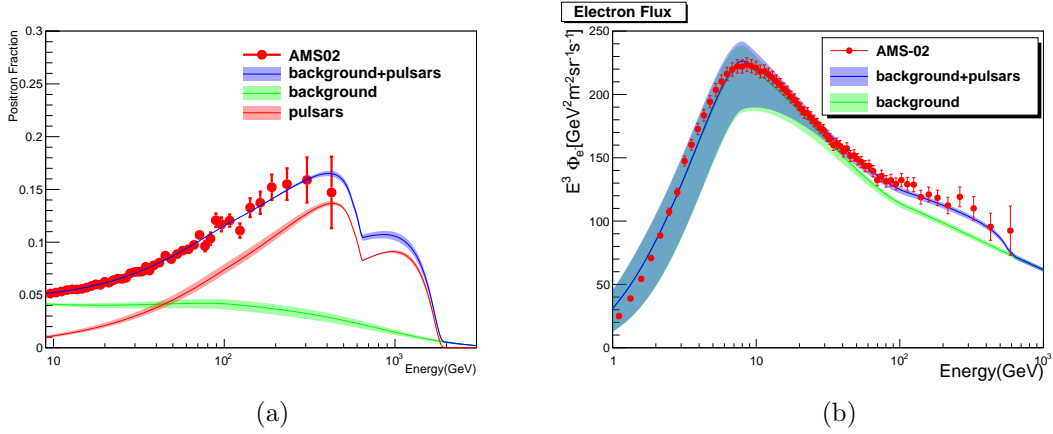

Figure 5: Three pulsars fit to the positron fraction is presented here as an example of multiple pulsars fit, as show in (a). Using the same parameters, (b) shows the fitted parameters from positron fraction reproduce the electron flux when the solar modulation potential 550 MV is applied here. The error band in (a) shows the variation of propagation parameters within 95% C.L., while that in (b) shows combined effect of propagation parameters and variation of solar modulation potential from 400 MeV to 800 MeV.

a decrease up to 600 GeV and after that a bump up to 2000 GeV, which is possible to be observed with more accumulating AMS-02 data.

Using the parameters from the fit, we can reproduce the electron flux measured by AMS-02 [2] in Fig. 5 (b). It shows that our electron background estimation in Section 2 + pulsar contribution matches the experimental data especially at high energies. Fig. 5 also shows that the effect of the uncertainty due to the propagation model is small at high energy. The solar modulation potential is taken as 550 MV in the best fit result. The solar modulation potential is varied between 400 MV and 800 MV to show that its effect on low energy is quite large. To reproduce the low energy electron flux more accurately, we need a monthly low energy electron fluxes, which may be published by AMS collaboration to model solar modulation.

6 Discussion and conclusion

In this work, we investigate the possibility that the rise of the positron fraction measured by AMS-02 can be explained by pulsars. The propagation parameters and the injection spectrums of nuclei and electrons are tuned according to the Boron-to-Carbon ratio and the proton flux. It will be better to tune those parameters with Boron-to-Carbon ratio and proton flux measured by AMS-02 since they are in the

same data taking period as the lepton fluxes. We find both the single pulsar model and the multiple pulsar model can explain the AMS-02 data very well. Six nearby pulsars are investigated as the single pulsar sources of the high energy positrons and finally four survive from all the conditions. The χ^2 s of these single pulsars in this work are much smaller than those in [21], mainly because we set the cut-off energy equals to 5000 GeV while the authors of [21] set it to 1000 GeV. With three mostly contributing pulsars, the multiple pulsars model predicts a positron fraction with a decrease up to 600 GeV and a bump up to 2000 GeV. For the low energy, a simple solar modulation potential can not explain the measurement well. Thus, we need the monthly electron fluxes which can describe solar activity during the whole period.

It is shown that the positron excess measured by AMS-02 can be explained by the pulsar scenario. Since the multiple pulsars can explain the experimental data well, it will be difficult to exclude pulsar scenario by isotropy. With accumulating AMS-02 data and future experiments, we can see the positron fraction behavior up to higher energy which will either confirm or reject the multiple pulsars scenario. If we consider other scenarios such as Dark Matter, we have to look into other productions, antiproton for instance, which have no contribution from pulsars.

A Solving the diffusion energy-loss equation

To fix the notation and for the pedagogical purpose, in this appendix we give a brief review on solving the diffusion energy-loss equation [30, 35, 38, 39, 42]. The diffusion energy-loss equation is given by

$$\left[\frac{\partial}{\partial t} - D(E)\nabla^2 - \frac{\partial}{\partial E}b(E) \right] f(\vec{x}, t, E) = Q(\vec{x}, t, E) \quad (20)$$

where $f(\vec{x}, t, E)$ is the particle number density per unit energy interval, $D(E) > 0$ is the diffusion coefficient, $b(E) \equiv -dE/dt > 0$ is the energy loss rate, and $Q(\vec{x}, t, E)$ is the source term.

A.1 Green function for the diffusion energy-loss equation

The Green function $G(\vec{x}, t, E; \vec{x}_0, t_0, E_0)$ of (20) is defined as

$$\left[\frac{\partial}{\partial t} - D(E)\nabla^2 - \frac{\partial}{\partial E}b(E) \right] G(\vec{x}, t, E; \vec{x}_0, t_0, E_0) = \delta^3(\vec{x} - \vec{x}_0)\delta(t - t_0)\delta(E - E_0) \quad (21)$$

The solution of (21) has been given in Ref. [66]. To fix the notation, let us briefly review the derivation. Define

$$\phi(\vec{x}, t, E; \vec{x}_0, t_0, E_0) \equiv b(E)G(\vec{x}, t, E; \vec{x}_0, t_0, E_0) \quad (22)$$

Substituting $G = \phi/b$ into (21) gives

$$\left[\frac{\partial}{\partial t} - b(E) \frac{\partial}{\partial E} - D(E) \nabla^2 \right] \phi(\vec{x}, t, E; \vec{x}_0, t_0, E_0) = b(E) \delta^3(\vec{x} - \vec{x}_0) \delta(t - t_0) \delta(E - E_0) \quad (23)$$

Let us make the variable transformation $(t, E) \rightarrow (t', \lambda)$ as follows,

$$t' \equiv t - \tau(E, E_0), \quad \text{with} \quad \tau(E, E_0) \equiv \int_E^{E_0} \frac{d\tilde{E}}{b(\tilde{E})} \quad (24)$$

$$\lambda(E, E_0) \equiv \int_E^{E_0} d\tilde{E} \frac{D(\tilde{E})}{b(\tilde{E})} \quad (25)$$

The Jacobian matrix of this transformation is easily obtained as

$$\frac{\partial(t', \lambda)}{\partial(t, E)} \equiv \begin{pmatrix} \frac{\partial t'}{\partial t} & \frac{\partial t'}{\partial E} \\ \frac{\partial \lambda}{\partial t} & \frac{\partial \lambda}{\partial E} \end{pmatrix} = \begin{pmatrix} 1 & \frac{1}{b(E)} \\ 0 & -\frac{D(E)}{b(E)} \end{pmatrix} \quad (26)$$

whose inverse is

$$\frac{\partial(t, E)}{\partial(t', \lambda)} \equiv \begin{pmatrix} \frac{\partial t}{\partial t'} & \frac{\partial t}{\partial \lambda} \\ \frac{\partial E}{\partial t'} & \frac{\partial E}{\partial \lambda} \end{pmatrix} = \begin{pmatrix} 1 & \frac{1}{D(E)} \\ 0 & -\frac{b(E)}{D(E)} \end{pmatrix} \quad (27)$$

Thus,

$$\frac{\partial}{\partial \lambda} = \frac{\partial t}{\partial \lambda} \frac{\partial}{\partial t} + \frac{\partial E}{\partial \lambda} \frac{\partial}{\partial E} = \frac{1}{D(E)} \left[\frac{\partial}{\partial t} - b(E) \frac{\partial}{\partial E} \right] \quad (28)$$

Substituting the relation $\partial_t - b(E)\partial_E = D(E)\partial_\lambda$ into (23) implies

$$\begin{aligned} \left(\frac{\partial}{\partial \lambda} - \nabla^2 \right) \phi &= \frac{b(E)}{D(E)} \delta^3(\vec{x} - \vec{x}_0) \delta(t - t_0) \delta(E - E_0) \\ &= \frac{b(E_0)}{D(E_0)} \delta^3(\vec{x} - \vec{x}_0) \delta(t - t_0) \delta(E - E_0) \end{aligned} \quad (29)$$

It follows from eq. (26) that

$$\det \left[\frac{\partial(t', \lambda)}{\partial(t, E)} \right] = -\frac{D(E)}{b(E)} \quad (30)$$

which implies

$$\begin{aligned}\delta(t - t_0)\delta(E - E_0) &= \left| \frac{D(E_0)}{b(E_0)} \right| \delta(t' - t_0)\delta(\lambda) \\ &= \frac{D(E_0)}{b(E_0)} \delta(t' - t_0)\delta(\lambda)\end{aligned}\quad (31)$$

where in the second equality we have used the properties: $D(E_0) > 0$ and $b(E_0) > 0$. Substituting (31) into (29), we obtain

$$\left(\frac{\partial}{\partial \lambda} - \nabla^2 \right) \phi = \delta(t' - t_0) \delta^3(\vec{x} - \vec{x}_0) \delta(\lambda) \quad (32)$$

As is well known, the Green function, which can be written as $G(\vec{x} - \vec{x}_0, \lambda)$ in the spherically asymmetric approximation, of the diffusion equation satisfies

$$\left(\frac{\partial}{\partial \lambda} - \nabla^2 \right) G(\vec{x} - \vec{x}_0, \lambda) = \delta^3(\vec{x} - \vec{x}_0) \delta(\lambda) \quad (33)$$

with $\lambda \geq 0$. The solution of (33) is

$$G(\vec{x} - \vec{x}_0, \lambda) = \frac{1}{(4\pi\lambda)^{3/2}} \exp \left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda} \right] \quad (34)$$

Comparing (32) with (33), we can read off the solution of ϕ as follows

$$\begin{aligned}\phi &= \delta(t' - t_0) \frac{1}{(4\pi\lambda)^{3/2}} \exp \left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda} \right] \\ &= \delta[t - t_0 - \tau(E, E_0)] \frac{1}{(4\pi\lambda)^{3/2}} \exp \left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda} \right]\end{aligned}\quad (35)$$

where in the second equality we have used (24). Thus, we finally get the solution of (21) as follows

$$G(\vec{x}, t, E; \vec{x}_0, t_0, E_0) = \frac{\phi}{b(E)} = \frac{\delta[t - t_0 - \tau(E, E_0)]}{b(E)[4\pi\lambda(E, E_0)]^{3/2}} \exp \left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda(E, E_0)} \right] \quad (36)$$

where the functions $\tau(E, E_0)$ and $\lambda(E, E_0)$ are defined in eqs. (24) and (25), respectively.

A.2 Solution for a burst-like source

Once we know the Green function, eq. (36), we can write down the solution of eq. (20) for a generic source as follows

$$f(\vec{x}, t, E) = \int d^3\vec{x}' dt' dE' G(\vec{x}, t, E; \vec{x}', t', E') Q(\vec{x}', t', E') \quad (37)$$

In particular, for a burst-like source, the source function is proportional to $\delta^3(\vec{x} - \vec{x}_0)\delta(t - t_0)$, that is,

$$Q(\vec{x}, t, E) = Q(E)\delta^3(\vec{x} - \vec{x}_0)\delta(t - t_0) \quad (38)$$

where $Q(E)$ is an arbitrary function of E , \vec{x}_0 is the position of the source, and t_0 is the instantaneous time when the source bursts. Substituting eqs. (36) and (38) into eq. (37), we obtain

$$\begin{aligned} f(\vec{x}, t, E) &= \int d^3\vec{x}' dt' dE' \frac{\delta[t - t' - \tau(E, E')]}{b(E)[4\pi\lambda(E, E')]^{3/2}} \exp\left[-\frac{(\vec{x} - \vec{x}')^2}{4\lambda(E, E')}\right] Q(E')\delta^3(\vec{x}' - \vec{x}_0)\delta(t' - t_0) \\ &= \int dE' \frac{\delta[t - t_0 - \tau(E, E')]}{b(E)[4\pi\lambda(E, E')]^{3/2}} \exp\left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda(E, E')}\right] Q(E') \end{aligned} \quad (39)$$

Denote the solution of the equation

$$0 = t - t_0 - \tau(E, E') = t - t_0 - \int_E^{E'} \frac{d\tilde{E}}{b(\tilde{E})} \quad (40)$$

is $E' = E_0$, then we have

$$\delta[t - t_0 - \tau(E, E')] = b(E_0)\delta(E' - E_0) \quad (41)$$

where we have used

$$\left| \frac{d\tau}{dE'} \right|_{E'=E_0} \delta[t - t_0 - \tau(E, E')] = \delta(E' - E_0) \quad (42)$$

Substituting eq. (41) into eq. (39), we have

$$\begin{aligned} f(\vec{x}, t, E) &= \int dE' \frac{b(E_0)\delta(E' - E_0)}{b(E)[4\pi\lambda(E, E')]^{3/2}} \exp\left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda(E, E')}\right] Q(E') \\ &= \frac{Q(E_0)}{[4\pi\lambda(E, E_0)]^{3/2}} \frac{b(E_0)}{b(E)} \exp\left[-\frac{(\vec{x} - \vec{x}_0)^2}{4\lambda(E, E_0)}\right] \end{aligned} \quad (43)$$

where the initial energy E_0 is defined as the solution of eq. (40). In other words, if we know $t - t_0$ and E , we can find E_0 by solving the equation

$$t - t_0 = \tau(E, E_0) = \int_E^{E_0} \frac{d\tilde{E}}{b(\tilde{E})} \quad (44)$$

Define the diffusion distance r_{dif} as

$$r_{\text{dif}}(E, E_0) \equiv \sqrt{4\lambda(E, E_0)} = 2\sqrt{\int_E^{E_0} d\tilde{E} \frac{D(\tilde{E})}{b(\tilde{E})}} \quad (45)$$

we can rewrite eq. (43) as

$$f(\vec{x}, t, E) = \frac{Q(E_0)}{\pi^{\frac{3}{2}} r_{\text{dif}}^3} \frac{b(E_0)}{b(E)} \exp\left(-\frac{r^2}{r_{\text{dif}}^2}\right) \quad (46)$$

with $r^2 \equiv (\vec{x} - \vec{x}_0)^2$.

A.3 Solution for a burst-like source with power-law spectrum

Consider the case when the function $Q(E)$ in eq. (38) is a power-law function, that is,

$$Q(E) = Q_0 E^{-\alpha} \exp\left(-\frac{E}{E_{\text{cut}}}\right) \quad (47)$$

where Q_0 is a normalization constant, α is the spectral index, and E_{cut} is the cutoff energy. The diffusion coefficient $D(E)$ and the energy loss rate $b(E)$ are assumed to take the form

$$D(E) = \beta D_0 \left(\frac{E}{E_0}\right)^\delta \quad (48)$$

$$b(E) = b_0 E^2 \quad (49)$$

where $\beta \equiv v/c$ is the ratio of velocity to speed of light, the constant D_0 and the index δ can be figured out by the background fitting in Sec. 2, the constant b_0 is given in Sec. 3, and E_0 should be determined by eq. (44).

Let us calculate the initial energy E_0 first. Denote the diffusion time $t_{\text{dif}} \equiv t - t_0$. It follows from eqs. (44) and (49) that

$$t_{\text{dif}} = \int_E^{E_0} \frac{d\tilde{E}}{b_0 \tilde{E}^2} = \frac{1}{b_0} \left(\frac{1}{E} - \frac{1}{E_0}\right) \quad (50)$$

which implies

$$\frac{1}{E} - \frac{1}{E_0} = b_0 t_{\text{dif}} \quad (51)$$

from which, we see $\frac{1}{E} > b_0 t_{\text{dif}}$, that is, $E < \frac{1}{b_0 t_{\text{dif}}}$. Denote $E_{\text{max}} \equiv 1/(b_0 t_{\text{dif}})$, then

$$\frac{1}{E} - \frac{1}{E_0} = \frac{1}{E_{\text{max}}} \quad (52)$$

which gives

$$E_0 = \frac{E E_{\text{max}}}{E_{\text{max}} - E} \quad (53)$$

Thus, we obtain the following pieces in eq. (46):

$$\begin{aligned} Q(E_0) &= Q_0 E_0^{-\alpha} \exp\left(-\frac{E_0}{E_{\text{cut}}}\right) = Q_0 \left(\frac{E E_{\text{max}}}{E_{\text{max}} - E}\right)^{-\alpha} \exp\left(-\frac{E E_{\text{max}}}{E_{\text{cut}}(E_{\text{max}} - E)}\right) \\ &= Q_0 E^{-\alpha} \left(1 - \frac{E}{E_{\text{max}}}\right)^{\alpha} \exp\left[-\frac{E/E_{\text{cut}}}{(1 - E/E_{\text{max}})}\right] \end{aligned} \quad (54)$$

$$\frac{b(E_0)}{b(E)} = \frac{E_0^2}{E^2} = \left(1 - \frac{E}{E_{\text{max}}}\right)^{-2} \quad (55)$$

Substituting eqs. (54) and (55) into eq. (46), we obtain

$$f(\vec{x}, t, E) = \frac{Q_0 E^{-\alpha}}{\pi^{\frac{3}{2}} r_{\text{dif}}^3} \left(1 - \frac{E}{E_{\text{max}}}\right)^{\alpha-2} \exp\left[-\frac{E/E_{\text{cut}}}{(1 - E/E_{\text{max}})} - \frac{r^2}{r_{\text{dif}}^2}\right] \quad (56)$$

which is consistent with previous works (for example, eq. (6) of Ref. [42]).

Now let us figure out the diffusion distance r_{dif} . To this end, we substitute eqs. (48) and (49) into eq. (25), and get

$$\begin{aligned} \lambda(E, E_0) &= \int_E^{E_0} d\tilde{E} \frac{\beta D_0 \left(\frac{\tilde{E}}{E_0}\right)^{\delta}}{b_0 \tilde{E}^2} = \frac{\beta D_0}{E_0^{\delta} b_0} \int_E^{E_0} d\tilde{E} \tilde{E}^{\delta-2} \\ &= \frac{\beta D_0}{E_0^{\delta} b_0 (\delta - 1)} (E_0^{\delta-1} - E^{\delta-1}) \end{aligned} \quad (57)$$

which can also be written as

$$\lambda(E, E_0) = \beta D_0 \left(\frac{E}{E_0}\right)^{\delta} \frac{t_{\text{dif}}}{b_0 t_{\text{dif}} (\delta - 1)} \frac{1}{E} \left[\left(\frac{E_0}{E}\right)^{\delta-1} - 1 \right] \quad (58)$$

Comparing the above equation with eq. (48), $E_{\text{max}} \equiv 1/(b_0 t_{\text{dif}})$ and $E_0/E = (1 - E/E_{\text{max}})^{-1}$, we obtain

$$\lambda(E, E_0) = \frac{D(E) t_{\text{dif}} E_{\text{max}}}{(1 - \delta) E} \left[1 - \left(1 - \frac{E}{E_{\text{max}}}\right)^{1-\delta} \right] \quad (59)$$

Thus, the diffusion distance r_{dif} is given by

$$r_{\text{dif}} \equiv 2\sqrt{\lambda(E, E_0)} = 2\sqrt{\frac{D(E) t_{\text{dif}} E_{\text{max}}}{(1 - \delta) E} \left[1 - \left(1 - \frac{E}{E_{\text{max}}}\right)^{1-\delta} \right]} \quad (60)$$

which is consistent with previous works (for example, eq. (10) of Ref. [33] and eq. (7) of Ref. [42]).

Acknowledgments
