Partial resampling to approximate covering integer programs∗

Antares Chen† David G. Harris‡ Aravind Srinivasan§

Abstract

We consider column-sparse covering integer programs, a generalization of set cover, which have attracted a long line of research developing (randomized) approximation algorithms. We develop a new rounding scheme based on the Partial Resampling variant of the Lovász Local Lemma developed by Harris & Srinivasan (2013).

This achieves an approximation ratio of $1 + \frac{\ln(\Delta_1 + 1)}{a_{\text{min}}} + O \left( \log(1 + \sqrt{\log(\Delta_1 + 1) / a_{\text{min}}}) \right)$, where $a_{\text{min}}$ is the minimum covering constraint and $\Delta_1$ is the maximum $\ell_1$-norm of any column of the covering matrix (whose entries are scaled to lie in $[0, 1]$). When there are additional constraints on the sizes of the variables, we show an approximation ratio of $\ln \Delta_0 + O(\log \log \Delta_0)$ (where $\Delta_0$ is the maximum number of non-zero entries in any column of the covering matrix). We also show nearly-matching inapproximability and integrality-gap lower bounds. These results improve asymptotically, in several different ways, over results shown by Srinivasan (2006) and Kolliopoulos & Young (2005).

We show also that the rounding process leads to negative correlation among the variables. This allows us to automatically handle multi-criteria programs, efficiently achieving approximation ratios which are essentially equivalent to the single-criterion case and apply even when the number of criteria is large.

1 Introduction

We consider covering integer programs (CIPs), which are defined as follows (with $\mathbb{Z}_+$ denoting the set of non-negative integers). There are solution variables $x_1, \ldots, x_n \in \mathbb{Z}_+$, and for $k = 1, \ldots, m$, a system of $m$ covering constraints of the form:

$$\sum_i A_{ki} x_i \geq a_k$$

Here, each $A_k$ is an $n$-long non-negative vector; by scaling, we can assume that $A_{ki} \in [0, 1]$ and $a_k \geq 1$. We can write this more compactly as $A_k \cdot x \geq a_k$, and we also write $Ax \geq a$ if $A_k \cdot x \geq a_k$ for all $k$. We let $N$ denote the total number of non-zero entries in $A$; in general, we can store and process $A$ in $O(N)$ time.

∗ A preliminary version of this paper appeared in the proceedings of the Symposium on Discrete Algorithms (SODA) 2016.

We may optionally have constraints on the size of the solution variables, namely, that we require
\[ x_i \in \{0, 1, \ldots, d_i\}; \] these are referred to as the multiplicity constraints. Finally, we have some linear
objective function, represented by a vector \( C \in [0, \infty)^n \). Our goal is to minimize \( C \cdot x \), subject to
the multiplicity and covering constraints.

This generalizes the set cover problem, which can be viewed as a special case with \( a_k = 1, A_{ki} \in \{0, 1\} \). Solving set cover or integer programs exactly is NP-hard [15], so a common strategy is to
obtain a solution which is approximately optimal. There are at least three ways one may obtain
an approximate solution, where OPT denotes the optimal solution-value for the given instance:

1. the solution \( x \) may violate the optimality constraint, that is, \( C \cdot x \geq \text{OPT} \);
2. \( x \) may violate the multiplicity constraint: i.e., \( x_i > d_i \) for some \( i \);
3. \( x \) may violate the covering constraints: i.e., \( Ax \not\geq a \).

These three criteria are in competition. For our purposes, we will demand that our solution \( x \)
completely satisfies the covering constraints. We will seek to satisfy the multiplicity constraints
and optimality constraint as closely as possible. Our emphasis will be on the optimality constraints,
that is, we seek to ensure that
\[ C \cdot x \leq \beta \times \text{OPT} \]
where \( \beta \geq 1 \) is minimized. The parameter \( \beta \) is referred to as the approximation ratio. More
precisely, we will derive a randomized algorithm with the goal of satisfying \( \mathbb{E}[C \cdot x] \leq \beta \times \text{OPT} \),
where the expectation is taken over our algorithm’s randomness.

Many approximation algorithms for set cover and its extensions give approximation ratios as a
function of \( m \), the total number of constraints: e.g., it is known that the greedy algorithm has
approximation ratio \((1 - o(1)) \ln m \) [21]. We often prefer a scale-free approximation ratio, that
does not depend on the problem size but only on its structural properties. Two cases that are
of particular interest are when the matrix \( A \) is row-sparse (a bounded number of variables per
constraint) or column-sparse (each variable appears in a bounded number of constraints). We will
be concerned solely with the column-sparse setting in this paper. The row-sparse setting, which
generalizes problems such as vertex cover, typically leads to very different types of algorithms than
the column-sparse setting.

Two common parameters used to measure the column sparsity of such systems are the maximum
\( \ell_0 \) and \( \ell_1 \)-norms of the columns; that is,
\[ \Delta_0 = \max_i \#k : A_{ki} > 0, \quad \Delta_1 = \max_i \sum_k A_{ki} \]
Since the entries of \( A \) are in \([0, 1]\), we have \( \Delta_1 \leq \Delta_0 \); it is also possible that \( \Delta_1 \ll \Delta_0 \).

Approximation algorithms for column-sparse CIPs typically yield approximation ratios which are
a function of \( \Delta_0 \) or \( \Delta_1 \), and possibly other problem parameters as well. These algorithms fall into
two main classes. First, there are greedy algorithms which start by setting \( x = 0 \), then increment
\( x_i \) where \( i \) is chosen in some manner which “looks best” in a myopic way for the residual problem.
These were first developed by [6, 14, 18] for set cover, and later analysis (see [9]) showed that they
give essentially optimal approximation ratios for set cover. These were extended to CIP in [10] to
show an approximation ratio of $1 + \ln \Delta_0$, and by [7] to get approximation ratio $1 + \ln \Delta_1$. These greedy algorithms are often powerful, but are somewhat rigid. In addition, greedy algorithms do not yield “oblivious” approximation ratios — that is, they can only operate with knowledge of the objective function.

An alternative, and often more flexible, class of approximation algorithms is based on linear relaxation. There are a number of possible linear relaxations, but the simplest is one which we refer to as the basic LP. This LP has the same covering constraints as the original CIP, but replaces the constraint $x_i \in \{0, 1, \ldots, d_i\}$ with the weaker constraint $x_i \in [0, d_i]$. The set of feasible points to the basic LP is a polytope, and one can find its exact optimal fractional solution $\hat{x}$. As this is a relaxation, $C \cdot \hat{x} \leq \text{OPT}$. It thus suffices to turn the solution $\hat{x}$ into a random integral solution $x$ satisfying $E[C \cdot x] \leq \beta(C \cdot \hat{x})$. We will also see some stronger LP formulations, such as the Knapsack-Cover (KC) inequalities.

These linear relaxations can be solved using general-purpose LP solvers, or faster, specialized algorithms tailored for CIP (such as [4, 25, 26]). Alternatively, in some cases the basic LP has a generic solution, for example by setting $x$ to be a constant vector. We will mostly ignore the issue of how to solve the linear relaxation, and focus in this paper on how to transform it into an integral solution. Randomized rounding is often employed for this step. The simplest scheme, first applied to this context by [20], is to simply draw $x_i$ as independent Bernoulli($\alpha \hat{x}_i$), for some $\alpha > 1$. When this is used, simple analysis using Chernoff bounds shows that this yields a solution $x$ such that $C \cdot x$ is within a factor of $1 + O\left(\frac{\log m}{a_{\min}} + \sqrt{\frac{\log m}{a_{\min}}} \right)$ from the optimum, where $a_{\min} = \min_k a_k \geq 1$.

As is typical of randomized rounding algorithms, the conversion from the fractional to the integral solution does not depend on the specific objective function; in this sense, it is “oblivious”, yielding a good expected value for any objective function.

In [22], Srinivasan gave a scale-free method of randomized rounding (ignoring multiplicity constraints), based on the FKG inequality and some proof ideas behind the Lovász Local Lemma (LLL). This gave an approximation ratio of $1 + O\left(\frac{\log(\Delta_0 + 1)}{a_{\min}} + \sqrt{\frac{\log a_{\min}}{a_{\min}}} + \frac{\log(\Delta_0 + 1)}{a_{\min}}\right)$. The rounding scheme, by itself, only gave a positive (exponentially small) probability of achieving the desired approximation ratio. The algorithm of [22] also included a polynomial-time derandomization using the method of conditional expectations; this derandomization however requires knowledge of the objective function.

The algorithm of Srinivasan can potentially cause a large violation in the multiplicity constraints. In [16], Kolliopoulos & Young considered how to adapt the algorithm of [22] to respect the multiplicity constraints. They gave two algorithms, which offer different types of approximation ratios. The first algorithm takes parameter $\epsilon \in (0, 1]$, violates each multiplicity constraint “$x_i \leq d_i$” to at most “$x_i \leq \lceil (1 + \epsilon)d_i \rceil$”, and has approximation ratio of $O\left(1 + \frac{\log(\Delta_0 + 1)}{a_{\min} + \epsilon^2}\right)$. We refer to this situation as $\epsilon$-respecting multiplicity. The second algorithm meets the multiplicity constraints exactly and achieves approximation ratio $O(1 + \log \Delta_0)$.

1.1 Our contributions

In this paper, we give new randomized rounding schemes, based on the partial resampling variant of the LLL developed in [12] and some proof ideas developed in [11] for the LLL applied to systems
of correlated constraints. (See Appendix A for a more detailed comparison between this algorithm and the LLL). The approximation ratio for our algorithms will typically depend on a key parameter $\gamma$, which we define as

$$\gamma = \frac{\ln(\Delta_1 + 1)}{a_{\min}}$$

We show the following result:

**Theorem 1.1.** Let $\hat{x}$ be a fractional solution for the basic LP. Our randomized algorithm runs in expected time $O(N)$, and generates a solution $x \in \mathbb{Z}_+^n$ satisfying the covering constraints with probability one, and with

$$E[x_i] \leq \hat{x}_i(1 + \gamma + 10\ln(1 + \sqrt{\gamma}))$$

This automatically implies that $E[C \cdot x] \leq \beta C \cdot \hat{x} \leq \beta \times \text{OPT}$ for $\beta = 1 + \gamma + 10\ln(1 + \sqrt{\gamma})$. Our algorithm has several advantages over previous techniques.

1. We get approximation ratios in terms of $\Delta_1$, the maximum $\ell_1$-norm of the columns of $A$.
2. When $\Delta_1$ is small, our approximation ratios is asymptotically smaller than that of [22]. In particular, we avoid the $\sqrt{\frac{\log a_{\min}}{a_{\min}}}$ term in our approximation ratio.
3. When $\Delta_1$ is large, then our approximation ratio is roughly $\gamma$; this is asymptotically optimal (including having the correct coefficient), and improves on [22].
4. This algorithm is quite efficient, essentially as fast as reading in the matrix $A$.
5. The algorithm is oblivious to the objective function — although it achieves a good approximation factor for any objective $C$, the algorithm itself does not use $C$ in any way.

Our partial resampling algorithm in its simplest form could significantly violate the multiplicity constraints. We can modify it so that multiplicity constraints are satisfied or nearly-satisfied, at the cost of a worsened approximation ratio. These results, which improve in all cases over the corresponding approximation ratios of [16], are summarized as follows;

**Theorem 1.2.** There is a randomized algorithm running in expected polynomial time, yielding a solution $x \in \mathbb{Z}_+^n$ which satisfies the covering constraints, multiplicity constraints, and has

$$C \cdot x \leq (\ln \Delta_0 + O(\log \log \Delta_0))\text{OPT}$$

**Theorem 1.3.** Let $\hat{x}$ be a fractional solution for the basic LP. For any given $\epsilon \in (0, 1]$, our algorithm yields a solution $x \in \mathbb{Z}_+^n$ satisfying the covering constraints with probability one, and with

$$x_i \leq \lceil \hat{x}_i(1 + \epsilon) \rceil, \quad E[x_i] \leq \hat{x}_i(1 + \epsilon + 4\gamma/\epsilon)$$

There are many ways of parameterizing CIP’s; we have chosen to focus on the parameters such as the minimum RHS value $a_{\min}$, the maximum $\ell_1$-column norm $\Delta_1$, and most importantly the ratio $\ln(\Delta_1 + 1)/a_{\min}$. We show a number of nearly-matching lower bounds, which demonstrate that our approximation ratios cannot be significantly improved without changing their functional form or taking account of further information about the underlying CIP system. The formal statements of these results contain numerous qualifiers and technical conditions, but we summarize these here.
1. When $\Delta_0$ is large, then any polynomial-time algorithm to solve the CIP while respecting multiplicity constraints must have approximation ratio $\ln \Delta_0 - O(\log \log \Delta_0)$.

2. An algorithm for CIP without multiplicity constraints, whose approximation ratio is a function $f(\gamma)$, must have $f(\gamma) \geq \max(\gamma, 1 + \gamma/2)$.

3. For large $\gamma$, the integrality gap between the basic LP and integral solutions which $\epsilon$-respect multiplicity, is of order $\Omega(\gamma/\epsilon)$.

4. The basic LP has integrality gap $\max(\gamma, 1 + \gamma/2)$.

Finally, we show that the values of $x_i$ generated by our algorithm have a form of negative correlation. Thus, sums of the form $C \cdot x$ will be concentrated. This property means that we can solve CIP instances with multiple objective functions $C_1, \ldots, C_r$ “for free” — due to concentration, each $\ell$ satisfies $C_\ell \cdot x \approx C_\ell \cdot \hat{x}$ with high probability and in particular there is a good probability that $C_\ell \cdot x \approx C_\ell \cdot \hat{x}$ simultaneously for all $\ell$.

**Theorem 1.4** (Informal). Suppose that a CIP instance with fractional solution $\hat{x}$ has $r$ objective functions $C_1, \ldots, C_r$, whose entries are in $[0, 1]$ and such that $C_\ell \cdot \hat{x} \geq \Omega(\log r)$ for all $\ell = 1, \ldots, r$. Then our algorithm generates a solution $x$ satisfying the covering constraints with probability one with probability at least $1/2$ satisfies

$$\forall \ell \quad C_\ell \cdot x \leq \beta(C_\ell \cdot \hat{x}) + O(\sqrt{\beta(C_\ell \cdot \hat{x})} \log r)$$

where $\beta = 1 + \gamma + 10 \ln(1 + \sqrt{\gamma})$.

We find it interesting that one can “boil down” the parameters $\Delta_1, a_{\text{min}}$ into a single parameter $\gamma$, which seems to completely determine the behavior of our rounding algorithms.

### 1.2 Outline

In Section 2 we develop a randomized rounding algorithm, which generates a binary vector $x \in \{0, 1\}^n$ so that $E[x_i] \approx \alpha \hat{x}_i$ where $\hat{x}$ is a solution to the basic LP and $\alpha$ is a parameter which is chosen appropriately. The basic form of this algorithm only works if the entries of $\hat{x}$ are small; by using a deterministic quantization scheme, we then extend it to arbitrary values of $x_i$.

In Section 3 we simplify our approximation ratios for CIP without multiplicity constraints in terms of two key parameters: a lower bound $a_{\text{min}}$ on the RHS values $a_k$, and an upper bound $\Delta_1$ on the $\ell_1$-norm of the columns of $A$. These parameters are somewhat traditional in the analysis of CIP rounding.

In Section 4 we extend these results to respect the multiplicity constraint. This requires parameterizing in terms of $\Delta_0$, and uses a stronger LP than the basic LP.

In Section 5 we construct a variety of lower bounds on achievable approximation ratios. These are based on integrality gaps as well as hardness results, and show that the approximation ratios developed in Section 3 are essentially optimal for most values of $\epsilon$ and $\ln(\Delta_1 + 1)/a_{\text{min}}$ (particularly when $\ln(\Delta_1) \gg a_{\text{min}}$).
In Section 6 we show that our randomized rounding scheme obeys a negative correlation property. This allows us to show concentration bounds on the sizes of the objective functions $C_\ell \cdot x$, which in turn allows us to give approximation schemes in the presence of multiple objective functions.

## 2 The rounding algorithm

We first consider, in Section 2.1, the case when all the values of $\hat{x}$ are small; this will turn out to be the critical case for understanding the overall algorithm. Section 2.2 will demonstrate how to extend our analysis to arbitrary values of $\hat{x}$.

### 2.1 The case when all entries of $\hat{x}$ are small

For the purposes of Section 2.1, we assume that $\sigma \in [0, 1]$ and $\alpha > 1$ are given parameters, which we will discuss how to set later on. We also assume that $\hat{x} \in [0, 1/\alpha]^n$ and $A \cdot \hat{x} \geq a$. Under these assumptions, we use Algorithm 1, named RELAXATION:

**Algorithm 1** The RELAXATION algorithm

```
1: function RELAXATION($\hat{x}, A, a, \sigma, \alpha$)
2: for $i = 1, \ldots, n$ do
3:     $x_i \sim Bernoulli(\alpha \hat{x}_i)$
4: while $A \cdot x \ngeq a$ do $\triangleright$ The covering constraints are not all satisfied
5:     Let $k$ be minimal such that $A_k \cdot x < a_k$
6:     for $i$ from 1, $\ldots$, $n$ do
7:         if $x_i = 0$ then $x_i \sim Bernoulli(\sigma A_k \alpha \hat{x}_i)$
8: return $x$
```

The RELAXATION algorithm only increments the variables $x_i$. When a constraint is satisfied, it remains satisfied until the end of the algorithm. This implies that RELAXATION terminates with probability one. The key technical issue is to bound the probability that $x_i = 1$ at the conclusion of the RELAXATION algorithm.

**Theorem 2.1.** Let $\hat{x} \in [1, 1/\alpha]^n$ satisfy $A \cdot \hat{x} \geq a$ for parameters $\sigma \in [0, 1], \alpha > -\frac{\ln(1-\sigma)}{\sigma}$. Then for any $i \in [n]$, the probability that $x_i = 1$ at the conclusion of the RELAXATION algorithm is at most

$$P(x_i = 1) \leq \alpha \hat{x}_i \left(1 + \sigma \sum_k e^{\sigma A_k \hat{x} (1 - \sigma)^{A_{k_i}} - 1}\right)$$

We will need many intermediate results and analyses before we prove this theorem.

Whenever we encounter an unsatisfied constraint $k$ and draw new values for the variables (lines 6–7), we refer to this as resampling the constraint $k$. There is an alternative way of looking at the resampling procedure, which seems counter-intuitive but will be crucial for our analysis. Instead
of setting each variable \(x_i = 1\) with probability \(\sigma A_k i \alpha \hat{x}_i\), we instead select a subset \(Y \subseteq [n]\), where each \(i\) currently satisfying \(x_i = 0\) goes into \(Y\) independently with probability \(\sigma A_k i\). Then, for each variable \(i \in Y\), we draw \(x_i \sim \text{Bernoulli}(\alpha \hat{x}_i)\). It is clear that this two-part sampling procedure is equivalent to Algorithm 1. In this interpretation, we say that \(Y\) is the resampled set for constraint \(k\). If \(i \in Y\) we say that variable \(i\) is resampled in an iteration.

Throughout this section, we define \(p_i = \alpha \hat{x}_i\) and \(q_i = 1 - p_i\). Our assumption on the size of \(\hat{x}\) implies that \(p_i \in [0, 1]\).

**Lemma 2.2.** Let \(Z_1, \ldots, Z_j\) be subsets of \([n]\). The probability that the first \(j\) resampled sets for constraint \(k\) are respectively \(Z_1, \ldots, Z_j\) is at most \(\prod_{\ell=1}^j f_k(Z_{\ell})\), where we define

\[
f_k(Z) = (1 - \sigma)^{-a_k} \left( \prod_{i \in [n] - Z} 1 - A_{ki} \sigma \right) \left( \prod_{i \in Z} q_i A_{ki} \sigma \right)
\]

**Proof.** For any integer \(T \geq 0\), any integer \(j \geq 0\), any sets \(Z_1, \ldots, Z_j \subseteq [n]\) and any vector \(v \in \{0, 1\}^n\), we define the following random process and the following event \(E(T, j, Z_1, \ldots, Z_j, v)\): Suppose that instead of drawing \(x \sim \text{Bernoulli}(\alpha \hat{x}_i)\) as in line 3 of RELAXATION, we set \(x = v\), and we continue the remaining steps of the RELAXATION algorithm (lines 4–8) until done. We say that, in this process, event \(E(T, j, Z_1, \ldots, Z_j, v)\) has occurred if:

1. There are less than \(T\) total resamplings,
2. There are at least \(j\) resamplings of constraint \(k\),
3. The first \(j\) resampled sets for constraint \(k\) are respectively \(Z_1, \ldots, Z_j\).

We claim now that for any \(Z_1, \ldots, Z_j\), and \(v \in \{0, 1\}^n\), and any integer \(T \geq 0\), we have

\[
P(E(T, j, Z_1, \ldots, Z_j, v)) \leq \frac{\prod_{\ell=1}^j f_k(Z_{\ell})}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i}
\]  
(1)

We shall prove (1) by induction on \(T\). For the base case \((T = 0)\) this is trivially true, because \(E(T, j, Z_1, \ldots, Z_j, v)\) is impossible (there must be at least 0 resamplings), and so the LHS of (1) is zero while the RHS is non-negative. We move on to the induction step.

If \(Av \geq \alpha\), then the RELAXATION algorithm performs no resamplings. Thus, if \(j \geq 1\), then event \(E(T, j, Z_1, \ldots, Z_j, v)\) is impossible and again (1) holds. On the other hand, if \(j = 0\), then the RHS of (1) is equal to one, and again this holds vacuously. So we suppose \(Av \leq \alpha\) and \(j \geq 1\); let \(k'\) be minimal such that \(A_{k'} v < a_{k'}\). Then the first step of RELAXATION is to resample constraint \(k'\).

We observe that if \(v_i = 1\) for any \(i \in Z_1 \cup \cdots \cup Z_j\), then the event \(E(T, j, Z_1, \ldots, Z_j, v)\) is impossible. The reason for this is that we only resample variables which are equal to zero; thus variable \(i\) can never be resampled for the remainder of the RELAXATION algorithm. In particular, we will never have \(i\) in any resampled set. Thus, as \(i \in Z_1 \cup \cdots \cup Z_j\), it is impossible for \(Z_1, \ldots, Z_j\) to eventually be the resampled sets for constraint \(k\). So if \(v_i = 1\) for any \(i \in Z_1 \cup \cdots \cup Z_j\) then (1) holds vacuously. Let us assume that \(v_i = 0\) for all \(i \in Z_1 \cup \cdots \cup Z_j\).
Let $x'$ denote the value of the variables after the first resampling ($x'$ is a random variable). Then we observe that the remaining steps of the RELAXATION algorithm are equivalent to what would have occurred if we had set $x = x'$ initially.

Now, suppose that $k' \neq k$. Then after the first resampling, the event $E(T, j, Z_1, \ldots, Z_j, v)$ becomes equivalent to the event $E(T - 1, j, Z_1, \ldots, Z_j, x')$. By our inductive hypothesis, if we condition on a fixed value of $x'$ we have

$$P(E(T, j, Z_1, \ldots, Z_j, v) | x') = P(E(T - 1, j, Z_1, \ldots, Z_j, x')) \leq \frac{\prod_{i=1}^j f_k(Z_i)}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i}.$$ 

Integrating out $x'$, we thus have

$$P(E(T, j, Z_1, \ldots, Z_j, v)) \leq \frac{\prod_{i=1}^j f_k(Z_i)}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i}.$$

Next, suppose that $k = k'$. Observe that the following are necessary events for $E(T, j, Z_1, \ldots, Z_j, v)$:

(A1) $Y = Z_1$, where $Y$ is the first resampled set for constraint $k' = k$.

(A2) For any $i \in Z_1 \cap (Z_2 \cup \cdots \cup Z_j)$, in the first resampling step (which includes variable $i$), we draw $x_i = 0$.

(A3) $E(T - 1, j - 1, Z_2, Z_3 \ldots, Z_j, x')$

The condition (A2) follows from the observation, made earlier, that $E(T - 1, j - 1, Z_2, Z_3 \ldots, Z_j, x')$ is impossible if $x'_i = 1$ but $i \in Z_2 \cup \cdots \cup Z_j$. Any such $i \in Z_1$ must be resampled (due to condition (A1)), and it must be resampled to become equal to zero.

Let us first bound the probability of the condition (A1). Since $v_i = 0$ for all $i \in Z_1$, we have

$$P(Y = Z_1) = \left( \prod_{i \in Z_1} A_{k_i} \right) \left( \prod_{i \notin Z_1, v_i = 0} (1 - A_{k_i}) \right) = \prod_{i \in [n] - Z_1} (1 - A_{k_i}) \prod_{i \in Z_1} A_{k_i} \prod_{i = 1} (1 - A_{k_i})^{-1}.$$

By definition of $k'$, we have $A_k v < a_k$ and so $\prod_{i:v_i=1} (1 - A_{k_i})^{-1} \leq (1 - \sigma)^{-a_k}$, further implying:

$$P(Y = Z_1) \leq (1 - \sigma)^{-a_k} \prod_{i \in [n] - Z_1} (1 - A_{k_i}) \prod_{i \in Z_1} A_{k_i} \sigma. \quad (2)$$

Next, let us consider the probability of (A2). For each $i \in Y$ we draw $x_i \sim \text{Bernoulli}(p_i)$; thus, the total probability of event (A2), conditional on (A1), is at most $\prod_{i \in Z_1 \cap (Z_2 \cup \cdots \cup Z_j)} q_i$.

Finally, let us consider the probability of event (A3), conditional on (A1) and (A2). The event $E(T - 1, j - 1, Z_2, Z_3 \ldots, Z_j, x')$ is conditionally independent of events (A1) and (A2), given $x'$. We
integrate over \( x' \) and use the induction hypothesis to get:

\[
P((A3) \mid (A1), (A2)) = \sum_{v' \in \{0,1\}^n} P(\mathcal{E}(T - 1, j - 1, Z_2, \ldots, Z_j, v') P(x' = v')
\leq \sum_{v' \in \{0,1\}^n} \frac{\prod_{\ell=2}^k f_k(Z_{\ell})}{\prod_{i \in Z_2 \cup \cdots \cup Z_j} q_i}
\]

As (A1), (A2), and (A3) are necessary conditions for \( \mathcal{E}(T, j, Z_1, \ldots, Z_j, v) \), this shows that

\[
P(\mathcal{E}(T, j, Z_1, \ldots, Z_j, v)) \leq (1 - \sigma)^{-a_k} \prod_{i \in [n] - Z_1} (1 - A_{ki}) \prod_{i \in Z_1} A_{ki} \prod_{i \in Z_1 \cap (Z_2 \cup \cdots \cup Z_j)} q_i \times \prod_{i \in Z_2 \cup \cdots \cup Z_j} q_i
f_k(Z_1) \times \frac{\prod_{\ell=2}^k f_k(Z_{\ell})}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i}
\]

and the induction claim again holds.

Thus, we have shown that (i) holds for any integer \( T \geq 0 \), sets \( Z_1, \ldots, Z_j \), and \( v \in \{0, 1\}^n \). Next, for any sets \( Z_1, \ldots, Z_j \) and \( v \in \{0, 1\}^n \), let us define the event \( \mathcal{E}(j, Z_1, \ldots, Z_j, v) \) to be the event that, if we start the RELAXATION algorithm with \( x = v \), then the first \( j \) resampled sets for constraint \( k \) are respectively \( Z_1, \ldots, Z_j \); we make no condition on the total number of resamplings. We have an increasing chain

\[
\mathcal{E}(0, j, Z_1, \ldots, Z_j, v) \subseteq \mathcal{E}(1, j, Z_1, \ldots, Z_j, v) \subseteq \mathcal{E}(2, j, Z_1, \ldots, Z_j, v) \subseteq \ldots
\]

and \( \mathcal{E}((j, Z_1, \ldots, Z_j, v) = \bigcup_{T=0}^{\infty} \mathcal{E}(T, j, Z_1, \ldots, Z_j, v) \). By countable additivity of the probability measure,

\[
P(\mathcal{E}(j, Z_1, \ldots, Z_j, v)) = \lim_{T \to \infty} P(\mathcal{E}(T, j, Z_1, \ldots, Z_j, v)) \leq \frac{\prod_{i \in Z_1} f_k(Z_i)}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i}
\]

So far, we have computed the probability of having \( Z_1, \ldots, Z_j \) be the first \( j \) resampled sets for constraint \( k \), given that \( x \) is fixed to an arbitrary initial value \( v \). We now can compute the probability that \( Z_1, \ldots, Z_j \) are the first \( j \) resampled sets for constraint \( k \) given that \( x \) is drawn as independent Bernoulli(\( p_i \)).

In the first step of the RELAXATION algorithm, we claim that a necessary event for \( Z_1, \ldots, Z_j \) to be the first \( j \) resampled sets is to have \( x_i = 0 \) for each \( i \in Z_1 \cup \cdots \cup Z_j \); the rationale for this is equivalent to that for (A2). This event has probability \( \prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i \). Subsequently the event \( \mathcal{E}(j, Z_1, \ldots, Z_j, x) \) must occur.

The probability of \( \mathcal{E}(j, Z_1, \ldots, Z_j, x) \), conditional on \( x_i = 0 \) for all \( i \in Z_1 \cup \cdots \cup Z_j \), is at most \( \frac{\prod_{i \in Z_1} f_k(Z_i)}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i} \). (by a similar argument to that of computing the probability of (A3) conditional on
(A1), (A2)). Thus, the overall probability that the first $j$ resampled sets for constraint $k$ are $Z_1, \ldots, Z_j$ is at most
\[
\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i \times \prod_{\ell=1}^j \frac{f_k(Z_\ell)}{\prod_{i \in Z_1 \cup \cdots \cup Z_j} q_i} = \prod_{\ell=1}^j f_k(Z_\ell)
\]
which completes the proof. \hfill \square

We next compute $\sum_{Z \subseteq [n]} f_k(Z)$; such sums will recur in our calculations.

**Proposition 2.3.** Suppose $\alpha > -\frac{\ln(1-\sigma)}{\sigma}$. For any constraint $k$ define
\[
s_k = (1 - \sigma)^{-a_k} e^{-\sigma A_k \hat{x}}
\]
Then $\sum_{Z \subseteq [n]} f_k(Z) \leq s_k < 1$ for all $k = 1, \ldots, m$.

**Proof.** We have:
\[
\sum_{Z \subseteq [n]} f_k(Z) = \sum_{Z \subseteq [n]} (1 - \sigma)^{-a_k} \prod_{i \in [n] - Z} (1 - A_{ki} \sigma) \prod_{i \in Z} q_i A_{ki} \sigma
\]
\[
= (1 - \sigma)^{-a_k} \prod_{i \in [n]} (1 - A_{ki} \sigma) + (q_i A_{ki} \sigma)
\]
\[
= (1 - \sigma)^{-a_k} \prod_{i \in [n]} (1 - A_{ki} p_i \sigma) \leq (1 - \sigma)^{-a_k} e^{-\sigma \sum_i p_i} = (1 - \sigma)^{-a_k} e^{-\sigma A_k \hat{x}}
\]

Also, since $A_k \hat{x} \geq a$, we have $s_k = (1 - \sigma)^{-a_k} e^{-\sigma A_k \hat{x}} < (1 - \sigma)^{-a_k} e^{-\sigma a_k \frac{\ln(1-\sigma)}{\sigma}} = 1$. \hfill \square

**Proposition 2.4.** For any constraint $k$ and any $i \in [n]$, we have
\[
\sum_{Z \subseteq [n]} f_k(Z) \leq s_k A_{ki} \sigma
\]

**Proof.** We have:
\[
\sum_{Z \subseteq [n]} f_k(Z) = \sum_{Z \subseteq [n]} (1 - \sigma)^{-a_k} \prod_{\ell \in [n] - Z} (1 - A_{k\ell} \sigma) \prod_{\ell \in Z} q_{\ell} A_{k\ell} \sigma
\]
\[
= (1 - \sigma)^{-a_k q_i A_{ki} \sigma} \prod_{\ell \in [n] - \{i\}} (1 - A_{k\ell} \sigma) + (q_i A_{k\ell} \sigma)
\]
\[
= (1 - \sigma)^{-a_k q_i A_{ki} \sigma} \prod_{\ell \in [n] - \{i\}} (1 - A_{k\ell} p_i \sigma)
\]
\[
\leq (1 - \sigma)^{-a_k q_i A_{ki} \sigma e^{A_{ki} p_i} e^{-\sigma A_k \hat{x}}} = s_k (1 - p_i) A_{ki} \sigma e^{A_{ki} p_i}
\]
Now note that $A_{ki} \leq 1, \sigma \leq 1$ and hence $(1 - p_i) e^{A_{ki} p_i} \leq 1$. The claimed bound then holds. \hfill \square

10
To gain some intuition about this expression \( s_k \), note that if we set \( \sigma = 1 - 1/\alpha \) (which is not necessarily the optimal choice for the overall algorithm), then \( s_k = \alpha^a_k e^{-A_k \cdot \hat{x}(\alpha-1)} \), which can be recognized as the Chernoff lower-tail bound. Namely, this is an upper bound on the probability that a sum of independent \([0, 1]\)-random variables, with mean \( \alpha A_k \cdot \hat{x} \), will become as small as \( a_k \). This makes sense: at the very first step of the algorithm (before any resamplings are performed), \( A_k \cdot x \) is precisely a sum of independent Bernoulli variables with mean \( \alpha A_k \cdot \hat{x} \). The event we are measuring (the probability that a constraint \( k \) is resampled) is precisely the event that this sum is smaller than \( a_k \).

We are finally able to bound the running time and distribution on \( x_i \) for this algorithm.

**Proposition 2.5.** Suppose \( \alpha > -\frac{\ln(1-\sigma)}{\sigma} \). The expected number of resamplings of constraint \( k \) made by the algorithm RELAXATION is at most \( \frac{1}{e^{\sigma \alpha A_k \cdot \hat{x}} (1-\sigma)^{a_k} - 1} \).

**Proof.** A necessary condition to have at least \( r \) resamplings is that there are sets \( Z_1, \ldots, Z_r \) which are respectively the first \( r \) resampled sets for constraint \( k \). A union-bound over \( Z_1, \ldots, Z_r \) gives:

\[
P(\geq r \text{ resamplings}) \leq \sum_{Z_1, \ldots, Z_r \subseteq [n]} P(Z_1, \ldots, Z_r \text{ are first resampled sets for constraint } k)
\]

\[
\leq \sum_{Z_1, \ldots, Z_r \subseteq [n]} f_k(Z_1) \cdots f_k(Z_r) \quad \text{(Lemma 2.2)}
\]

\[
= \left( \sum_{Z \subseteq [n]} f_k(Z) \right)^r \leq s_k^r \quad \text{(Proposition 2.3)}
\]

Since \( s_k < 1 \), the expected number of resamplings of constraint \( k \) is at most

\[
\sum_{r=1}^{\infty} s_k^r = \frac{1}{1/s_k - 1} = \frac{1}{(1-\sigma)^{a_k} e^{\sigma \alpha A_k \cdot \hat{x}} - 1}
\]

We are now prepared to prove Theorem 2.1.

**Proof of Theorem 2.1.** There are two possible ways to have \( x_i = 1 \): either \( x_i = 1 \) at the initial sampling, or \( x_i \) first becomes equal to one during the \( j \)th resampling of constraint \( k \). The former event has probability \( p_i \). If the latter event occurs, there must be sets \( Z_1, \ldots, Z_j \) such that:

1. (B1) The first \( j \) resampled sets for constraint \( k \) are respectively \( Z_1, \ldots, Z_j \)
2. (B2) \( i \in Z_j \)
3. (B3) During the \( j \)th resampling of constraint \( k \), we set \( x_i = 1 \).

For any sets \( Z_1, \ldots, Z_j \) and \( k \in [m] \), the probability that \( Z_1, \ldots, Z_j \) satisfy (B1) is at most \( f_k(Z_1) \cdots f_k(Z_j) \) by Lemma 2.2. Since (B3) occurs after (B1), (B2) are determined, it has probability of \( p_i \) conditional on (B1), (B2). Thus, for any fixed \( Z_1, \ldots, Z_j \), the probability that events (B1)–(B3) hold is at most \( p_i f_k(Z_1) \cdots f_k(Z_j) \).
We now describe the overall process. Suppose we are given some vector \( \hat{y} \) contributing of \( \gamma \) multiplier and \( \hat{i} \) subdivision step. We will subdivide a variable \( y \) the RELAXATION algorithm on this subdivided fractional solution, obtaining an integral solution variables can force all the entries in the fractional solution to be arbitrarily small. We can run the maximum size of the resulting value \( x \). Unfortunately, this process of repeated subdivision prevents us from having good control over appearances in the covering system, we replace it by \( y \) given a variable \( i \) variables \( y \) variables can force all the entries in the fractional solution to be arbitrarily small. We can run the maximum size of the resulting value \( x \). Unfortunately, this process of repeated subdivision prevents us from having good control over

\[
E[x_i] \leq \alpha \hat{x}_i \left( 1 + \sigma \sum_k \frac{A_{ki}}{1 - \sigma} \right)
\]

We also bound the *maximum* (not just expected) size of the value \( x_i \). Note that if our goal is *solely* to achieve (3), without regard to the size of \( x_i \), then there is a straightforward method: given a variable \( i \), and a solution to the LP with fractional value \( \hat{x}_i \), we sub-divide it into two new variables \( y_1, y_2 \) with fractional values \( \hat{y}_1, \hat{y}_2 \) such that \( \hat{y}_1 + \hat{y}_2 = \hat{x}_i \). Now, whenever the variable \( x_i \) appears in the covering system, we replace it by \( y_1 + y_2 \). This process of repeatedly sub-dividing variables can force all the entries in the fractional solution to be arbitrarily small. We can run the RELAXATION algorithm on this subdivided fractional solution, obtaining an integral solution \( y_1, y_2 \) and hence \( x_i = y_1 + y_2 \).

Unfortunately, this process of repeated subdivision prevents us from having good control over the maximum size of the resulting value \( x_i \). Instead, we use a truncation process after the first subdivision step. We will subdivide a variable \( i \) into two components, \( \hat{y}_1, \hat{y}_2 \), where \( \hat{y}_2 \in [0, 1/\alpha]^n \) and \( \hat{y}_1 \) is large. We then deterministically form \( y_1 \) by setting \( y_1 = \gamma \hat{y}_1 \), for some appropriate multiplier \( \gamma \) and form \( y_2 \) by running RELAXATION on the residual problem (after removing the contribution of \( y_1 \)).

We now describe the overall process. Suppose we are given some vector \( \hat{x} \in [0, \infty)^n \). For each

2.2 Extension to the case where \( \hat{x}_i \) is Large

In the previous section, we described the RELAXATION algorithm under the assumption that \( \hat{x} \in [0, 1/\alpha]^n \). This assumption was necessary because each variable \( i \) is chosen to be drawn as a Bernoulli random variable with probability \( p_i = \alpha \hat{x}_i \). In this section, we describe how to extend the RELAXATION algorithm to an arbitrary vector \( \hat{x} \in [0, \infty)^n \). Our goal is to construct a randomized process, generating a vector \( x \in \mathbb{Z}_{\geq 0}^n \), with the property that

\[
\mathbb{E}[x_i] \leq \alpha \hat{x}_i \left( 1 + \sigma \sum_k \frac{A_{ki}}{1 - \sigma} \right)
\]
variable \( i \), let \( v_i = \lfloor \hat{x}_i / \theta \rfloor \), where we define
\[
\theta = \frac{-\ln(1 - \sigma)}{\alpha \sigma}
\]
Let us then define \( F_i = \hat{x}_i - v_i \theta = \hat{x}_i \mod \theta \) and also
\[
G_i = \begin{cases} 
0 & \text{if } F_i < 1/\alpha \\
1 & \text{if } F_i \geq 1/\alpha 
\end{cases}, \quad \hat{x}_i' = \begin{cases} 
F_i & \text{if } F_i < 1/\alpha \\
0 & \text{if } F_i \geq 1/\alpha 
\end{cases}
\]
We now form the residual problem by setting
\[
a_k' = a_k - \sum_i A_{ki} (G_i + v_i)
\]
which satisfies the condition that \( x' \in [0, 1/\alpha]^n \) for \( k = 1, \ldots, m \). We then run the RELAXATION algorithm on the residual problem. This is summarized in Algorithm 2, Rounding.

**Algorithm 2** The Rounding algorithm

1: function Rounding (\( \hat{x}, A, \sigma, \alpha \))
2: Compute \( x' = \text{RELAXATION}(\hat{x}', A, a', \sigma, \alpha) \)
3: Return \( x = G + v + x' \)

It is easy see that the solution vector returned by the Rounding algorithm satisfies the covering constraints \( A \cdot x \geq a \). Let us show a few additional properties before bounding the expected and maximum size of the value \( x_i \).

**Proposition 2.6.** For any \( i \in [n] \) we have \( \hat{x}_i - v_i \theta - G_i \theta \leq \hat{x}_i' \leq \hat{x}_i - v_i \theta - G_i / \alpha \)

**Proof.** If \( G_i = 0 \), then both of the bounds hold with equality. So suppose \( G_i = 1 \). In this case, \( 1/\alpha \leq \hat{x}_i - v_i \theta \leq \theta \). So \( \hat{x}_i - v_i \theta - G_i / \alpha \geq \theta - 1/\alpha \geq 0 \) and \( \hat{x}_i - v_i \theta - G_i \theta \leq \theta - \theta = 0 \) as required. \( \Box \)

**Proposition 2.7.** For any constraint \( k \), we have \((1 - \sigma)^{a_k} e^{\sigma \alpha A_k \cdot \hat{x}'} \geq (1 - \sigma)^{a_k} e^{\sigma \alpha A_k \cdot \hat{x}}\).

**Proof.** Let \( r = \sum_i A_{ki} (G_i + v_i) \), so that \( a_k' = a_k - r \). By Proposition 2.6,
\[
A_k \cdot \hat{x}' = \sum_i A_{ki} \hat{x}_i' \geq \sum_i A_{ki} (\hat{x}_i - v_i \theta - G_i \theta) = a_k - r \theta
\]
Then
\[
(1 - \sigma)^{a_k'} e^{\sigma \alpha A_k \cdot \hat{x}'} = (1 - \sigma)^{a_k - r} e^{\sigma \alpha A_k \cdot \hat{x}'} \geq (1 - \sigma)^{a_k - r} e^{\sigma \alpha (a_k - r \theta)} = (1 - \sigma)^{-a_k} e^{-\sigma a_k} \quad \Box
\]

We summarize our analysis of the Rounding algorithm:
Theorem 2.8. Let $\sigma \in [0, 1], \alpha > -\ln(1-\sigma)/\sigma$. Suppose that $A\hat{x}$ ≥ $a$ for a vector $\hat{x} \in [0, \infty)^n$.

Then at the end of the ROUNDING algorithm, for each $i \in [n]$ we have

$$x_i \leq \left\lceil \frac{\hat{x}_i - \alpha \sigma}{-\ln(1-\sigma)} \right\rceil$$

with probability one.

$$E[x_i] \leq \alpha \hat{x}_i \left(1 + \sigma \sum_k e^{\sigma \alpha a_k (1-\sigma) a_k - 1}\right)$$

The expected number of resamplings of constraint $k$ for the RELAXATION algorithm is at most $1/(e^{\sigma \alpha a_k (1-\sigma) a_k - 1})$.

Proof. Let us first show the bound on size of $x_i$. We must show that $x_i \leq \lceil \hat{x}_i/\theta \rceil$. If $\hat{x}_i$ is not a multiple of $\theta$, then $x_i = x'_i + G_i + \lfloor \hat{x}_i/\theta \rfloor$. If $G_i = 1$, then $\hat{x}'_i = 0$ which implies that $x'_i = 0$. So $G_i + x'_i \leq 1$ and hence $x_i \leq 1 + \lfloor x_i/\theta \rfloor = \lceil x_i/\theta \rceil$. If $\hat{x}_i$ is a multiple of $\theta$, then $G_i = \hat{x}'_i = 0$ and $x_i = \lfloor \hat{x}_i/\theta \rfloor = \lceil \hat{x}_i/\theta \rceil$.

We next turn to bounding $E[x_i]$. Define $T = 1 + \sigma \sum_k A_{ki} e^{\sigma \alpha a_k (1-\sigma) a_k - 1}$. By Theorem 2.1 and Proposition 2.7, the probability that $x'_i = 1$ is at most

$$P(x'_i = 1) \leq \alpha \hat{x}'_i \left(1 + \sigma \sum_k \frac{A_{ki}}{(1-\sigma)^{a_k} e^{\sigma \alpha A_k x'_i} - 1}\right) \leq \alpha \hat{x}'_i T$$

So we estimate $E[x_i]$ by:

$$E[x_i] = v_i + G_i \leq v_i + G_i + \alpha \hat{x}'_i T \leq v_i + G_i + \alpha (\hat{x}_i - \theta v_i - G_i/\alpha) T \leq v_i (1 - \alpha \theta) + \alpha \hat{x}_i T \leq \alpha \hat{x}_i T$$

as $\alpha \theta = -\ln(1-\sigma)/\sigma \geq 1$.

The bound on the expected number of resamplings is similar.

\[\square\]

3. Bounds in terms of $a_{\min}, \Delta_1$

So far, we have given bounds on the behavior of ROUNDING algorithm which are as general as possible; Theorem 2.8 can be applied to systems which have multiple types of variables and constraints. We can simplify these bounds by reducing them to two simple parameters, namely $\Delta_1$, the maximum $\ell_1$-norm of any column of $A$, and $a_{\min} = \min_k a_k$. Our proceeding analysis assumes $a_{\min} \geq 1, \Delta_1 \geq 1$ which can be ensured by a simple pre-processing step described in Theorem 3.3.

Theorem 3.1. Suppose we are given a covering system with $\Delta_1 \geq 1, a_{\min} \geq 1$ and with a fractional solution $\hat{x}$ to the basic LP. With appropriate choices of $\sigma, \alpha$ we may run the ROUNDING algorithm to obtain a solution $x \in \mathbb{Z}_n^+$ satisfying

$$E[x_i] \leq \hat{x}_i (1 + \gamma + 10 \ln(1 + \sqrt{\gamma})),$$

$$x_i \leq \left\lceil \hat{x}_i \frac{2\gamma}{\ln(1 + \gamma)} \right\rceil$$

with probability one.

The expected running time of this algorithm is $O(N)$.
Proof. Set \( \sigma = 1 - 1/\alpha \) and \( \alpha = 1 + \frac{\ln(1-\sigma)}{\sigma} > 1 \). Note that \( -\frac{\ln(1-\sigma)}{\sigma} = \alpha \cdot \frac{\ln \alpha}{\alpha-1} < \alpha \). For the bound on the size of \( x_i \), Theorem 2.8 gives:

\[
x_i \leq \left[ \frac{\hat{x}_i \gamma + 4 \ln(1 + \sqrt{\gamma})}{\ln(1 + \gamma + 4 \ln(1 + \sqrt{\gamma}))} \right] ;
\]

and simple analysis shows that this \( \hat{x}_i \gamma + 4 \ln(1 + \sqrt{\gamma})/\ln(1 + \gamma + 4 \ln(1 + \sqrt{\gamma})) \leq \frac{2\gamma}{\ln(1+\gamma)} \).

For its expected value, Theorem 2.8 gives:

\[
\mathbb{E}[x_i] \leq \hat{x}_i \alpha \left( 1 + \frac{A_{k_i}}{\sum_k (1-\sigma)a_k e^{\sigma a_k} - 1} \right) = \hat{x}_i \alpha \left( 1 + \frac{A_{k_i}}{e^{a_k(\alpha-1)} - 1} \right)
\]

\[
\leq \hat{x}_i \alpha \left( 1 + (1 - 1/\alpha) \frac{A_{k_i}}{e^{a_k(\alpha-1)} - 1} \right) \leq \hat{x}_i \left( \alpha + (\alpha - 1) \frac{\Delta_1}{e^{a_k(\alpha-1)} - 1} \right)
\]

\[
= \hat{x}_i \left( \alpha + (\alpha - 1) \frac{\gamma - 1}{e^{a_k(\alpha-1)} - 1} \right)
\]

\[
\leq \hat{x}_i \left( 1 + \gamma + 10 \ln(1 + \sqrt{\gamma}) \right) \quad \text{by Proposition B.1}
\]

Next, let us analyze the runtime of this procedure. The initial steps of rounding and forming the residual can be done in time \( O(N) \).

By Theorem 2.8 the expected number of resamplings of constraint \( k \) is at most

\[
\frac{1}{e^{a_k(\alpha-1)} - 1} \leq \frac{1}{e^{a_k(\alpha-1)} e^{a_{\min}} - 1} \leq \frac{1}{(\Delta_1 + 1)} \frac{(\alpha - 1 - \ln \alpha)}{\gamma} - 1 \leq \frac{1}{2} \frac{(\alpha - 1 - \ln \alpha)}{\gamma} - 1
\]

Simple analysis shows that \( (\alpha - 1 - \ln \alpha)/\gamma \geq 1 \) for all values of \( \gamma \geq 0 \), and hence this is at most 1. In each resampling step, we must draw a new random value for all the variables. If constraint \( k \) has \( N_k \) non-zero entries, this can be easily done in time \( O(N_k) \). Thus, the overall expected time for all resamplings is at most \( \sum_k O(N_k) = O(N) \). \( \Box \)

At some cost to the approximation ratio, Theorem 3.1 can be modified to \( \epsilon \)-respect the multiplicity constraint.

**Theorem 3.2.** Consider a CIP with \( \Delta_1 \geq 1, a_{\min} \geq 1 \), and a solution \( \hat{x} \) to its basic LP. Let \( \epsilon \in [0,1] \) be given. Then, with an appropriate choice of \( \sigma, \alpha \) the Rounding algorithm runs in expected time \( O(N) \) to produce a solution \( x \in \mathbb{Z}^+_n \) satisfying

\[
\mathbb{E}[x_i] \leq \hat{x}_i (1 + \epsilon + 4\gamma/\epsilon), \quad x_i \leq \lceil \hat{x}_i (1 + \epsilon) \rceil \quad \text{with probability one}
\]

**Proof.** Set \( \alpha = \frac{-(1+\epsilon) \ln(1-\sigma)}{\sigma} \), where \( \sigma \in (0,1) \) is a parameter to be determined. Then by Theorem 2.8 we have \( x_i \leq \lceil \hat{x}_i (1 + \epsilon) \rceil \) at the end of the Rounding algorithm.

We clearly have \( \alpha \geq \frac{-\ln(1-\sigma)}{\sigma} \) and so by Theorem 2.8

\[
\mathbb{E}[x_i] \leq \alpha \hat{x}_i \left( 1 + \frac{A_{k_i}}{\sum_k (1-\sigma)a_k e^{\sigma a_k} - 1} \right) \leq \alpha \hat{x}_i \left( 1 + \frac{\Delta_1}{(1-\sigma) e^{a_{\min} \epsilon} - 1} \right)
\]
Now set $\sigma = 1 - e^{-\gamma/\epsilon}$, which is in the range $(0, 1)$. Substituting in this value gives

$$E[x_i] \leq \hat{x}_i (\epsilon^{-1} (2 + \frac{1}{e^{\gamma/\epsilon} - 1})(1 + \epsilon) \gamma)$$

Simple calculus shows that $\epsilon^{-1} (2 + \frac{1}{e^{\gamma/\epsilon} - 1})(1 + \epsilon) \gamma \leq 1 + \epsilon + (2 + 2/\epsilon) \gamma$. By our assumption that $\epsilon \in [0, 1]$ this is at most $1 + \epsilon + 4\gamma/\epsilon$ as desired. The bound on the running time follows the same lines as Theorem 3.1.

We now show how to ensure that $a_{\min} \geq 1, \Delta_1 \geq 1$.

**Theorem 3.3.** Given a covering system $A, a$, we can produce in time $O(N)$ a modified system $A', a'$ which satisfies the following properties:

1. The integral solutions of $A, a$ are precisely the same as the integral solutions of $A', a'$;
2. $a'_{\min} \geq 1$ and $\Delta'_1 \geq 1$;
3. $\gamma' = \ln(\Delta'_1 + 1)/a'_{\min}$.

**Proof.** If any entry $A_{ki}$ has $A_{ki} > a_k$, replace it with $A_{ki} = a_k$. This step can only decrease $\Delta_1$.

After this step, one can assume that $A_{ki} \leq a_k$ for all $k, i$. Now suppose there are some constraints with $a_k \leq 1$. In this case, replace row $A_k$ with $A'_k = A_k/a_k$ and replace $a_k$ with $a'_k = 1$. Because of our assumption that $A_{ki} \leq a_k$ for all $k, i$, the new row of the matrix still satisfies $A'_k \in [0, 1]^n$.

This ensures that $a'_k \geq 1$ for all $k$. Also, every column in the matrix is scaled up by at most $1/a_k \leq 1/a_{\min}$, so $\Delta'_1 \leq \Delta_1/a_{\min}$ and $a'_{\min} = 1$. We then have

$$\gamma' = \ln(\Delta'_1 + 1)/a'_{\min} = \ln(\Delta_1/a_{\min} + 1) \leq \frac{\ln(\Delta_1 + 1)}{a_{\min}} = \gamma.$$

Finally, if $\Delta_1 < 1$, then we can scale up both $A, a$ by $1/\Delta_1$ to obtain $A' = A/\Delta_1, a' = a/\Delta_1$. This gives $\Delta' = 1, a'_{\min} = a_{\min}/\Delta_1$ and $\gamma' = \frac{\ln(1+1)}{a_{\min}/\Delta_1} \leq \frac{\ln(\Delta_1 + 1)}{a_{\min}} = \gamma$. □

**Corollary 3.4.** For a CIP instance without multiplicity constraints, there is an algorithm to generate a feasible solution $x \in \mathbb{Z}_+^n$ in expected polynomial time with

$$C \cdot x \leq (1 + \gamma + O(\ln(1 + \sqrt{\gamma})))OPT$$

where OPT is the optimal integral solution to the original CIP.

**Proof.** First, apply Theorem 3.3 to ensure that $\Delta_1 \geq 1, a_{\min} \geq 1$; the resulting CIP has a parameter $\gamma' = \frac{\ln(\Delta'_1 + 1)}{a'_{\min}/\Delta'_1} \leq \ln(1 + m)$. Next, find an optimal solution $z \in [0, \infty)^n$ to the corresponding basic LP, of value $Z = C \cdot z$. Clearly $Z \leq OPT$ since $Z$ is a relaxation.

Now suppose we apply Theorem 3.1 and denote the solution we obtain (which is a random variable) by $x \in \mathbb{Z}_+^n$. This solution $x$ satisfies $E[C \cdot x] \leq (1 + \gamma' + 10\ln(1 + \sqrt{\gamma}))Z \leq (1 + \gamma + 10\ln(1 + \sqrt{\gamma}))Z$.  

16
Also, since \( x \) satisfies all the covering constraints, then \( x \) is also a solution to the linear program \( Z \); this implies that \( C \cdot x \geq Z \) with probability one.

By applying Markov’s inequality to the non-negative random variable \( C \cdot x - Z \), we see that
\[
P(C \cdot x \geq (1 + \gamma + 20 \ln(1 + \sqrt{\gamma}))Z) \leq \frac{\gamma + 10 \ln(1 + \sqrt{\gamma})}{\gamma + 20 \ln(1 + \sqrt{\gamma})} \leq 1 - \Omega\left(\frac{1}{\log(1 + \sqrt{\gamma})}\right) \leq 1 - \Omega\left(\frac{1}{\log m}\right)
\]

Thus, after repeating this process for \( O(\log m) \) iterations (in expectation), we achieve an integral solution which satisfies the covering constraints and which satisfies \( C \cdot x \leq (1 + \gamma + O(\ln(1 + \sqrt{\gamma})))OPT \).

Corollary 3.4 requires solving the basic LP exactly, which although polynomial-time may still be slow. There has been significant work in developing faster approximate LP solvers for specialized types of linear systems, including the basic LP of CIP. Most recently, Wang et al. [25] gave an algorithm to obtain a \((1 + \delta)\)-approximate solution to this LP in \( \tilde{O}(N/\delta) \) time. (The \( \tilde{O} \) factor here hides polylogarithmic terms.) Combined with our fast randomized rounding, this gives overall fast approximation algorithms for CIP.

**Theorem 3.5.** For a CIP instance without multiplicity constraints, there is an algorithm that obtains a feasible solution \( x \in \mathbb{Z}^n_+ \) in \( \tilde{O}(N/\delta) \) time satisfying
\[
C \cdot x \leq (1 + \delta)(1 + \gamma + O(\ln(1 + \sqrt{\gamma})))OPT
\]
where \( OPT \) is the optimal integral solution to the original CIP.

**Proof.** Apply the Wang et al. algorithm to obtain a \((1 + \delta)\)-approximate solution. When we apply Theorem 3.1 to it, this generates a solution \( x \) whose expected value is at most \( E[C \cdot x] \leq (1 + \delta)(1 + \gamma + 10 \ln(1 + \sqrt{\gamma})) \). By Markov’s inequality, after \( O(1/\delta) \) expected iterations, we achieve an integral solution which has \( C \cdot x \leq (1 + 2\delta)(1 + \gamma + 10 \ln(1 + \sqrt{\gamma})) \). Since each application of Theorem 3.1 takes time \( O(N) \), the rounding process takes \( O(N/\delta) \) time.

## 4 Respecting multiplicity constraints

We next describe a rounding algorithm to exactly preserve the multiplicity constraints. We follow here the approach of [16], which in turn builds on an approach of [3], by constructing a stronger linear program via the knapsack-cover (KC) inequalities. This LP has exponential size, but can be approximately optimized in polynomial time. We then round the resulting solution using Theorem 3.1. The key to the KC inequalities is to form a residual problem, given that a set of variables \( X \) is “pinned” to their maximal values.

**Definition 4.1** (The pinned-residual problem). Fix a CIP problem with constraint matrix \( A \), RHS vector \( a \), and multiplicity constraints \( d \). Given any \( X \subseteq [n] \), we define the pinned-residual, denoted \( PR(X) \), to be a new CIP problem \( A', a', d \) which we obtain as follows. For every \( i \in X \), we first set variable \( x_i \) to be equal to its maximum value \( d_i \), and then form a residual CIP instance \( A'' \), \( a'' \) involving only the variables \( [n] - X \). If any residual RHS value \( a''_k \) is negative, then we discard that constraint. If \( a''_k \in [0, 1) \), then we rescale constraint \( k \), by dividing \( A''_k \) by \( a''_k \). We then let \( A', a' \) denote the results of these transformations.
Proposition 4.2 ([10], [3]). For any $X \subseteq [n]$, the following hold:

1. Any integral solution to the original CIP also satisfies PR($X$).
2. PR($X$) has $a'_{\min} \geq 1, \Delta'_1 \leq \Delta_0$, where $\Delta_0$ is the maximum $\ell_0$-column norm of $A$.

Theorem 4.3. There is an expected-polynomial time algorithm to find a feasible solution $x \in \mathbb{Z}_n^+$ for a CIP instance with $C \cdot x \leq (\ln \Delta_0 + O(\log \log \Delta_0)) \cdot \text{OPT}$, where $\text{OPT}$ is the optimal integral solution.

Proof. Let $\gamma_0 = \ln(\Delta_0 + 1)$ and let $\delta = \frac{2^{\gamma_0}}{\ln(1 + \gamma_0)}$.

We begin by finding a fractional solution $\hat{x}$ which minimizes $C \cdot \hat{x}$, subject to the conditions that $\hat{x}_i \in [0, d_i]$ and such that $\hat{x}$ satisfies PR($\{i \mid \hat{x}_i \geq d_i/\delta\}$). This can be done using the ellipsoid method: given some putative $\hat{x}$, one can form PR($\{i \mid \hat{x}_i \geq d_i/\delta\}$) and determine which constraint in it, if any, is violated. (See [16] for more details.) By Proposition 4.2, any optimal integral solution satisfies PR($Y$) for all $Y \subseteq [n]$, so $C \cdot \hat{x} \leq \text{OPT}$.

Let $X = \{i \mid \hat{x}_i \geq d_i/\delta\}$. We set $x_i = d_i$ for $i \in X$ and use the Rounding algorithm to obtain a solution $x$ for PR($X$). We will check that this satisfies the multiplicity constraints and that the resulting $E[C \cdot x]$ is close to OPT.

For $i \in X$, we clearly have $x_i \leq d_i$. By Proposition 4.2, PR($X$) has parameter $\gamma' = \ln(\Delta'_1 + 1)/a'_{\min} \leq \gamma_0$. So for $i \notin X$, we have $x_i \leq \lceil \delta \hat{x}_i \rceil$; this is at most $\lceil d_i \rceil = d_i$ by definition of $X$. So $x$ satisfies the multiplicity constraints.

For $i \in X$, we have $E[x_i] \leq d_i \leq \hat{x}_i \delta \leq x_i(\gamma_0 + O(1))$. For $i \notin X$, Theorem 3.1 shows $E[x_i] \leq \hat{x}_i(1 + \gamma' + 10 \ln(1 + \sqrt{\gamma'})) \leq \hat{x}_i(1 + \gamma_0 + 10 \ln(1 + \sqrt{\gamma_0}))$. Combining these two cases,

$$E[C \cdot x] \leq (1 + \gamma_0 + c \ln(1 + \sqrt{\gamma_0})) \cdot \text{OPT}$$

Since $x$ satisfies the covering constraints and multiplicity constraints, $C \cdot x \geq \text{OPT}$ with probability one. Applying Markov’s inequality to the non-negative random variable $C \cdot x - \text{OPT}$ and noting that $\gamma_0 \leq O(\log m)$, we see that after repeating this process for $O(\log m)$ iterations (in expectation), we achieve a solution $x$ satisfying all the multiplicity constraints as well as

$$C \cdot x \leq (1 + \gamma_0 + 2c \ln(1 + \sqrt{\gamma_0})) \cdot \text{OPT} \leq (\ln \Delta_0 + O(\log \log \Delta_0)) \cdot \text{OPT}$$

5 Lower bounds on approximation ratios

We now provide lower bounds on the approximation ratios for CIP algorithms. These bounds fall into two categories, namely, inapproximability of CIP (which follows from inapproximability of set cover), and integrality gaps for the basic LP. The formal statements of these results contain numerous qualifiers and technical conditions. We summarize these informally here:
1. Under the hypothesis $P \neq NP$, any polynomial-time algorithm to solve the CIP without multiplicity constraints must have approximation ratio $\max(\gamma, 1 + \gamma/2)$. Likewise, the basic LP has integrality gap $\max(\gamma, 1 + \gamma/2)$.

2. Under the hypothesis $P \neq NP$, any polynomial-time algorithm to solve the CIP with multiplicity constraints must have approximation ratio $\ln \Delta_0 - O(\ln \ln \Delta_0)$.

3. The gap between solutions to the basic LP, and integral solutions which $\epsilon$-respect the multiplicity constraints, can be as large as $\Omega(\gamma/\epsilon)$.

We contrast these lower bounds with the upper bounds achieved by our algorithms:

1. For CIP without multiplicity constraints, Theorem 3.1 gives an approximation ratio close to $\gamma$ (for large $\gamma$) and of order $1 + O(\sqrt{\gamma})$ (for small $\gamma$).

2. For CIP with multiplicity constraints, Theorem 4.3 gives an approximation ratio of $\ln \Delta_0 + O(\log \log \Delta_0)$.

3. For $\epsilon$-respecting multiplicity constraints, Theorem 3.2 gives an approximation ratio of order $O(\gamma/\epsilon)$.

5.1 Hardness results

Set cover is a well-studied special case of CIP, with a number of precise hardness results known. These hardness results are all based on a construction of Feige [9] relating approximation of set cover to exactly solving SAT. This construction was adapted by Trevisan [23] to set cover in which the sets have bounded size; this closely parallels CIP with bounded column sums. We quote the result of Trevisan:

**Theorem 5.1** ([23]). There is an absolute constant $c > 0$ with the following property. Assuming $P \neq NP$, any polynomial-time algorithm to approximate set cover on instances where the sets have size at most $B$, must have an approximation ratio of at least $\ln B - c \ln \ln B$.

**Proposition 5.2.** Assuming $P \neq NP$, there is any absolute constant $c > 0$ with the following property. For any polynomial-time algorithm $A$ to approximate CIP and any integer value $d \geq 2$ there exist problem instances with $\Delta_0 \leq d$ for which $A$ has approximation ratio at least $\ln d - c \ln \ln d$.

**Proof.** A set cover instance on a domain $[n]$ in which the sets have size at most $d$ can be encoded as a CIP with $\Delta_0 \leq d$. To do so, let $x_j$ be an indicator variable that the set $S_j$ appears in the cover. Then for each item $i \in [n]$ we have a constraint $\sum_{j : i \in S_j} x_j \geq 1$. The $\ell_0$-column norms corresponding to a variable $x_j$ is $|S_j| \leq d$.

Thus, suppose for contradiction that some polynomial-time algorithm guarantees approximation ratio $r < \ln d - c \ln \ln d$ for some value of $d$. Then the approximation algorithm for CIP, using the above encoding, would also give an approximation algorithm for set cover instances with sets of size at most $d$; this contradicts Theorem 5.1.

---

1See [5] for a crisp formulation of the result, which appears only implicitly in the original work [23].
Thus, when $\Delta_0$ is large, the approximation ratio of Theorem 4.3 is optimal up to first-order. We next show inapproximability as a function of $\Delta_1, a_{\min}$. This construction depends on a combinatorial result of [2] on the independence number of hypergraphs, which we defer to the appendix.

**Proposition 5.3.** Assuming $P \neq NP$, there is any absolute constant $c > 0$ with the following property. For any polynomial-time algorithm $A$ to approximate CIP without multiplicity constraints, and any integers $d \geq 2, a \geq 2$, there exist problem instances with $\Delta_1 \leq d, a_{\min} \geq a$ for which $A$ has approximation ratio at least

$$\frac{\ln d - c \ln \ln d}{a(1 - (ed)^{-1/(a-1)})}$$

**Proof.** Let us fix $d, a$, and consider any algorithm $A$ which guarantees approximation ratio $r$. Consider a set cover instance on a domain $[n]$ in which the sets have size at most $d$. Form a CIP instance, which has a constraint for each $i \in [n]$ given by

$$\sum_{j: i \in S_j} x_j \geq a$$

This CIP has $\Delta_1 \leq d$ and $a_{\min} = a$. Now, suppose the set cover instance has an optimal solution $S$ with $|S| = k$. Then the CIP has a corresponding solution of value $ak$ derived by setting $x_j = a$ for $S_j \in S$, and $x_j = 0$ otherwise. The algorithm $A$ then generates an integral solution $x$ with $\sum_j x_j \leq rak$.

Consider now the multi-set $S'$, which contains $x_j$ copies of each set $S_j$. Every $i \in [n]$ appears in at least $a$ sets of $S'$, and $|S'| \leq rak$. (These are both counted with multiplicity). Thus, by Proposition B.2 after polynomial time we find a set cover $S'' \subseteq S'$ of size at most

$$|S''| \leq rak(1 - (ed)^{-1/(a-1)})$$

Note that although $S'$ is a multi-set, we can take $S''$ to be an ordinary set (and, in particular, a solution to the original set cover instance).

By Theorem 5.1 we must have $ra(1 - (ed)^{-1/(a-1)}) \geq \ln d - c \ln \ln d$. \qed

**Proposition 5.4.** Assuming $P \neq NP$, suppose that a polynomial-time algorithm to approximate CIP without multiplicity constraints guarantees an approximation ratio $f(\gamma)$, where $f$ is an increasing function. Then for all $\gamma > 0$ we have

$$f(\gamma) \geq \frac{\gamma}{1 - e^{-\gamma}}$$

**Proof.** For every integer $a \geq 2$ and $d = \lfloor e^{a\gamma} \rfloor$, Proposition 5.3 shows

$$f(\gamma) \geq f\left(\frac{\ln d}{a}\right) \geq \frac{\ln d - c \ln \ln d}{a(1 - (ed)^{-1/(a-1)})} \geq \frac{\ln(e^{a\gamma} - 1) - c \ln(e^{a\gamma})}{a(1 - (e^{a\gamma} + 1)^{-1/(a-1)})}$$

Since this holds for every integer $a \geq 2, f(\gamma)$ must be at least equal to the limit of the RHS as $a \to \infty$, which is $\frac{\gamma}{1 - e^{-\gamma}}$. \qed
Note that \( f(\gamma) \geq \max(1 + \gamma/2, \gamma) \). To our knowledge, this is the first non-trivial hardness result in the regime \( \gamma \approx 0 \); previous works show, for instance, approximation ratios or integrality gaps of the form \( \Omega(\gamma) \), which is of course vacuous when \( \gamma \approx 0 \). Note in particular that the bound of Theorem 3.1 is optimal to first order (as a function of \( \gamma \)) as \( \gamma \to \infty \), and is off by a polynomial factor (as a function of \( \gamma \)) as \( \gamma \to 0 \).

5.2 Integrality gaps

We next show a variety of integrality gaps for the basic LP. These constructions work as follows: we give a CIP instance, an upper bound on the weight of the fractional solution \( \hat{T} \) for the basic LP, and a lower bound on the weight of any integral solution \( T \). This implies that any algorithm which starts from the basic LP solution must cause the weight to increase by at least \( T/\hat{T} \). These integrality gaps are all adapted from a well-known folklore result on the integrality gap of set cover.

**Theorem 5.5 (Folklore).** For any \( \delta > 0 \) and \( m \) sufficiently large, there are set cover instances on ground set \([m]\) where the basic LP has integrality gap \((1 - \delta) \ln m\).

The construction is based on forming the sets \( S \) randomly. For the sake of completeness, we prove a (slightly more precise) form of Theorem 5.5 in Appendix C. Please also see [24] for an explicit construction with integrality gap \( \Omega(\ln m) \).

**Proposition 5.6.** For any integer \( a \geq 2 \) there is a CIP instance on \( m \) constraints which share a common RHS value \( a \), where the basic LP has integrality gap at least

\[
\frac{\ln m - C \ln \ln m}{a(1 - (em)^{-1/(a-1)})}
\]

for a universal constant \( C \).

**Proof.** Consider the set cover instance \( S \) of Theorem C.1 with optimal integral solution \( T \) and fractional solution \( \hat{T} \) where \( T/\hat{T} \geq \ln m - O(\ln \ln m) \). Form the corresponding CIP instance \( I \), in which the RHS value is set to \( a \) instead of 1. The optimal fractional solution value is precisely \( \hat{T}' = a\hat{T} \).

Suppose that \( I \) has an optimal integral solution \( S' \) of weight \( T' \). This solution can be viewed as a multiset which covers every element in the ground set at least \( a \) times. By Proposition 3.2 this implies \( S \) itself has a subcover of size at most

\[
t = T'(1 - \frac{1}{1 - (em)^{-1/(a-1)}})
\]

(Here, we are using the trivial bound, that each set has size at most \( m \).)

Since \( t \geq T \), we must have

\[
\frac{T'}{T} \geq \frac{T}{(1 - (em)^{-1/(a-1)})aT} \geq \frac{\ln m - O(\ln \ln m)}{a(1 - (em)^{-1/(a-1)})}
\]
Note that the integrality gap is of order \( \max(\gamma, 1 + \gamma/2) \) (for large enough values of \( m \)).

**Proposition 5.7.** Let \( \epsilon \in (0, 1) \) and \( a \geq 1 \) be an integer. For any \( \delta > 0 \) and \( m \) sufficiently large, there is a CIP instance on \( m \) constraints which share a common RHS value \( a \) and a parameter \( d \geq 0 \) such that the fractional solution \( \hat{x} \in [0, d]^n \) has objective value \( \hat{T} \), the optimal integral solution in \( x \in \{0, 1, \ldots, \lfloor (1 + \epsilon)d \rfloor \}^n \) has objective value \( T \), and

\[
T/\hat{T} \geq \frac{\ln m - O(\ln \ln m)}{ae} \geq \Omega(\gamma/\epsilon)
\]

**Proof.** Let \( \mathcal{S} = \{S_1, \ldots, S_n\} \) be the set cover instance of Theorem 5.5 on ground set \([m]\). Form the CIP instance \( A \) on \( n + m \) variables, wherein for each \( k \in [m] \) we have a constraint

\[
aK(1 + \epsilon) + 1 x_{n+k} + \sum_{i \in [n], S_i \ni k} x_i \geq a
\]

The objective function we use is \( C \cdot x = \sum_{i=1}^n x_i \); that is, each variable \( x_1, \ldots, x_n \) has weight one, and each variable \( x_{n+1}, \ldots, x_{n+m} \) has weight zero. We set \( d_i = \infty \) for \( i = 1, \ldots, n \) and we set \( d_i = K \) for \( i = m + 1, \ldots, m + n \); here \( K \) is an arbitrarily large integer parameter (In particular, for \( K \) sufficiently large, all the coefficients in this constraint are in the range \([0, 1]\)).

Suppose now that \( \hat{z}_1, \ldots, \hat{z}_n \) is an optimal fractional solution to the basic LP of \( \mathcal{S} \). Then let \( v = \frac{a(1+\epsilon K)}{1+(1+\epsilon)K} \) and consider the fractional solution \( \hat{x} \) defined by

\[
\hat{x}_i = \begin{cases} v \hat{z}_i & \text{if } i \leq n \\ K & \text{if } n+1 \leq i \leq n+m \end{cases}
\]

For any constraint \( k \) we have

\[
\frac{a}{K(1 + \epsilon) + 1} \hat{x}_{m+k} + \sum_{S_i \ni k} \hat{x}_i = \frac{a}{K(1 + \epsilon) + 1} K + v \sum_{S_i \ni k} \hat{z}_i \geq \frac{a}{K(1 + \epsilon) + 1} K + v = a
\]

and so \( \hat{x} \) is a valid fractional solution to \( A \); its objective function is \( \hat{T} \leq \sum_{i=1}^n v \hat{x}_i = v \hat{T}' \), where \( \hat{T}' \) is the optimal fractional solution to the basic LP of \( \mathcal{S} \).

On the other hand, consider an integral solution \( x \) to \( A \). As \( x_{m+k} \leq \lfloor (1 + \epsilon)K \rfloor \), every \( k \in [m] \) satisfies:

\[
\frac{a}{K(1 + \epsilon) + 1} (1 + \epsilon)K + \sum_{S_i \ni k} x_i \geq a
\]

which implies that \( \sum_{S_i \ni k} x_i > 0 \). Since \( x \) is integral, this implies that \( x \) is a solution to \( \mathcal{S} \). Thus, \( T \geq T' \), where \( T' \) is the optimal integral solution to \( \mathcal{S} \).

So \( T/\hat{T} \geq \frac{T'}{v \hat{T}'} \geq \frac{\ln m - O(\ln \ln m)}{ae} \). Taking the limit as \( K \to \infty \), we see that the integrality gap is at least \( \frac{\ln m - O(\ln \ln m)}{ae} \) for \( K \) sufficiently large. \( \square \)
6 Negative correlation for RELAXATION

We will show that the values of $x$ produced by the RELAXATION algorithm obey a type of negative correlation property. Our main result will be the following:

**Theorem 6.1.** Suppose $x \in [0, 1/\alpha)^n$ and $\alpha > \frac{-\ln(1-\sigma)}{\sigma}$. For any $R \subseteq [n]$, we have

$$P(\bigwedge_{i \in R} x_i = 1) \leq \prod_{i \in R} \rho_i$$

where we define the vector $\rho \in [0, \infty)^n$ by

$$\rho_i = \alpha \hat{x}_i \left(1 + \sum_k A_{ki} \left(1 - \sigma \sum_{a_k \in \sigma A_k} A_k \cdot \hat{x} - 1\right) \right)$$

We will show this via a type of “witness” construction, similar to Lemma 2.2; however, instead of providing a witness for the event that $x_i = 1$, we will provide a witness for the event that simultaneously $x_i = \cdots = x_s = 1$.

For any variable $i$, only one of the following cases hold: $x_i = 1$ at the initial sampling, $x_i$ first becomes equal to one during some resampling of a constraint $k$, or $x_i = 0$ at the end of the algorithm. If $x_i = 1$ for the first time at the $j^{th}$ resampling of constraint $k$, we say $i$ turns at $(k, j)$. If $x_i = 1$ initially, we say that $i$ turns at 0.

Suppose we are given any set $I \subseteq [n]$, any integers $J_1, \ldots, J_m \geq 0$, and an array of sets $Z = \langle Z_{k,j} \mid k = 1, \ldots, m, j = 1, \ldots, J_k \rangle$. We define the event $E(I, J, Z)$ to be the following:

1. For each $k = 1, \ldots, m$, the first $J_k$ resampled sets for constraint $k$ are respectively $Z_{k,1}, \ldots, Z_{k,J_k}$
2. Each $i \in I$ turns at 0 or some $(k, j)$ where $1 \leq j \leq J_k$.

Let us set $p_i = \alpha \hat{x}_i$ and $q_i = 1 - p_i$. We similarly define the event $E(I, J, Z, v)$ for any $v \in \{0, 1\}^n$ to be that the event $E(I, J, Z)$ occurs, if we start the RELAXATION algorithm by setting $x = v$ (instead of drawing $x$ as independent Bernoulli($p_i$)), and the event $E(T, I, J, Z, v)$ to be the event that $E(I, J, Z, v)$ occurs and the RELAXATION algorithm terminates in less than $T$ resamplings.

Given any integers $J_1, \ldots, J_k$, we define $\text{prefix}(J)$ to be the set of all pairs $(k, j)$ where $1 \leq j \leq J_k$.

**Proposition 6.2.** Suppose that $x_i \in [0, 1/\alpha)^n$. Let $v \in \{0, 1\}^n$, $I \subseteq [n]$, and $J, Z$ be given. Then

$$P(E(I, J, Z)) \leq \prod_{i \in I} p_i \prod_{(k, j) \in \text{prefix}(J)} f_k(Z_{k,j})$$

Proof. Let us define $D = \bigcup_{(k, j) \in \text{prefix}(J)} Z_{k,j}$. We prove by induction on $T$ that for any $T \geq 0$ we have

$$P(E(T, I, J, Z, v)) \leq \prod_{i \in I \cap D} p_i \prod_{(k, j) \in \text{prefix}(J)} f_k(Z_{k,j}) \prod_{i \in D} q_i$$
A few details of the proof which are identical to Lemma 2.2 are omitted for clarity.

Let \( k \) be minimal such that \( A_k \cdot x < a_k \). If \( J_\ell \geq 1 \) for any \( \ell < k \) then the event \( \mathcal{E}(T, I, J, Z, v) \) is impossible and we are done. If \( J_k = 0 \), then \( \mathcal{E}(T, I, J, Z, v) \) is equivalent to \( \mathcal{E}(T - 1, I, J, Z, x') \) where \( x' \) is the value of the variables after a resampling; for this we use the induction hypothesis and we are done.

So suppose \( J_k \geq 1 \). Define \( D' = \bigcup_{(k',j') \in \text{prefix}(J)} Z_{k',j'} \). Then the following are necessary events to have \( \mathcal{E}(T - 1, I, J, Z, x') \):

(C1) \( Z_{k,1} \) is selected as the resampled set for constraint \( k \)

(C2) The event \( \mathcal{E}(T - 1, I', J', Z', x') \) occurs, where \( x' \) is the value of the variables after resampling, where \( I' = I \cap D' \), and \( J', Z' \) are derived by setting \( J_k' = J_k - 1 \) and by \( Z_{k,1}', \ldots, Z_{k,J_k-1}' = Z_{k,2}', \ldots, Z_{k,J_k}' \) (and all other entries remain the same)

(C3) For all \( i \in (Z_{k,1} - D') \cap I \) we resample \( x_i = 1 \)

(C4) For all \( i \in Z_{k,1} \cap D' \) we resample \( x_i = 0 \)

The rationale for (C3) is that we require \( i \in I \) to turn at some \((k',j') \in \text{prefix}(J)\), and in addition \( Z_{k',j'} \) is the \( j'^{th} \) resampled set for constraint \( k' \). This would imply that \( i \in Z_{k',j'} \). However, there is only one such \((k',j')\), namely \((k',j') = (k,1)\). Thus, we are requiring \( i \) to become resampled to \( x_i = 1 \).

The rationale for (C4) is the same as in Lemma 2.2 if we resample \( x_i = 1 \), then \( x_i \) can never be resampled again. In particular, we cannot have \( i \) in any future resampled set. Thus if \( x_i' = 1 \) but \( i \in Z_{k,1} \cap D' \), then the event (C2) is impossible.

As in Lemma 2.2 the event (C1) has probability \( (1 - \sigma)^{a_k} \prod_{i \in [n]} (1 - A_{ki} \sigma) \prod_{i \in Z_{k,1}} \frac{A_{ki} \sigma}{1 - A_{ki} \sigma} \).

Event (C3), conditional on (C1), has probability \( \prod_{i \in (Z_{k,1} - D') \cap I} p_i \).

Event (C4), conditional on (C1), (C3), has probability \( \prod_{i \in Z_{k,1} \cap D'} q_i \).

By induction hypothesis, event (C2), conditional on (C1), (C3), (C4), has probability

\[
P((C2)) \leq \prod_{i \in I - D'} p_i \times \prod_{i \in D'} q_i \times \prod_{(k',j') \in \text{prefix}(J')} f_{k'}(Z_{k',j'})
\]

Multiplying these probabilities, after some rearrangement, gives us the desired bound on \( P(\mathcal{E}(T, I, J, Z, v)) \), thus completing the induction. This immediately gives

\[
P(\mathcal{E}(I, J, Z, v)) = \lim_{T \to \infty} P(\mathcal{E}(T, I, J, Z, v)) \leq \prod_{i \in I - D} p_i \times \frac{\prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j})}{\prod_{i \in D} q_i}
\]

Finally, to obtain a bound on \( P(\mathcal{E}(I, J, Z)) \), we observe that if \( i \in D \), then \( x_i \) must be equal to zero during the initial sampling. Also, if \( i \in I - D \), then \( x_i \) must be equal to one during the initial
sampling. This has probability \( \prod_{i \in I - D} p_i \prod_{i \in D} q_i \). Conditional on this event, \( P(\mathcal{E}(I, J, Z, x)) \leq \prod_{i \in I - D} p_i \times \prod_{\substack{(k,j) \in \text{prefix}(J) \\&\\ f_k(Z_{k,j})}} \prod_{i \in D} q_i \). Thus, multiplying the probabilities together,

\[
P(\mathcal{E}(I, J, Z)) \leq \prod_{i \in I} p_i \prod_{\substack{(k,j) \in \text{prefix}(J)}} f_k(Z_{k,j})
\]

\[\square\]

**Proposition 6.3.** Let \( R \subseteq [n] \). Suppose that at the end of the RELAXATION algorithm we have \( x_i = 1 \) for all \( i \in R \). Then there is a set \( R' \subseteq R \) and an injective function \( h : R' \to [m] \), as well as non-negative integers \( J_1, \ldots, J_m \) and sets \( Z_{k,j} \) for \( j = 1, \ldots, J_k \) which satisfy the following properties:

(D1) Each \( i \in R' \) has \( J_{h(i)} \geq 1 \) and \( i \in Z_{h(i), J_{h(i)}} \)

(D2) Each \( k \notin h(R') \) has \( J_k = 0 \)

(D3) Each \( i \in R \) turns at either 0 or at some \( (k, j) \in \text{prefix}(J) \).

**Proof.** Let \( S_0 \subseteq R \) denote the set of variables \( i \in R \) which turn at 0. For each \( k = 1, \ldots, m \) let \( S_k \subseteq R \) denote the variables \( i \in R \) which turn at constraint \( k \), where each \( i \in S_k \) turns at \( (k, L_i) \). The sets \( S_0, S_1, \ldots, S_m \) partition \( R \).

Now for each \( k = 1, \ldots, m \) we define \( J_k = \max_{i \in S_k} L_i \) and form the set \( R' \) by selecting, for each \( k \in [m] \) with \( S_k \neq \emptyset \), exactly one \( i \in S_k \) with \( L_i = J_k \) (there may be more than one; in which case we select \( i \) arbitrarily). We define \( f \) by mapping this \( i \in S_k \) to \( k \).

Note that we must have \( i \in Z_{h(i), J_{h(i)}} \), as we are assuming that \( L_i = J_k \) where \( k = h(i) \).

Also, each \( i \in S_k \) must turn at \( (k, L_i) \) and \( L_i \leq J_k \), thus (D3) is satisfied. \(\square\)

We are now ready to prove our main result.

**Proof of Theorem 6.1.** By Proposition 6.3, there exist \( R', h, Z_{k,j}, J \) satisfying (D1), (D2), (D3). Lemma 6.2 shows that for any \( Z, J \) satisfying (D1), (D2), condition (D3) holds with probability at most \( \prod_{i \in R} p_i \prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j}) \). Taking a union bound over all such \( J, Z_{k,j} \) gives

\[
P(\bigwedge_{i \in R} x_i = 1) \leq \sum_{\substack{R', h, Z, J \\text{satisfying (D1), (D2)}}} \prod_{i \in R} p_i \prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j}) \tag{4}
\]

We must enumerate over all \( R', h, Z, J \) satisfying (D1), (D2). Suppose now that \( R' \) and \( h \) are fixed. To simplify the notation, suppose without loss of generality that \( R' = \{1, \ldots, r\} \). We now consider the following process to enumerate over \( Z, J \):

1. We select any vector of integers \( J' \in \mathbb{Z}_r^+ \), and sets \( Z'_{i,j} \) where \( j \leq J'_i \).
2. For each \( i \in R' \), we select a set \( W_i \subseteq [n] \) with \( i \in W_i \).

3. We define \( J \) by \( J_{h(i)} = J'_i + 1 \) for \( i = 1, \ldots, r \), and all other value of \( J \) are equal to zero. Also for \( j = 1, \ldots, J'_i \) we set \( Z_{h(i),j} = Z'_i, j \) and finally \( Z_{h(i),J'_i+1} = W_i \).

For a fixed \( R', h \) this process enumerates every \( Z, J \) satisfying (D1), (D2) exactly once. Furthermore, for any \( J', Z', W \), we have

\[
\prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j}) = \sum_{W_1 \supseteq 1, \ldots, W_r \supseteq i \in R'} \prod_{i=1}^r J'_i \prod_{i,j} f_h(i) \prod_{i \in R'} f_k(Z_{k,j})
\]

Summing over possible values for \( Z', J', W \) gives:

\[
\sum_{Z, J \text{ satisfying (D1), (D2)}} \prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j}) = \prod_{i=1}^r (\sum_{W \subseteq [n], W \supseteq i} f_h(i) \sum_{j' \geq 0} Z_{h(i),1, \ldots, J_{h(i),\ell}} f_{k(i)}(Z_{k(i),\ell}))
\]

\[
\leq \prod_{i=1}^r s_{h(i)} A_{h(i),i} \times \sum_{j' \geq 0} (s_{h(i)})^{j'} \quad \text{(Propositions 2.3, 2.4)}
\]

\[
= \prod_{i \in R'} \frac{s_{h(i)} A_{h(i),i}}{1 - s_{h(i)}}
\]

Summing over \( R' \subseteq R \) and injective \( h : R' \to [m] \) gives:

\[
\sum_{R', h, Z, J \text{ satisfying (D1), (D2)}} \prod_{i \in R} p_i \prod_{(k,j) \in \text{prefix}(J)} f_k(Z_{k,j}) \leq \prod_{i \in R} p_i \sum_{R' \subseteq R \text{ injective } h : R' \to [m]} \prod_{i \in R'} \frac{s_{h(i)} A_{h(i),i}}{1 - s_{h(i)}}
\]

\[
\leq \prod_{i \in R} p_i \sum_{R' \subseteq R \text{ injective } h : R' \to [m]} \prod_{i \in R'} \frac{s_{h(i)} A_{h(i),i}}{1 - s_{h(i)}}
\]

\[
= \prod_{i \in R} p_i (1 + \sum_{k=1}^m \frac{s_{k} A_{k,i}}{1 - s_{k}}) = \prod_{i \in R} p_i
\]

\[\square\]

### 6.1 Multiple Objective Functions

One may extend the CIP framework, so that instead of a single linear objective, we have multiple objectives \( C_1 \cdot x, \ldots, C_r \cdot x \). We also may have some over-all objective function \( D \) which combines them; for example, we might have \( D = \max_{\ell} C_{\ell} \cdot x \) or we might have \( D = \sum_{\ell} (C_{\ell} \cdot x)^2 \).

We note that the greedy algorithm, which is powerful for set cover, is not obviously useful in this case. However, depending on the precise form of the function \( D \), it may be possible to solve the
fractional relaxation to optimality. For example, if $D = \max_{\ell} C_\ell \cdot x$, then this amounts to a linear program of the form $\min t$ subject to $C_1 \cdot x \leq t, \ldots, C_r \cdot x \leq t$.

For our purposes, the algorithm used to solve the fractional relaxation is not relevant. Suppose we are given some solution $\hat{x}$. We now want to find a solution $x$ such that simultaneously $C_\ell \cdot x \approx C_\ell \cdot \hat{x}$ for all $\ell$. Showing bounds on the expectations alone is not sufficient — it might be the case that $E[C_\ell \cdot x] \leq \beta C_\ell \cdot \hat{x}$, but the random variables $C_1 \cdot x, \ldots, C_r \cdot x$ are negatively correlated.

Srinivasan, in [22], gave a randomized rounding scheme to provide this simultaneous approximation guarantee. The randomized rounding, by itself, succeeded with exponentially small probability; Srinivasan also described how to derandomize the process in time $O(n^{\log r})$; this derandomization unfortunately caused a loss to the resulting approximation ratio and was only polynomial-time for constant $r$.

Our strategy in this case will be to use the negative correlation result to show a concentration of the quantities $C_\ell \cdot x$. This will establish that there is a good probability that $C_\ell \cdot x \approx E[C_\ell \cdot x]$ for all $\ell = 1, \ldots, r$. Thus, our algorithm automatically gives good approximation ratios for multi-criteria problems; the ratios are essentially the same as for the single-criterion setting, and there is no extra computational burden.

These concentration bounds are similar to Chernoff bounds, which we define next.

**Definition 6.4 (The Chernoff upper-tail).** For $t \geq \mu$ with $\delta = \delta(\mu, t) = t/\mu - 1 \geq 0$, the Chernoff upper-tail bound is defined as

$$C\text{hernoff-}U(\mu, t) = \left(\frac{e^\delta}{(1 + \delta)^{1 + \delta}}\right)^\mu$$

(5)

That is to say Chernoff-$U(\mu, t)$ is the Chernoff bound that a sum of $[0, 1]$-bounded and independent random variables with mean $\mu$ will be above $t$.

**Theorem 6.5.** Let $C \in [0, 1]^n$, let $\hat{x} \in [0, \infty]^n$ be a solution to the CIP instance, and let $\alpha > -\frac{\ln(1-\sigma)}{\sigma}$ for $\sigma \in [0, 1]$. Then, after running the Rounding algorithm,

$$P(C \cdot x > t) \leq C\text{hernoff-}U(C \cdot \rho, t)$$

Proof. Letting $v_i, G_i, \hat{x}_i, a_k', x'$ be the variables which occur during the Rounding algorithm, we have

$$P(C \cdot x > t) = P(C \cdot (v\theta + G + x') > t) = P(C \cdot x' > t - C \cdot (v\theta + G))$$

Let $\rho'$ be the vector corresponding to the $\hat{x}' \in [1, 1/\alpha]^n$. The value of $C \cdot x'$ is a sum of random variables $C_i x'_i$, each of which is in the range $[0, 1]$. These random variables obey a negative-correlation property as shown in Theorem 6.11. This implies that they obey the same upper-tail Chernoff bounds as would a sum of random variables $X_i$ which are independent and satisfy $E[X_i] = \rho'_i$. Therefore,

$$P(C \cdot x' > t - C \cdot (v\theta + G)) \leq C\text{hernoff-}U(C \cdot \rho', t - C \cdot (v\theta + G))$$

Thus,

$$P(C \cdot x > t) \leq C\text{hernoff-}U\left(\alpha \sum_i C_i \hat{x}_i (1 + \sigma \sum_k \frac{A_{ki}}{(1 - \sigma a_k e^{\sigma A_k \hat{x}_i}}), t - C \cdot (v\theta + G)\right)$$

(6)
The function Chernoff-U(\(\mu, t\)) is always an increasing function of \(\mu\). So we can show an upper bound for this expression by giving an upper bound for the \(\mu\) term in the (6). We first apply Propositions 2.6 and 2.7 to give:

\[
x'_i \left(1 + \sigma \sum_k \frac{A_{ki}}{(1 - \sigma)\sigma_k e^{\sigma_k A_k} x'_i - 1}\right) \leq (\hat{x}_i - v_i \theta - G_i/\alpha) T_i
\]

where we define

\[
T_i = 1 + \sigma \sum_k \frac{A_{ki}}{(1 - \sigma)\sigma_k e^{\sigma_k A_k} - 1}
\]

Substituting this upper bound into (6) yields:

\[
P(C \cdot x > t) \leq \text{Chernoff-U}\left(\alpha \sum_i C_i(\hat{x}_i - v_i \theta - G_i/\alpha) T_i, t - C \cdot (v \theta + G)\right)
\]

\[
\leq \text{Chernoff-U}\left(\sum_i C_i(\rho_i - (v_i \alpha \theta + G_i)), t - C \cdot (v \theta + G)\right)
\]

\[
\leq \text{Chernoff-U}\left((C \cdot \rho) - (C \cdot (v \theta + G)), t - (C \cdot (v \theta + G))\right)
\]

\[
\leq \text{Chernoff-U}(C \cdot \rho, t) \quad \text{(as Chernoff-U}(\mu, t) \leq \text{Chernoff-U}(\mu - x, t - x))
\]

\[\square\]

**Corollary 6.6.** Suppose we are given a covering system as well as a fractional solution \(\hat{x}\). Suppose that the entries of \(C_\ell\) are in \([0, 1]\). Then, with an appropriate choice of \(\sigma, \alpha\) we may run the ROUNDEL algorithm in expected time \(O(mn)\) to obtain a solution \(x \in \mathbb{Z}^n_+\) such that

\[
P(C_\ell \cdot x > t) \leq \text{Chernoff-U}(\beta C_\ell \cdot \hat{x}, t)
\]

for \(\beta = 1 + \gamma + 10 \ln(1 + \sqrt{\gamma})\).

A Comparison with the Lovász Local Lemma

One rounding scheme that has been used for similar types of integer programs is based on the Lovász Local Lemma (LLL); we contrast this with our approach taken here.

The LLL, first introduced in [8], is often used to sample a rare combinatorial structure from a probability space. In the basic form of randomized rounding, one must ensure that the probability of a “bad-event” (an undesirable configuration of a subset of the variables) — namely, that $A_k \cdot x < a_k$ — is on the order of $1/m$; this ensures that, with high probability, no bad events occur. This accounts for the term $\log m$ in the approximation ratio. The power of the LLL comes from the fact that the probability of a bad-event is not compared with the total number of events, but only with the number of events it affects. Thus, one may obtain approximation ratios which are independent of $m$. At a heuristic level, the LLL should apply to the CIP problem. CIP has a bad-event corresponding to each covering constraint. Furthermore, because of our assumption that the system is column-sparse, each variable only affects a limited number of these bad-events. Thus, it should be possible to use the LLL to obtain a scale-free approximation ratio.

There has been prior work applying the LLL to packing integer programs, such as [17]. One technical problem with the LLL is that it only depends on whether bad-events affect each other, not the degree to which they do so. Bad-events which are only slightly correlated are still considered as dependent by the LLL. Thus, a weakness of the LLL for integer programs with arbitrary coefficients (i.e. allowing $A_{ki} \in [0,1]$), is that potentially all the entries of $A_{ki}$ could be extremely small yet non-zero, causing every constraint to affect each other by a tiny amount. For this reason, it is more straightforward to obtain approximation ratios in terms of $\Delta_0$ as opposed to $\Delta_1$. In [13], Harvey addressed this technical problem by applying a careful, multi-step quantization scheme with iterated applications of the LLL, to discrepancy problems with coefficient matrices where the $\ell_1$ norm of each column and each row is “small”. This multi-step process, however, invariably loses a constant factor in the approximation ratio. (For packing problems with no constraint-violation allowed, good approximations parametrized by $\Delta_0$, but not in general by $\Delta_1$, are possible [1].)
The LLL, in its classical form, only shows that there is a small probability of avoiding all the bad-events. Thus, it does not lead to efficient algorithms. In [19], Moser & Tardos solved this long-standing problem by introducing a resampling-based algorithm. This algorithm initially samples all random variables from the underlying probability space, and will continue resampling subsets of variables until no more bad-events occur. Most applications of the LLL, such as [13], would yield polynomial-time algorithms using this framework.

In the context of integer programming, the Moser-Tardos algorithm can be extended in ways which go beyond the LLL itself. In [12], Harris & Srinivasan described a variant of the Moser-Tardos algorithm based on “partial resampling”. In this scheme, when one encounters a bad-event, one only resamples a random subset of the variables (where the probability distribution on which variables to resample is carefully chosen). This was applied for “assignment-packing” integer programs with small constraint violation. These bounds, like those of [13], depend on $\Delta_1$.

It is possible to formulate the CIP problem in the LLL framework, and to view our algorithm as a variant of the Moser-Tardos algorithm. This would achieve qualitatively similar bounds, albeit with asymptotics which are noticeably worse than the ones we give here. In particular, using the LLL directly, one cannot achieve approximation factors of the form $1 + \gamma$ when $\gamma \to \infty$; one obtains instead an approximation ratio of $1 + c\gamma$ where $c$ is some constant strictly larger than one. The case when $\gamma \to 0$ is more complicated and there the LLL-based approaches appear to be asymptotically weaker by super-constant factors.

The technical core of the RELAXATION algorithm is an adaptation of the partial resampling MT algorithm of [12] combined with a methodology of [11] to yield improved probabilistic guarantees for LLL systems with correlated constraints. Because so many different problem-specific techniques and calculations are combined with a variety of LLL techniques, we view the connection with the LLL as more an informal motivation than a technical guide.

B Some technical lemmas

Proposition B.1. For $\gamma > 0$ and $a \geq 1$, we have

$$\alpha + (\alpha - 1) \frac{e^{a\gamma} - 1}{e^{a(\alpha - 1)} - \alpha - 1} \leq 1 + \gamma + 10 \ln(1 + \sqrt{\gamma})$$

where $\alpha = 1 + \gamma + 4 \ln(1 + \sqrt{\gamma})$

Proof. Let us first calculate $\frac{e^{a\gamma}}{e^{a(\alpha - 1)} - \alpha - 1}$:

$$\frac{e^{a\gamma}}{e^{a(\alpha - 1)} - \alpha - 1} = \left(e^{\gamma + \ln \alpha - (\alpha - 1)}\right)^a = \left(e^{\ln(1 + \gamma + 4 \ln(1 + \sqrt{\gamma})) - 4 \ln(1 + \sqrt{\gamma})}\right)^a$$

Simple analysis shows that $1 + \gamma + 4 \ln(1 + \sqrt{\gamma}) \leq (1 + \sqrt{\gamma})^4$, which (as $a \geq 1$) in turn shows that
this expression is less than one. Because of this fact, we can estimate
\[ \alpha + (\alpha - 1) \frac{e^{\alpha \gamma} - 1}{e^{\alpha(a-1)} - 1} \leq \alpha + (\alpha - 1) \frac{e^{\alpha \gamma}}{e^{\alpha(a-1)}} = \alpha + (\alpha - 1) \left( e^{\ln(1+\gamma+4\ln(1+\sqrt{\gamma})) - 4\ln(1+\sqrt{\gamma})} \right)^a \]
\[ \leq \alpha + (\alpha - 1) e^{\ln(1+\gamma+4\ln(1+\sqrt{\gamma})) - 4\ln(1+\sqrt{\gamma})} \]
\[ = 1 + \gamma + 4\ln(1+\sqrt{\gamma}) + \frac{(1 + \gamma + 4\ln(1+\sqrt{\gamma}))\gamma + 4\ln(1+\sqrt{\gamma})}{(1+\sqrt{\gamma})^4} \]

We now claim that
\[ \frac{(1 + \gamma + 4\ln(1+\sqrt{\gamma}))\gamma + 4\ln(1+\sqrt{\gamma})}{(1+\sqrt{\gamma})^4} \leq 6\ln(1+\sqrt{\gamma}) \]
which will show our claim. For, observe that
\[ \frac{(1 + \gamma + 4\ln(1+\sqrt{\gamma}))\gamma + 4\ln(1+\sqrt{\gamma})}{(1+\sqrt{\gamma})^4} \leq \frac{(1 + \gamma + 4\sqrt{\gamma})(\gamma + 4\sqrt{\gamma})}{(1+\sqrt{\gamma})^4} \]
and so it will suffice to show that \( f(\gamma) \leq 0 \), where \( f(\gamma) = \frac{(1+\gamma+4\sqrt{\gamma})(\gamma+4\sqrt{\gamma})}{(1+\sqrt{\gamma})^4} - 6\ln(1+\sqrt{\gamma}) \). We can compute the derivative \( f'(\gamma) \) as
\[ f'(\gamma) = \frac{-1 - \sqrt{\gamma} - 23\gamma - 14\gamma^{3/2} - 3\gamma^2}{(1+\sqrt{\gamma})^5\sqrt{\gamma}} \]
The numerator is a polynomial in \( \sqrt{\gamma} \) with integer coefficients, and so it can be algorithmically verified (e.g. by using the decidability of the first-order theory of real-closed fields) that it is negative. Since the denominator is clearly positive, it follows that \( f'(\gamma) \leq 0 \). So \( f(\gamma) \leq f(0) \). On the other hand, it is simple to verify that \( f(0) = 0 \).

**Proposition B.2.** Consider a set cover instance \( S \) with \( |S| = n \) on ground set \([m]\), in which the sets have size at most \( d \), and every \( i \in [m] \) appears in at least \( a \geq 2 \) sets. Then \( S \) has a solution of cardinality at most \( n(1 - (ed)^{-1/(a-1)}) \), which can be found via a deterministic polynomial-time algorithm.

**Proof.** View the set cover instance as a hypergraph \( H \) on vertex set \([m]\) with edge set \( S \). A solution to \( S \) is precisely an edge cover for the hypergraph \( H \). An edge cover of \( H \) corresponds to a vertex cover of the dual graph \( H' \), which in turn is the complement of an independent set of \( H' \).

The dual graph \( H' \) has \( n \) vertices, maximum degree \( d \) and minimum edge size \( a \). Therefore, as shown in [2], it has an independent set \( W \) of size \( |W| \geq \frac{n}{(d+a-1)} \), which can be found in deterministic polynomial time. Thus \( H' \) has a vertex cover of size \( n - |W| \).

To simplify this expression, we estimate this further:
\[ \left( \frac{d + 1/(a-1)}{d} \right) = \frac{d + 1/(a-1)}{d} \times \frac{d - 1 + 1/(a-1)}{d - 1} \times \ldots \times \frac{1 + 1/(a-1)}{1} \]
\[ \leq e^{\frac{1}{a-1}} e^{(d-1)/(a-1)} \ldots e^{\frac{1}{a-1}} = e^{\frac{1}{a-1}} \leq e^{\frac{1}{a-1}} = (ed)^{\frac{1}{a-1}} \]
C Proof of Theorem 5.5

In this section, we prove a slightly more precise form of Theorem 5.5:

**Theorem C.1.** For any \( m \geq 1 \) there is a set cover \( S \) instance on ground set \([m]\), with \( |S| = n = m \), and with integrality gap at least \( \ln m - c \log \log m \) for some universal constant \( c \geq 0 \).

**Proof.** We generate the collection \( S_1, \ldots, S_n \) randomly as follows: for each value \( i \in [m] \) we select exactly \( s \) positions \( a_1, \ldots, a_s \) uniformly at random in \([n]\) without replacement, and we add element \( i \) to the sets \( S_{a_1}, \ldots, S_{a_s} \). Here \( s = \lceil pn \rceil \), and \( n \to \infty \) and \( p \to 0 \) as functions of \( m \).

We can form a fractional solution \( \hat{x} \) by setting \( \hat{x}_j = 1/s \) for every \( j = 1, \ldots, n \). As each element \( i \in [m] \) appears in exactly \( s \) sets, this is a valid fractional solution. Thus, the optimal fractional solution value \( \hat{T} \) satisfies \( \hat{T} \leq n/s \leq 1/p \).

Now, consider a putative integral solution \( x \) of weight \( t \); we can view this as a \( t \)-element subset of \([n]\). For each \( i \in [m] \), there is a probability of \( \left( \frac{n-t}{s} \right) / \left( \begin{pmatrix} n \end{pmatrix} \right) \) that \( x \) does not cover element \( i \). Since the elements \( i \in [m] \) select their index sets independently, the total probability that \( x \) is a valid solution is at most

\[
(1 - \frac{\left( \frac{n-t}{s} \right)}{\begin{pmatrix} n \end{pmatrix}})^m \leq \exp(-m \frac{\left( \frac{n-t}{s} \right)}{\begin{pmatrix} n \end{pmatrix}}) \leq e^{-m \left( \frac{n-t}{s} \right)} \leq e^{-m(1-t/n)}
\]

To upper-bound the probability that \( S \) has a satisfying solution of weight \( t \), we take a union-bound over all such integral \( x \).

\[
P(S \text{ has a solution of weight } t) \leq \binom{n}{t} e^{-m(1-t/n)t} \leq e^{t \ln n - m(1-p)t^t + mt^2/n}
\]

If this expression is smaller than one, then with positive probability no such integral solution exists. Hence, we can ensure that all integral solutions satisfy \( T > t \). Now, some simple analysis shows that this approaches 0 when \( n = m, p = 1/\ln m \) and \( t = p^{-1}(\ln m - 10 \ln \ln m) \). Thus

\[
\frac{T}{\hat{T}} \geq \frac{p^{-1}(\ln m - 10 \ln \ln m)}{1/p} \geq \ln m - O(\log \log m)
\]

\( \square \)
