Quantum metrology is being gradually studied for weak measurement systems. For weak measurement systems with thermal state pointer, we find that in the displacement space corresponding to imaginary weak values, the maximal QFI after successful postselection can attain the level of thermal fluctuations, without surpassing total QFI, and that QFI which increases with increasing temperature can constantly improve the measurement precision. These results are much better than that of weak measurement with pure state (i.e., Gaussian state) pointer. On the other hand, in Kerr nonlinear interaction systems with weak measurement, and by using thermal state pointer, we obtain in the phase space successful postselection and postselected measurements both achieve the Heisenberg limit of quantum metrology, and show weak measurement with thermal states only obtain classical Fisher information (CFI) which increases with increasing temperature and achieves classical enhanced scaling of \( N^2 \). Moreover, weak measurement with thermal states has an advantage over that with coherent states or mixed states of the light because generating these states with more large uncertainty are limited under the current technology, but thermal states with more large uncertainly are very easy to achieve with increasing temperature in nature, regardless of thermal states of the light or the matter.

I. INTRODUCTION

Quantum metrology is committed to enhancing measurement precision and developing measurement techniques that give better precision than the same measurement performed in a classical framework, therefore, it has aroused substantial interest owing to its vital importance in physics and other sciences [1–10]. By now, for the estimation of a parameter \( \chi \) with a pointer state that contains on average \( N \) particles, a major way to improving measurement precision is by utilizing non-classical resources, such as quantum entanglement [11–13] and squeezed states [14–17], which indicate that an improved measurement precision can surpass the standard quantum limit (\( \delta \chi \propto 1/\sqrt{N} \)) or even achieves the Heisenberg limit (\( \delta \chi \propto 1/N \)). However, the difficulty in generating highly entangled states and fragility of such states is the open challenge to enhance measurement precision beyond classical techniques in practical applications. Moreover, whether quantum resource is essential for quantum enhanced precision. Recently, by considering photon coupling with coherent state pointer, the quantum Fisher information (QFI) can show a quantum scaling of \( N^2 \) [18], even without any quantum resources, and soon it was experimentally verified via coherent light as a pointer [19]. Meanwhile, for the mixed states with modulating the power of coherent light, measurement precision can theoretically attain Heisenberg scaling in weak measurement [20]. Thermal states are real classical states in nature, but they are not considered as the pointers in the original weak measurement protocol because their thermal fluctuations increase with temperature [21]. Therefore, in most weak measurement studies, the pure states (i.e., Gaussian states) are generally considered to be the pointers. However, we have shown that by using thermal states as the pointers can amplify weak measurement effect [22]. These results motivate us to pursue innovative precision metrology schemes.

In this paper, we study quantum metrology of thermal states based on weak measurement to bridge this gap. We show that in the displacement space corresponding to imaginary weak values, at weak measurement limit the maximal QFI after successful post-selection can attain the level of thermal fluctuations, without surpassing total QFI, that weak measurement with thermal states offer better precision relative to weak measurement with pure states (i.e., Gaussian states), and that as the temperature increases, QFI is also increased, thereby constantly improving the precision of parameter estimation. On the other hand, for Kerr nonlinear interaction systems with weak measurement, we surprisingly find that in the phase space successful postselection and postselected measurement can beat the standard quantum limit and achieve the Heisenberg limit of quantum metrology using classical resources, i.e., thermal states, that it is shown that weak measurement with thermal states only obtain classical Fisher information (CFI) increasing when temperature increases, and it has an advantage over weak
Suppose the initial system state is $\chi$, the system observable $A$, $\sigma$ is a system observable, $A \leq 0$. Then we consider the initial pointer state $|a_i\rangle = (\frac{\sin \frac{\theta}{2}}{\cos \frac{\theta}{2}}) = e^{\frac{i\pi}{2}}$, where $\sigma = \text{Boltzmann constant}$ and $z = e^{-\frac{\hbar}{k_B T}}$, where $k_B$ is the Boltzmann constant and $T$ is the temperature.

The evolution of the total system after an interaction $U(t) = e^{-i\chi A_q}$ is given by

$$\rho(z) = e^{-i\chi A_q}|\psi_i\rangle \langle \psi_i| \otimes \rho_{th}(z) e^{i\chi A_q}. \quad (2)$$

For Eq. (2), in momentum $p$ coordinate space we have

$$\rho^p(z) = \sum_{i,j=1,n=0}^{2,\infty} \int_{-\infty}^{\infty} \left(1 - z\right)^{2n} c_i^* c_j |a_i\rangle \langle a_j| G_n(p_i) \times G_n(p'_j)d\rho dp' \langle p|\langle p'|. \quad (3)$$

$$G_n(p_i) = H_n(\sqrt{2}\sigma p_i) \phi_0(p_i), \quad (4)$$

where $\phi_0(p_i) = (\frac{2\pi}{\sqrt{2\sigma}})^{-1/4} \exp(-\sigma^2 p_i^2)$ with $p_i = p + a_i \chi$ and $\sigma$ is zero point fluctuation, and $H_n$ is Hermite Polynomial.

Under this dynamics, each of the eigenstates $|a_i\rangle$ of the system observable $A$ is entangled with the pointer state wavefunctions, which is translated by the different $a_i \chi$ proportional to the eigenvalue $a_i$. When $|a_i - a_j\chi$ is much larger than the width $\sqrt{\frac{1+2}{\Delta^2}}$ of $\rho_{th}(z)$, this becomes a strong measurement, meaning that the overlap

$$O_{ij} := \left(\frac{1+z}{1-z}\right)^{-1/2} \sum_{i \neq j} \exp(4\sigma^2 p_i p_j - 2\sigma^2 (p_i^2 + p_j^2)) \langle 1 - z^2 \rangle |\phi_0(p_i) \phi_0(p_j) dp \quad (5)$$

between each pair of shifted wavefunctions is vanishingly small. So the pointer state corresponding to different eigenvalues becomes completely separated. However, when $|a_i - a_j\chi$ is relatively small and the wavefunctions are no longer well resolved, the measurement is said to be weak [27].

When the postselected state of the measured system

$$|\psi_n\rangle = \sum_{i=1}^{2} c_i^* |a_i\rangle$$

with $c_1 = \cos \frac{\theta}{2}$ and $c_2 = \sin \frac{\theta}{2}$ $(0 \leq \theta_f \leq \pi)$ is performed for the total system [34], then $\rho^p(z)$ reduces to

$$\rho^p(z) = \sum_{i,j=1,n=0}^{2,\infty} \int_{-\infty}^{\infty} c_i^* c_j^* \langle 1 - z \rangle^{2n} G_n(p_i) \times G_n(p'_j) d\rho dp' \langle p|\langle p'|. \quad (6)$$

After measuring the pointer in the $p$ basis, and using identity $\psi(p) = \int_{-\infty}^{\infty} \delta(p - p') \psi(p') dp'$, and Mehler’s Hermite Polynomial Formula $\sum_{n=0}^{\infty} H_n(x)H_n(y) \frac{z^n}{n!} = \exp[z(x+y)2 - z^2]$, the probability distribution of Eq. (6) over $p$ becomes

$$P_{wm}(p) = \frac{1}{P_n(2\pi \nabla^2)^{-1/2}} \exp[-\frac{(p + a_i \chi)^2}{2\nabla^2}]$$

$$- 2rt(e^{-i\varphi} + e^{i\varphi}) \exp[-\frac{(p + a_i - z a_j)^2}{4\nabla^2}]$$

$$\times - \frac{(p + a_i - z a_j)^2}{2\nabla^2}] + t^2 \exp[-\frac{(p + a_j \chi)^2}{2\nabla^2}], \quad (7)$$

where $r = \cos \frac{\theta_f}{2} \cos \theta_f, t = \sin \frac{\theta_f}{2} \sin \theta_f, \nabla^2 = \frac{1+2}{\Delta^2}$, and the probability of successful postselection is

$$P_{a} = r^2 + t^2 - 2rt \exp[-\frac{(a_i - a_j)^2 \chi^2 \Delta^2}{2}] \cos \varphi, \quad (8)$$

where $\Delta^2 = \frac{1+2}{\Delta^2}$.

After postselection measurement, in position $q$ coordinate space the reduced state of Eq. (2) is given by

$$\rho^q(z) = \sum_{i,j=1,n=0}^{2,\infty} \int_{-\infty}^{\infty} c_i^* c_j^* \langle 1 - z \rangle^{2n} G_n(q) \times G_n(q') \exp(-i\varphi q_i - a_i - a_j) dq dq' \langle q'|q\rangle, \quad (9)$$

$$G_n(q) = H_n(\frac{q}{\sqrt{2\sigma}}) \phi_0(q), \quad (10)$$

The structure of our paper is as follows. In Sec. II, we give a discussion of quantum metrology of weak measurement with a thermal state pointer, including precision measurement in the displacement space and the phase space. In Sec. III, we obtain the conclusion of the work.

II. QUANTUM METROLOGY OF WEAK MEASUREMENT WITH THERMAL STATE POINTER

1. Precision measurement in the displacement space

I. Weak measurement amplification model

In the standard scenario of weak measurement [21,22], the interaction Hamiltonian between the system and the pointer is (assuming $\hbar = 1$)

$$\hat{H} = h\chi(t) \hat{A} \otimes \hat{q}, \quad (1)$$

where $A$ is a system observable, $q$ is the position observable of the pointer and $A$ to be measured is usually a two-level system and the pointer is a continuous system. $\chi(t)$ is a narrow pulse function with interaction strength $\chi$. The structure of our paper is as follows. In Sec. II, we give a discussion of quantum metrology of weak measurement with a thermal state pointer, including precision measurement in the displacement space and the phase space. In Sec. III, we obtain the conclusion of the work.
where $\phi_0(q) = (2\pi\sigma^2)^{1/4}\exp(-\frac{q^2}{2\sigma^2})$.

After measuring the pointer in $q$ basis, the probability distribution of Eq. (9) over $q$ is given by

$$P_{wm}(q) = \frac{1}{P_r}(2\pi\Delta^2)^{-1/2}\exp[-\frac{q^2}{2\Delta^2}][r^2 - rt \times (\exp[i\varphi - i(a_2 - a_1)q] + \exp[i(a_2 - a_1)q - i\varphi]) + t^2].$$

When the postselection fails (with probability $P_r = 1 - P_a$), namely, the failing postselected state of the measured system $|\psi_r\rangle = \sum c_i|a_i\rangle$ with $c_1 = \sin\frac{\theta}{2}$ and $c'_2 = \cos\frac{\theta}{2}$ is performed for the total system (2), we calculate carefully and obtain the probability distribution of failing postselection in p basis

$$P_{wm}(p) = \frac{1}{P_r}(2\pi\Delta^2)^{-1/2}[r^2 \exp(-\frac{(p + a_1)q)^2}{2\Delta^2})]
+ 2r't'(e^{-i\varphi} + e^{i\varphi})\exp[-\frac{(p + a_2\sigma_4)q}{2\Delta^2})]
- \frac{(p + a_2\sigma_4)q}{2\Delta^2}) + t^2 \exp[-\frac{(p + a_2\sigma_4)q}{2\Delta^2})],$$
and the probability distribution of failing postselection in q basis

$$P_{wm}(q) = \frac{1}{P_r}(2\pi\Delta^2)^{-1/2}\exp[-\frac{q^2}{2\Delta^2}][r^2 + r't'
\times (\exp[i\varphi - i(a_2 - a_1)q] + \exp[i(a_2 - a_1)q - i\varphi]) + t^2],$$

where $r' = \cos\frac{\theta}{2}\sin\frac{\theta}{2}$ and $t' = \sin\frac{\theta}{2}\cos\frac{\theta}{2}$.

II. Metric

In the precision metrology, a parameter estimation interested can be given by the Fisher information (FI) [23], and it is functional on such conditional probability distributions, and is defined as follows

$$F_\chi[P(s|\chi)] = \int_{-\infty}^{\infty} \frac{(\partial_s P(s|\chi))^2}{P(s|\chi)}ds,$$

where $s$ represents $p$ or $q$. The sensitive estimate of an unknown parameter is given by the observed statistics [24], i.e., Cramer-Rao bound limits

$$Var(\chi) \geq \frac{1}{NF_\chi},$$

where $Var(\cdot)$ is a variance expression and $N$ is the number of independent trials.

If the postselected weak measurement is applied to the precision metrology of a parameter estimation, the whole process is called weak measurement amplification strategy (i.e., WMA strategy). Conversely, the standard strategy is when there is no weak measurement, and it refers to the benchmark measurement strategy completely ignoring the degree of freedom of the system. For Eq. (15), one traces over the degree of freedom of the system and measures the particle in $p$ basis to give

$$P_{wm}^{\text{std}}(p, z) = \sum_{i=1}^{2} |c_i|^2 \phi(p + a_i\chi),$$

where $\phi(p + a_i\chi) = (2\pi\Delta^2)^{-1/2}\exp[-(p + a_i\chi)^2/(2\Delta^2)].$

Substitute (15) into the FI formula (14) and applying the Cauchy-Schwarz inequality, the quantum Fisher information (QFI) of the joint system state before post-selection in the momentum $p$ coordinate space is

$$Q_j(p) = -\int_{-\infty}^{\infty} \sum_{i=1}^{2} |c_i|^2 \phi(p + a_i\chi)(p + a_i\chi)a_i^2 dp$$
$$\leq -\int_{-\infty}^{\infty} \sum_{i=1}^{2} |c_i|^2 a_i^2 \phi(p + a_i\chi)(p + a_i\chi)^2 dp$$
$$= -\sum_{i=1}^{2} |c_i|^2 a_i^2 \leq |a_i|^2 \nabla^2.$$

We let $F_\chi(P_{\text{std}}(p, z))$ take the maximum value of (17), i.e., $F_\chi(P_{\text{std}}(p, z)) = |a_i|^2 \nabla^2$. However, when $z = 0$, $F_\chi(P_{\text{std}}(p, z = 0)) = |a_i|^2 \nabla^2$, which shows the highest FI of pure Gaussian states in a standard strategy. It can be seen from Eq. (17) that in a standard strategy using pure Gaussian states give the higher estimate of an unknown parameter $\chi$ than using thermal states. Therefore, the use of thermal states in weak measurement has no advantage over the use of pure states in terms of conventional measurement. Here we use QFI of pure states as the benchmark in the standard strategy.

In the WMA strategy, the QFI can be divided into three parts, and $F_\chi^\text{tot} = F_\chi^a + F_\chi^q + F_\chi^p$ (see QFI derivation of [15], where $F_\chi^a$ and $F_\chi^q$ denote the QFI of successful postselection (accepted information) and failing postselection (rejected information) for weak measurement, respectively, and $F_\chi^p$ is classical FI for projective measurement. Since $F_\chi^\text{tot}(p) \leq Q_j(p)$ [15], and in the momentum $p$ coordinate space, $Q_j(p) \leq F_\chi(P_{\text{std}}(p, z = 0))$. Therefore, $F_\chi^\text{tot}(p) \leq Q_j(p) \leq F_\chi(P_{\text{std}}(p, z = 0))$. 

Substitute (11) and (13) into the FI formula (14), re-
spectively, in the position $q$ coordinate space,

$$F^a_Q(q) = \frac{-4r^2t^2}{P^2_a} \exp[-(a_2 - a_1)^2 \chi^2 \Delta^2] \cos^2 \varphi \Delta^4$$

$$\times (a_2 - a_1)^4 \chi^2 + \frac{r^2t^2}{P^2_r}(a_2 - a_1)^2 (2\pi \Delta^2)^{-1/2} \times \int_{-\infty}^{\infty} q^2 \exp(-\frac{q^2}{2\Delta^2})(4 - (\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q])^2) dq/|r^2$$

$$+ t^2 - rt(\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q]), \quad (19)$$

and

$$F^a_Q(q) = \frac{-4r^2t^2}{P^2_r} \exp[-(a_2 - a_1)^2 \chi^2 \Delta^2] \cos^2 \varphi \Delta^4$$

$$\times (a_2 - a_1)^4 \chi^2 + \frac{r^2t^2}{P^2_r}(a_2 - a_1)^2 (2\pi \Delta^2)^{-1/2} \times \int_{-\infty}^{\infty} q^2 \exp(-\frac{q^2}{2\Delta^2})(4 - (\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q])^2) dq/|r^2$$

$$+ t^2 - rt(\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q]). \quad (20)$$

Moreover,

$$F^P_Q = \frac{P^2_a}{P^2_r} + \frac{P^2_r}{P^2_r}$$

$$= \frac{4r^2t^2}{P^2_r} \exp[-(a_2 - a_1)^2 \chi^2 \Delta^2] \times \cos^2 \varphi \Delta^4(a_2 - a_1)^4 \chi^2. \quad (21)$$

Therefore,

$$F^\text{tot}_Q(q) = r^2t^2(a_2 - a_1)^2(2\pi \Delta^2)^{-1/2} \int_{-\infty}^{\infty} \exp(-\frac{q^2}{2\Delta^2})$$

$$\times q^2(4 - (\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q])^2) dq/|r^2 + t^2 - rt(\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q])$$

$$+ 1/|r^2 + t^2 - rt(\exp[i(a_2 - a_1)\chi q - i\varphi] + \exp[i\varphi - i(a_2 - a_1)\chi q])$$

$$\leq 4rt(a_2 - a_1)^2(2\pi \Delta^2)^{-1/2} \int_{-\infty}^{\infty} q^2 \exp(-\frac{q^2}{2\Delta^2})$$

$$= 4rt(a_2 - a_1)^2 \Delta^2, \quad (22)$$

and the equality holds up if and only if $\cos \theta_2 = \sin \theta_2$ and $\cos \theta_2 = \sin \theta_2$. Set the average number of thermal states $\langle n \rangle = \frac{1}{1-z}$, the maximal account of $F^\text{tot}_Q(q)$ can be rewritten as $(a_2 - a_1)^2(2(n) + 1)\sigma^2$. Thus, the scaling $q$ coordinate space, there is no information for the joint state $\{2\}$, i.e., $Q_j(q) = 0$. Indicate that the QFI of Eq. (19)-Eq. (22) in the position space originate in postselected measurement, that is, QFI in the position space can be generated as long as projective measurement occurs.

However, our interesting attention in this paper is the Cramer-Rao bound for the WMA strategy, and how it compares to that for the standard strategy. In the limit of $N \rightarrow \infty$, their ratio is equal to $P_aF^a_Q(p)$ and $P_aF^a_Q(q)$ to $F^\text{std}_x(F^\text{std}(p, z = 0))$, respectively. The formers are corrected by the probability of successful postselection.

III. Ideal detector

Here we consider a stable and ideal detector (i.e., without technical imperfection). In the WMA strategy, if choosing to measure in momentum space or position space, one will obtain the displacement proportional to the real part of weak values or one proportional to the imaginary part of weak values, respectively. The corresponding conditional probability distribution is given by (7) or (11). Then taking a ratio of the WMA strategy to the standard strategy, for (2) and (18) we give

$$\frac{P_aF^a_Q(p)(p,w_m)(p)}{F_x(P^\text{std}(p, z = 0))} = P_a \int_{-\infty}^{\infty} \frac{\partial P_{w_m}(p)}{P_{w_m}(p)} dp/|a_i|^2 \left(1 + \frac{1}{4\sigma^2}\right). \quad (23)$$

The numerator of (23) is QFI for the momentum’s displacement proportional to real weak values. Note that is no larger than QFI of the joint system state (9) without postselection [13], i.e., $Q_j(p) = |a_i|^2 \nu^{-2}$. However, in weak measurement limit, i.e., $\chi \sigma \rightarrow 0$, $P_a \int_{-\infty}^{\infty} \frac{\partial P_{w_m}(p)}{P_{w_m}(p)} dp$ is equal to $(\omega_1 - \omega_2)\nu^{-2}$. Therefore, $P_a \int_{-\infty}^{\infty} \frac{\partial P_{w_m}(p)}{P_{w_m}(p)} dp \leq \frac{1}{\nu^2}$, and the equality holds up if and only if $\cos \theta_2 = \sin \theta_2$ and $\cos \theta_2 = \sin \theta_2$. It is clear that QFI for real weak values space using thermal state pointer can be no advantage for the purpose of estimating $\chi$.

Multiplying Eq. (8) by Eq. (19), I further give

$$P_aF^a_Q(q) \leq \frac{-4r^2t^2\Delta^4(a_2 - a_1)^4 \chi^2}{P^2_a} \exp[-(a_2 - a_1)^2 \chi^2 \Delta^2] \times (1 + \exp[-(a_2 - a_1)^2 \chi^2 \Delta^2])^2$$

$$\leq 4rt(a_2 - a_1)^2(2\pi \Delta^2)^{-1/2} \int_{-\infty}^{\infty} q^2 \exp(-\frac{q^2}{2\Delta^2})$$

$$= 4rt(a_2 - a_1)^2 \Delta^2, \quad (24)$$

and the equality holds up if and only if $\cos \theta_2 = \sin \theta_2$ and $\cos \theta_2 = \sin \theta_2$. Here we only consider WMA strategy, $F^\text{tot}_Q(q) = P_aF^a_Q(q)$. In the weak measurement limit, defined as $\chi \Delta \rightarrow 0$, $P_aF^a_Q(q) = (a_2 - a_1)^2 \Delta^2(1 + \cos \varphi)$, and the maximum value is $(a_2 - a_1)^2 \Delta^2$ when $\varphi = 0$ or
2π, i.e., |ψi⟩ and |ψ̃i⟩ are completely orthogonal, but
P_r F_Q = 0 and F^P_r = 0. In the strong measurement
limit, when χΔ ≫ 1, P_a F^s_r (q) = (a_2 - a_1)^2 Δ^2 / 2,
and F^P_r (q) = (a_2 - a_1)^2 Δ^2 / 2, and F^P_r = 0. These results
are discussed in the context of imaginary weak values
space in weak measurement. It can be seen that when the
uncertainty of the pointer state Δ is fixed, the measure-
ment precision in weak measurement limit is no better
than that in strong measurement limit. However, when
the parameter χ is fixed, the measurement precision is
always better because using a pointer state with larger
Δ is determined by high temperature. Thus QFIs are all
proportional to (a_2 - a_1)^2 Δ^2.

However, for (24) and (18) we have
\[
\begin{align*}
P_a F_Q |P_{wm}(q)| \\
F_χ(F_{std}(p, z = 0)) 
&\leq \frac{(a_2 - a_1)^2}{|a_1|_m} \left(1 + \frac{z}{1 - z}\right) \left[-\frac{r^2 t^2}{P_a} \exp(-k^2)k^2 \cos^2 \varphi \right. \\
&\left. + \frac{1}{2} r t (1 + \exp(-k^2/2)(1 - k^2) \cos \varphi)\right],
\end{align*}
\] where k^2 = (a_2 - a_1)^2 χ^2 Δ^2, and the equality holds up
if and only if \cos \frac{P_a}{q} = \sin \frac{P_a}{q} and \cos \frac{P_a}{q} = \sin \frac{P_a}{q}. The
numberator of (25) is QFI for the position’s displacement
proportional to the imaginary weak values.

Suppose the eigenvalues \lambda_1 = 1, a_2 = -1, implying that \lambda_1 = \max, and θ_i = θ_j = π/2. In weak
measurement regime, i.e., k ≪ 1 and ϕ ≪ 1, for example,
k^2 = 0.0005 with z = 0, ϕ = 0.05, P_a F_Q |P_{wm}(q)| = 0.8327
and k^2 = 0.0095 with z = 0, ϕ = 0.05, P_a F_Q |P_{wm}(q)| = 3.9478.
Moreover, when ϕ = π/2, P_a F_Q |P_{wm}(q)| = 1 + \frac{z}{1 - z}/2. These results suggest that as
z grows, the ratio of (25) can exceed 1. In other words,
by adjusting the temperature, we can give a better esti-
mate of an unknown parameter χ. Therefore, the result
breaks the inequality constraint in [21, 33]
\[
P_{postselection} F_{weak value} \leq F_{standard},
\] where is the postselection success probability. It is obvi-
ous that postselected weak measurement using thermal
state pointer, corresponding to the displacement propor-
tional to imaginary weak values, can increase the mea-
surement precision.

2. Precision measurement in the phase space

We now consider a scenario that particle-number dis-
tribution. The initial state of the quantum system |ψi⟩
and one of the quantum pointer ρ_{th}(z) are both the same
as before, while let the observable of the pointer be ŵ.
Thus in the Hamiltonian of Eq. (1) we only use ŵ in
stead of ˆq, the other is unchanged.

After the interaction U(t) = e^{-iχ A_n} for the initial state
of the total system, its time evolution is given by
\[
\rho(z) = e^{-iχ A_n} |ψi⟩⟨ψ| ⊗ ρ_{th}(z)e^{iχ A_n}.
\] Using QFI of the pure state |λ_m⟩: F_{Q,m} = 4(|λ'_m|/|λ_m|)^2
with |λ'_m⟩ = ∂λ_m/∂χ, |λ_m⟩ = ∂/∂λ_m/∂χ, and the convexity of the QFI of the mixed state:
Q ≤ \sum m λ_m F_{Q,m}, we can obtain QFI of the joint state
\[
Q_j = (a_1 - a_2)^2 (2(ns + |n|) \sin^2 θ_i,
\]
where |n⟩ = \frac{1}{\sqrt{2}}. Q_j is the maximum amount of infor-

mation when θ_i = π/2, and proportional to quantum scal-
ing (∼ |n|^2). From the expression of Eq. (26), it can be seen
that θ_i = 0, π will never provide a better than clas-
sical scaling. These correspond to two cases, namely,
the largest of the eigenstates of A: |ψ⟩ = |a_1⟩ or |a_2⟩, P_a F_Q = 0,
P_r F_Q = 0, and F^P_r = 0. Thus, F^P_r = 0.

When the postselected state of the measured system
\[|ψ_a⟩ = \sum_{n=0}^{∞} c_n'|a_i⟩ \] with \[c_1' = \cos \frac{θ_i}{2} \text{ and } c_2' = -\sin \frac{θ_i}{2} \text{ is made for the total system (27), }\]
the reduced state of the pointer is ρ_{n}^s(z) = \sum_{m,n} Θ_{a,n} |m⟩_m |n⟩_m (unnormalized), where
\[
Θ_{a,n} = (1 - z)z^n [r^2 + t^2 - rt(e^{-i(\varphi + \chi(a_1 - a_2)n)} + e^{i(\varphi + \chi(a_1 - a_2)n)}].
\]
Using identity \[\frac{1}{1 - z} = \sum_{n=0}^{∞} z^n, \] the probability of successful
postselection is
\[
P_a = r^2 + t^2 - rt(e^{-i\varphi (1 - z)}/(1 - ze^{-i\chi(a_1 - a_2)})
+ e^{i\varphi (1 - z)}/(1 - ze^{i\chi(a_1 - a_2)})].
\]
Thus, we can give the normalized state by
\[
ρ_{n}^s(z) = \sum_{m,n} Θ_{a,n} |m⟩_m |n⟩_m.
\]
Since ρ_{n}^s(z) is a mixed state, and satisfies diagonalization
form as \[ρ = \sum_m λ_m |λ_m⟩⟨λ_m|, \] where \{|λ_m⟩\} forms
an orthogonality and complete basis, with λ_m being the
weight of |λ_m⟩. According to the well-known formula,
the QFI of the mixed state with λ_m ≠ 0 is given by (see
QFI derivation of [32, 33]
\[
F_Q = \sum_m (λ'_m/λ_m)^2 + \sum_m λ_m F_{Q,m} - \sum_{m \neq n} \frac{8λ_m λ_n}{λ_m + λ_n}
× |⟨λ_m|λ'_n⟩|^2.
\]
The first term is the classical Fisher information for the
probability distribution \[P(m|λ) = λ_m(λ). \] The sec-

4\langle |λ_m⟩|X_m⟩ - |λ_m⟩|X_m⟩|^2$ for each pure state in the subset \{|λ_m⟩\}, with $λ_m ≠ 0$. The last term reduces the QFI and hence the estimation precision below the pure state case.

Substitute (31) into the QFI formula (32), we have

$$F_Q^a = \sum_{n=0}^{\infty} \frac{\Theta_a^2}{P_a} - \frac{2\Theta_a^2 P_a^2}{p_a^2} + \frac{\Theta_a^2 p_a^2}{p_a^2}$$

$$= \frac{1}{P_a} \sum_{n=0}^{\infty} \left( \frac{\Theta_a^2}{p_a^2} - \frac{P_a^2}{p_a^2} \right) \quad (33)$$

where $θ_a' = \partial θ_a/∂χ$, $P_a' = ∂P_a/∂χ$, and $P_a' = \sum_{n=0}^{\infty} θ_a'$.

It can be easily seen that the FI in Eq. (33) is not QFI, but is described by the classical Fisher information (CFI) for the probability distribution $F_a$ in Eq. (33).

When the postselection fails (with probability $P_r = 1 - P_a$), namely, the failing postselected state of the measured system $|ψ_r⟩ = \sum_{i=1}^{2} c_i' |a_i⟩$ with $c_1' = \sin \frac{θ}{2}$ and $c_2' = \cos \frac{θ}{2}$ is performed for the total system (27), the reduced state of the pointer (normalized) is given by

$$ρ_r^p(z) = \sum_{n=0}^{\infty} \frac{θ_r}{P_r} |n⟩_m ⟨n|_m, \quad (34)$$

where

$$θ_r = (1 - z)z^n [r'^2 + t'^2 + rt(e^{i(φ+χ(a_1-a_2)n})$$

$$+ e^{-i(φ+χ(a_1-a_2)n)})] \quad (35)$$

with $r' = \cos \frac{θ}{2} \sin \frac{θ}{2}$ and $t' = \sin \frac{θ}{2} \cos \frac{θ}{2}$. Note that the failing postselection is not considered in the original scheme and often ignored in experiments. Hence, the CFI of the failing postselection is given by

$$F_Q^r = \sum_{n=0}^{\infty} \left( \frac{θ_r^2}{P_r} - \frac{2θ_r^2 P_r^2}{p_r^2} + \frac{θ_r^2 p_r^2}{p_r^2} \right)$$

$$= \frac{1}{P_r} \sum_{n=0}^{\infty} \left( \frac{θ_r^2}{p_r^2} - \frac{P_r^2}{p_r^2} \right) \quad (36)$$

where $θ_r' = ∂θ_r/∂χ$, $P_r' = ∂P_r/∂χ$, and $P_r' = \sum_{n=0}^{\infty} θ_r'$.

Obviously, the CFI after the projective measurement is given by (15)

$$F_Q^p = \frac{P_p^2}{P_a} + \frac{P_r^2}{P_r}, \quad (37)$$

As $χ → 0$, $F_Q^p = \frac{4(a_1-a_2)^2}{1-(1-r^2+2t^2+2rt \cos ϕ)}(n^2)^2$, implying that $F_Q^p$ can reach the limit of QFI of the joint state $Q_j (\sim ⟨n^2⟩^2)$. Set $θ = θ_f = \frac{π}{2}$, and we find that

$$F_Q^p = (a_1-a_2)^2⟨n^2⟩^2, \quad (38)$$

Moreover, in this same situation, the CFIs for both the successful and failed postselection are $P_a F_Q^a = (a_2-a_1)^2 sin^2 ϕ(⟨n⟩^2 + ⟨n⟩)/(2-2cos ϕ)$ and $P_r F_Q^r = (a_2-a_1)^2 sin^2 ϕ(⟨n⟩^2 + ⟨n⟩)/(2+2cos ϕ)$. This shows that $P_a F_Q^a$ can achieve its maximal amount

$$P_a F_Q^a = (a_2-a_1)^2(⟨n⟩^2 + ⟨n⟩) \quad (39)$$

when $ϕ → 0$ or $2π$, i.e., $|ψ_1⟩$ and $|ψ_2⟩$ are completely orthogonal, but $P_r F_Q^r = 0$. As our calculation shows, whether the successful postselection or the projective measurement (postselected measurement), their FIs indeed scales at the Heisenberg limit ($F_Q ∼ ⟨n^2⟩^2$).

Hence,

$$F_Q^t = \sum_{n=0}^{∞} \left( \frac{θ_r^2}{P_r} + \frac{θ_r^2}{P_r} \right)$$

$$≤ 4rt(a_2-a_2)^2z(1+z)/(1-z)^2 \quad (40)$$

$$= (a_1-a_2)^2(2⟨n⟩^2 + ⟨n⟩) \sin θ_1 \sin θ_f,$$

and the equality holds up if and only if $cos \frac{θ}{2} = sin \frac{θ}{2}$ and $cos \frac{θ}{2} = sin \frac{θ}{2}$. We find that $F_Q^t ≤ Q_j$, and equality holds up when $θ_1 = θ_f$. The maximal $F_Q^t$ and $Q_j$ are found for $θ_1 = θ_f = π/2$, and equal to $(a_1-a_2)^2(2⟨n⟩^2 + ⟨n⟩)$. The results show that the Heisenberg scaling arises in weak measurement using thermal state as a pointer.

**CONCLUSION**

In summary, considering thermal states as the pointers in weak measurement, we have concluded that in the displacement space the QFI corresponding to real weak values is no advantage for the precision of parameter estimation. For imaginary weak values, we have shown that in the case of weak coupling ($χ → 0$) the maximal QFI after successful postselection can achieve the level of thermal fluctuations ($F_Q ∼ \frac{1}{1+z^2}σ^2$), and as the temperature increases, QFI is also increased, thereby improving the precision of parameter estimation, in sharp contrast with QFI using Gaussian states (i.e., pure states) as the pointers in the standard strategy which indicates that QFI only achieve the level of zero point fluctuations ($F_Q ∼ σ^2$).

In the phase space, however, our calculations show that not only successful postselection but postselected measurement itself only contain useful CFI when weak measurement use only classical resources, i.e., thermal states, and in weak measurement limit ($χ → 0$) their CFI can both attain the Heisenberg scaling ($F_Q ∼ ⟨n⟩^2$, $⟨n⟩ = \frac{1}{1-z}$) for the precision of parameter estimation. Obviously, weak measurement using thermal state pointer in phase space can yield classical-enhanced precision. As the temperature increases, CFI is further increased. Thus,
the measurement precision of the Heisenberg limit can be much larger than that of the classical measurement method. It is a known fact that thermal states are easy to be prepared under current experimental conditions. Our work provides a way to realize Heisenberg scaling precision, regardless of utilizing the light or the matter as a pointer.
