We propose a variation, based on very low energy and extremely intense photon sources, on the well established technique of Light-Shining-through-Wall (LSW) experiments for axion-like particle searches. With radiation sources at 30 GHz, we compute that present laboratory exclusion limits on axion-like particles might be improved by at least four orders of magnitude, for masses  $m_a \lesssim 0.01$  meV. This could motivate research and development programs on dedicated single-photon sub-THz detectors.

## I. INTRODUCTION

There is a vast literature describing the theoretical motivations for axion-like particles and the experimental techniques to investigate on their existence [1]. The topic has received a renovated attention because axions may well be among dark-matter constituents.

The purpose of this letter is to discuss a variation on the well-established technique of Light-Shining-through-Wall (LSW) experiments. We suggest to use

1. Very intense sub-THz sources: gyrotrons at frequencies  $\nu \approx 30$  GHz.
2. Single photon detectors for light in this frequency domain.

Gyrotron sources can provide photons from few to several 100 GHz.  $\nu \approx 30$  GHz is a value which allows to avoid the strong ambient microwave background still ensuring an extremely large photon yield<sup>1</sup>.

In a typical LSW experiment, the rate of events  $\dot{N}_{\text{evts}}$  is driven by  $\dot{N}_\gamma$ , the rate of photons delivered by the source

$$\dot{N}_{\text{evts}} \propto \dot{N}_\gamma P_{\gamma \rightarrow a} \times P_{a \rightarrow \gamma} \sim \dot{N}_\gamma G^4 H^4 L^4 \quad (1)$$

where  $G$  is the (unknown) photon-axion coupling,  $H$  is the strength of an external magnetic field and  $L$  is the length of the photons path under the action of  $H$ .  $P_{\gamma \rightarrow a} = P_{a \rightarrow \gamma}$  is the probability of photon-to-axion-conversion (and viceversa).

If  $G \lesssim 10^{-10}$  GeV<sup>-1</sup>, as suggested by CAST [2], and an external magnetic field  $H = 15$  T is devised along 50 cm, we have that  $(GHL)^4 \lesssim 10^{-35}$ .

Mega-Watt gyrotron sources can produce over  $\dot{N}_\gamma \approx 10^{28}$  photons/second with continuous emission (in the same conditions a 1 W LASER source yielding visible photons can reach  $\dot{N}_\gamma \approx 10^{18}$  where  $1 \text{ W} = 6 \times 10^{18} \text{ eV/sec}$ ). This would allow  $\approx 10$  LSW events per year at  $G \sim 10^{-10}$  GeV<sup>-1</sup>.

The number of expected events will grow by a factor of  $Q$  if a Fabry-Perot resonant cavity (for  $\approx 30$  GHz photons) with quality factor  $Q$  encloses the magnetic field region where photon-to-axion conversion is expected to occur. Quality factors of Fabry-Perot cavities in the microwave domain are known to be way larger than those typical for optical radiation ( $Q = 10^4 \div 10^5$  vs 50, see for example [3]). A gyrotron with a bandwidth matching the cavity quality factor must be eventually chosen for the real experimental setup.

On the other hand, detectors sensitive to a single photon in the frequency range around 30 GHz are needed, especially if we want to push the exclusion limits below  $G \sim 10^{-10}$  GeV<sup>-1</sup>. Such devices need dedicated research and development along the lines we will describe below.

If detectors of this kind will be engineered, low-energy LSW experiments would be far more reaching at probing low values of  $G$  couplings than those based on LASER sources. We include in Fig. 1 a qualitative scheme of the experimental setup we propose.

On the theory side, we expect that if the energy of photons from the source is lowered down to the (unknown) mass value of the axion, we might be producing large numbers of axions at rest. We will discuss about how to compute photon-axion-photon conversion probabilities as  $\mathcal{E}_\gamma$  approaches the  $\mathcal{E}_\gamma = m_a$  limit.

Indeed, photons at about 30 GHz have  $\approx 10^{-4}$  eV, so that  $\mathcal{E}_\gamma$  in principle might hit the  $m_a$  axion mass value; this is never the case for standard LSW configurations with visible light sources, where the approximation  $\mathcal{E}_\gamma \gg m_a$  is perfectly appropriate given the existing experimental limits on  $m_a$ .

Formulas describing photon-axion conversion rates are

<sup>1</sup> In tested gyrotrons, the average beam radius is  $\sim 1.3$  cm and the average axial spread is about 5.5%. The bandwidth is of the order of 30 MHz.

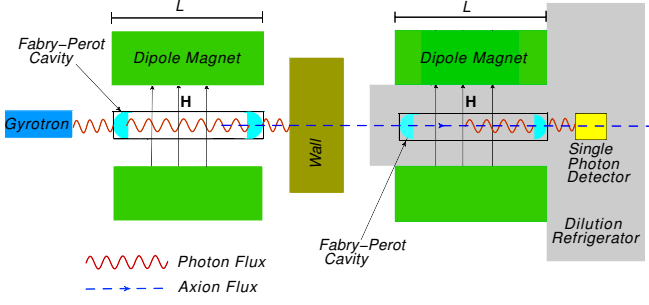

FIG. 1. Scheme of the LSW experiment with low energy photons. The dilution fridge should extend inside the dipolar magnet to easily accept photons from axion conversion. Such region would be thermally anchored to the cryostat mixing chamber residing at the base temperature of 10 mK. The regeneration cavity - if any - would then be placed in the fridge itself as well.

known to contain a factor of  $\mathcal{F} = \mathcal{E}_\gamma / \sqrt{\mathcal{E}_\gamma^2 - m_a^2}$ , which is typically set to 1 but might be of concern at very low photon energies.

In the next Section, we will discuss a formula for the conversion probability, which is also valid in the proximity of the  $\mathcal{E}_\gamma = m_a$  limit. We will conclude that the extension  $L$  of the magnetic region (in the photon beam direction) affects the denominator in the factor  $\mathcal{F}$ , shifting it to  $1/L + \sqrt{\mathcal{E}_\gamma^2 - m_a^2}$ .

Next, in a dedicated section, we will discuss the potentialities of a LSW experiment with 30 GHz photons, showing how far it could improve the actual exclusion limits. Paraphotons and chameleons searches will be addressed separately. We conclude with a discussion on the feasibility of single-photon microwave detectors.

During the preparation of this paper we learned that there are some ongoing studies on LSW with gyrotrons, although in a rather different energy range [4].

## II. LOW ENERGY PHOTON-AXION CONVERSION

By axion-like particles one generally means the quanta of a massive scalar or pseudoscalar field  $a$  coupled to photon  $\mathbf{A}$  by an interaction

$$\mathcal{L}_I = \frac{1}{4} G a F^{\mu\nu} \tilde{F}_{\mu\nu} = G a \mathbf{H} \cdot \partial_0 \mathbf{A} \quad (2)$$

Here, without loss of generality, the pseudoscalar case is considered. The coupling  $G$  has dimensions of the inverse of a mass and is a free parameter. The external field  $\mathbf{H}$  is chosen to be uniform in space and constant in time (static).

A real photon traveling in the  $x$  direction within an external magnetic field orthogonal to it has a finite probability to convert into an axion-like particle (ALP or ax-

ion for brevity) by exchanging 3-momentum  $\mathbf{q}$  with  $\mathbf{H}$ , while conserving the energy:  $\mathcal{E}_\gamma = \mathcal{E}_a$ .

Taking  $\mathbf{q}$  along the photon beam direction (the  $x$  direction) allows  $p^2 > 0$ ,  $p$  being the axion 4-momentum.

The inverse process is also possible: the axion has a finite probability to convert back into a photon carrying the same energy as the original one, and collinear to it.

The external static magnetic field is assumed to be uniform and equal to  $H$  within a volume  $L_x L_y L_z = L_x S$ , where  $L_x$  is along the photon beam direction and  $S$  is the effective transverse section of the region permeated by  $\mathbf{H}$ , crossed by the photon beam.

One generally analyzes the contribution to the photon-axion conversion S-matrix, where only  $q_x$  is exchanged with the magnetic field. Integrating  $\mathcal{L}_I$  in  $d^4x$ , we get the following  $\langle \gamma \gamma | a \rangle$  matrix element<sup>2</sup>

$$GH (2\pi)^3 \delta(q_y) \delta(q_z) \delta(\mathcal{E}_a - \mathcal{E}_\gamma) 2 \frac{\sin(q_x L_x/2)}{q_x} (\pm \mathcal{E}_\gamma) \quad (3)$$

depending if the photon is incoming/outgoing. The  $2 \sin(q_x L_x/2)/q_x$  factor comes from taking the integration range in the  $x$  variable in the finite interval  $[-L_x/2, L_x/2]$ , representing the extension of the external magnetic field along the longitudinal photon beam direction.

In the limit  $L_x \rightarrow \infty$ , we have  $2 \sin(q_x L_x/2)/q_x \rightarrow 2\pi \delta(q_x)$ . However,  $q_x = 0$  would be equivalent to  $p_x = k_x$ . Therefore, the energy delta-function would be zero for  $m_a \neq 0$ , *i.e.* no photon-axion transition would be allowed.

The conservation of energy derives from the fact that the external magnetic field is constant in time.

Using standard normalizations for photon and scalar wave functions in a box [5], the transition probability  $\gamma \rightarrow a$  is

$$dw_{a\gamma} = G^2 H^2 \frac{(2\pi)^3}{(2\mathcal{E}_a V)(2\mathcal{E}_\gamma V)} \delta(q_y) \delta(q_z) \delta(\mathcal{E}_a - \mathcal{E}_\gamma) \times \\ \times (ST) 4 \frac{\sin^2(q_x L_x/2)}{q_x^2} \mathcal{E}_\gamma^2 \frac{V}{(2\pi)^3} d^3p \quad (4)$$

where  $S \equiv (2\pi \delta(0))^2$  is the magnetic field transverse section introduced above and  $2\pi \delta(0) = T$  for the energy delta-function.  $V = L_x \cdot S$  is the volume with  $H \neq 0$ .

Considering that  $\mathcal{E}_a = \sqrt{p_x^2 + m_a^2}$  and  $q_y = p_y$ ,  $q_z = p_z$ , solving for  $p_x > 0$  only, with photon polarizations being fixed, we get the conversion rate per flux (as in [1])

<sup>2</sup> From (2), the Feynman rule at the photon-axion vertex for an incoming/outgoing photon is  $iG \mathbf{H} \cdot \boldsymbol{\epsilon}(k) (\mp i\mathcal{E}_\gamma)$ , where  $\boldsymbol{\epsilon}(k)$  is the transverse photon polarization vector. For a transverse photon, the sum over polarizations is  $\sum_\lambda |\mathbf{H} \cdot \boldsymbol{\epsilon}(k, \lambda)|^2 = H^2 \sin^2 \theta = H^2$ ,  $\theta = \pi/2$  being the angle between the photon direction and the orientation of the external magnetic field.

and [6])

$$\sigma = \frac{1}{\rho v} \int \frac{dw}{T} = SG^2 H^2 \frac{\sin^2(q_x L_x/2)}{q_x^2} \frac{\mathcal{E}_\gamma}{\sqrt{\mathcal{E}_\gamma^2 - m_a^2}} \quad (5)$$

where  $q_x = \mathcal{E}_\gamma - \sqrt{\mathcal{E}_\gamma^2 - m_a^2}$  and  $\rho v = \text{flux} = 1/V$ . This is the result generally used in the literature.

The factor  $\mathcal{E}_\gamma / \sqrt{\mathcal{E}_\gamma^2 - m_a^2}$  is usually set to 1 because it is assumed that  $\mathcal{E}_\gamma \gg m_a$  (in this case we also have  $q_x \approx m_a^2/2\mathcal{E}_\gamma \neq 0$ ) – most of the present experiments work in that regime.

However, when decreasing  $\mathcal{E}_\gamma$  in the sub-THz regions we want to explore, it might be that  $\mathcal{E}_\gamma \approx m_a$ . This formula would indicate that in the  $\mathcal{E}_\gamma \rightarrow m_a$  limit, the production probability dramatically increases for the production of axions at rest (which are of no use in a LSW experiment).

The photon energy regime we are mostly interested in is  $\mathcal{E}_\gamma \approx 10^{-4}$  eV. Therefore, we can safely compute reaction rates through formula (5) whenever axion masses are  $\lesssim 0.1$  meV.

### An alternative derivation

In what follows, we wish to discuss the  $\mathcal{E}_\gamma = m_a$  limit from a different standpoint. We will obtain a simple way of regulating the expression in (5).

FIG. 2. Photon-axion-photon conversion in an external magnetic field orthogonal to the photon direction;  $q_x$  can either be positive or negative. This scheme does not describe the typical LSW photon conversion: here the photon-axion-photon conversion occurs within the same transverse magnetic field area, along a region of arbitrary length  $L$ .

The diagram represented in Fig. 2 might be considered as a sort of photon self-energy contribution  $\Sigma(k)$  once the action of the external magnetic field is substituted by the emission and re-absorption of arbitrary values of the 3-momentum  $\mathbf{q}$  along  $x$ . We stress here that the physical situation we are studying now does not correspond to the LSW photon-axion-photon conversion for there is no wall in the scheme in Fig. 2. The scope of this Section is to explicitly show how the scale  $1/L$  plays the role of an infrared cutoff in the formula commonly used for the photon-axion conversion probability – something which we might have guessed on dimensional grounds only.

Another diagram will implicitly be included in which the photon converts into a bouncing axion against the magnetic wall, eventually regenerating a photon collinear to the original one (upon a second reflection in  $H$ ).

Indeed, if an interaction with axion-like particles of the kind of Eq. (2) exists, photons in external magnetic fields become unstable with respect to photon-to-axion decay and the conversion probability is expected to be proportional to the imaginary part of the self-energy diagram(s) in Fig. 2 (including the bouncing axion).

We will compute  $\Sigma(k)$  in Fig. 2, where the role of the external magnetic field is that of a sink/source of 3-momentum. Then, we use unitarity (cutting equations<sup>3</sup>) to re-obtain the rate of photon conversions in the external magnetic field

$$P = \frac{\text{Im}(\Sigma)}{\mathcal{E}_\gamma} \quad (6)$$

using the notations of Eq. (5),  $P = P_{\gamma \rightarrow a} = P_{a \rightarrow \gamma} = \sigma/S$ , and including the appropriate wave function normalization factors  $1/(\sqrt{2\mathcal{E}_\gamma})^2$ .

From now on, we will simplify the notation by setting  $L_x = L$ ,  $p_x = p$ ,  $k_x = k$ ,  $q_x = q$ .

As shown in the Appendix, we obtain for the self-energy

$$\Sigma(k) = -4 G^2 H^2 \mathcal{E}_\gamma^2 \int \frac{dq}{2\pi} \frac{\sin^2(qL/2)}{q^2 (p^2 - m_a^2 + i\epsilon)} \quad (7)$$

$\Sigma$  can be computed as a contour integral in the complex plane once the positions of the poles in the  $q$  integration variable are determined. From (6) we get

$$P = G^2 H^2 \frac{\mathcal{E}_\gamma}{\sqrt{\mathcal{E}_\gamma^2 - m_a^2}} \left( \frac{\sin^2(q_2 L/2)}{q_2^2} + (2 \rightarrow 1) \right) \quad (8)$$

where the poles in (7) are located at

$$\begin{aligned} q_1 &= \mathcal{E}_\gamma + p^* \\ q_2 &= \mathcal{E}_\gamma - p^* \\ p^* &= \sqrt{\mathcal{E}_\gamma^2 - m_a^2} \end{aligned} \quad (9)$$

The result (8) is in perfect agreement with Eq. (5). As explicitly shown in the Appendix, this result is obtained *only if*  $p^* \neq 0$ .

The expression in (8) includes automatically the case in which the axion recoils backwards with respect to the photon direction – this is also found in (5) provided that both  $p_x > 0$  and  $p_x < 0$  are included when solving the energy  $\delta$ -function.

We observe now that the wavelength associated to the virtual axion,  $\lambda = 1/p$ , must be of the same size of  $L$ ,

<sup>3</sup> We use  $2 \text{Im} A(k \rightarrow k) = \sum_f \int \Pi^f(d^3 p_f / (2\pi)^3 2E_f) |A(k \rightarrow f)|^2$ .

for the virtual process to occur within that region<sup>4</sup>. Say  $\lambda/2 < L$  – the entire wavelength of the virtual axion must be contained in the  $H \neq 0$  region. This means that we might estimate  $p > 1/2L$ .

Since  $p = k - q$  (linear momenta in the  $x$  direction), the contribution to  $\Sigma$  from forward<sup>5</sup> axions ( $p > 0$ ) corresponds to  $q < \mathcal{E}_\gamma$  and the above condition on  $p$  translates into  $q < \mathcal{E}_\gamma - 1/2L$  (where  $1/2L = 10^{-5}$  eV for  $L = 1$  cm). Similarly for backward ones.

When  $\mathcal{E}_\gamma \neq m_a$ , the  $q_2$  pole is located within the  $q$  region of forward axions, whereas the  $q_1$  pole is in the bouncing-axion region. The poles coincide and are both in the bouncing region when  $\mathcal{E}_\gamma = m_a$  (or  $p^* = 0$ ).

In order to estimate a physical upper bound on  $P$ , consider  $\mathcal{E}_\gamma \neq m_a$  but such that  $q_2 \lesssim m_a - 1/2L$  and  $q_1 \gtrsim m_a + 1/2L$  – in such a way to maximally approach  $m_a$  taking into account the above uncertainty on  $p$ . This amounts to cut a symmetric segment around  $q_1 = q_2 = m_a$  (we repeat that this specific point does not give contribution to formula (8) because it has  $p^* = 0$ ). Therefore, the minimum  $q_1 - q_2$  distance between the poles in (9), which still provides the result (8) is

$$\min(q_1 - q_2) = 1/L \quad (10)$$

Confronting with (29) in the Appendix, we can estimate for forward axions

$$P \lesssim G^2 H^2 \frac{\sin^2(qL/2)}{q^2} \frac{m_a}{1/L} \quad (11)$$

where

$$q \approx m_a - \frac{1}{2L} \quad (12)$$

We therefore argue the following formula for forward axions

$$P \simeq G^2 H^2 \frac{\sin^2(qL/2)}{q^2} \frac{\mathcal{E}_\gamma}{1/L + \sqrt{\mathcal{E}_\gamma^2 - m_a^2}} \quad (13)$$

with<sup>6</sup>  $q = q_2 = \mathcal{E}_\gamma - \sqrt{\mathcal{E}_\gamma^2 - m_a^2} - 1/2L$ . As usual, when  $\mathcal{E}_\gamma \gg m_a$  we have  $q \approx m_a^2/2\mathcal{E}_\gamma \neq 0$ .

This formula will be used to derive the results discussed in the next Section.

### III. THE POTENTIAL REACH OF A SUB-THZ LSW EXPERIMENT

In this Section, we discuss the potentialities of a Sub-THz-AXion (STAX) search experiment with a gyrotron source at 100 kW ( $\dot{N}_\gamma = 10^{27}$   $\gamma$ /sec) in a generation Fabry-Perot cavity with quality factor  $Q \sim 10^4$ . The static magnetic field is assumed to be  $H = 15$  T in a region with  $L = 50$  cm – this is the typical length scale over which such intense magnetic fields may be achieved with available technology.

From (13) and following equations, we see that, in typical LSW experiment conditions, where  $\mathcal{E}_\gamma \gg m_a$ ,  $q$  is a very small number. Therefore the  $\sin^2 x/x^2$  function in (13) can be approximated with 1 up to large  $L$  values (in the order of several meters).

For example, in order to observe (or exclude) an axion<sup>7</sup> with  $m_a \sim 10$   $\mu$ eV from photons with  $\mathcal{E}_\gamma \sim 30$  GHz = 20  $\mu$ eV, we have to deal with  $q \simeq 2.5$   $\mu$ eV whereas for  $\mathcal{E}_\gamma \sim 1$  eV,  $q \simeq 5 \times 10^{-5}$   $\mu$ eV. On the other hand, a size of  $L = 50$  cm corresponds to  $L \simeq 2.5$   $\mu$ eV<sup>-1</sup>.

The product  $qL/2$  is  $qL/2 \sim 3$  in the first case and  $qL/2 \approx 10^{-4}$  in the second case. The function  $\sin^2 x/x^2$  can be approximated with  $\sim 1$  on very long distances, for visible light, but this is not the case for 30 GHz, where  $L$  has to be  $L \lesssim 50$  cm. Larger values of  $L$  would bring the onset of the oscillation region in Fig. 3 down to smaller values of the axion mass. This would translate in a smaller sensitivity region in the exclusion plot.

Introducing a Fabry-Perot cavity allows to multiply the passages of the light beam produced by the source in the magnetic field. Since the quality factor  $Q$  is proportional to the energy stored in the cavity divided by the energy lost per cycle to the walls, the effective number of passages in the magnetic field gets increased and the LSW probability gains a factor of  $Q$  if a cavity is placed on the source side:  $G^4 H^4 L^4 Q$ .

Therefore, values of  $G$  lower by a factor of  $Q^{-1/4}$  can be probed in the  $G$  vs  $m_a$  plot in Fig. 3, as commented below.

In Fig. 3 we show the exclusion plots by ALPS and CAST. ALPS places the strictest limits within purely laboratory experiments while CAST places the strictest limits in astrophysical detection experiments.

Other projects to be quoted are OSQAR [7], IAXO [8] and ALPS-II [9]. All of them aim at extend the exclusion region in the  $M_a$  vs  $G$  plot. In particular, ALPS-II can reach a level very close to that of STAX in Fig. 3 ( $G$  down to  $2 \times 10^{-11}$  GeV<sup>-1</sup> [10] – dedicated magnets and optics might help to go towards  $10^{-12}$  GeV<sup>-1</sup> [11]). The IAXO collaboration aims at decreasing the sensitivity down to  $G \sim 10^{-12}$  GeV<sup>-1</sup> for masses up to about 0.02 eV [12]. As for OSQAR, it explores  $G$  between  $10^{-7}$  and  $10^{-8}$  GeV<sup>-1</sup>.

<sup>4</sup> The uncertainty on the position of the created/destroyed axion is  $\Delta x \approx L \Rightarrow \Delta p \gtrsim 1/L$  so that the minimum value of the axion momentum is  $p_{\min} = 0 + \Delta p \gtrsim 1/L$ .

<sup>5</sup> Backward axions have  $\mathcal{E}_\gamma - q = -|p| < -1/2L$  so that  $q > \mathcal{E}_\gamma + 1/2L$ .

<sup>6</sup> We also observe here that in the differentiation of the integral with respect to  $L$ , the terms due to the dependency on  $L$  of the integration limits do not contribute to the imaginary part of the integral as  $\epsilon \rightarrow 0$ .

<sup>7</sup> Just below the onset of the oscillation region in Fig. 3

We superimpose in the same plot the 90% CL exclusion limits that STAX may achieve in case of a null result. An exposure time of roughly one month and zero dark counts are considered.

Since we propose to use sub-THz photons, coherence of photon-to-axion conversion is lost, along with sensitivity, at smaller axion masses compared to other experiments (this is shown by the violent oscillations of the  $\sin^2(qL)/q^2$  function in the conversion probability). It is shown in the literature that such oscillations might be reduced introducing a low pressure gas in the generation cavity – in this case photons acquire an effective mass  $m^* \neq 0$  related to the sub-luminal velocity  $c/n(k)$  (the in-medium calculations are discussed in [13]).

The experimental set-up might further be improved with the addition of a second Fabry-Perot cavity in the region beyond the wall. As noticed in [14], a coherent axion beam may excite electromagnetic modes in a cavity immersed in an external magnetic field: regenerated photons can resonantly enhance at the same cavity frequency, with the effect of producing an increased axion-photon conversion probability by a factor of  $Q$  of the cavity (meaning an event probability increased to  $G^4 H^4 L^4 Q^2$  or smaller values of  $G$  by  $Q^{-1/2}$ ).

FIG. 3. 90% CL exclusion limits that STAX may achieve in case of a null result for axions with  $m_a \lesssim 0.02$  meV. An exposure time of one month and zero dark counts are considered. ‘STAX’ and ‘STAX 2’ configurations correspond to a 100 kW and 1 MW gyrotron sources respectively. The former provides  $10^{27}$   $\gamma$ /sec at 30 GHz.

In the axion mass range  $m_a \lesssim 0.02$  meV, STAX allows an extension of the exclusion region by a factor of  $\sim 10^4$

with respect to ALPS. Adding a second cavity, this gain would be larger by one more order of magnitude. The ALPS collaboration also foresees a second phase with a regeneration cavity: the ALPS II program. However, STAX II (see STAX II in Fig. 3) would still have a better sensitivity, by about a factor of ten.

The lower shaded straight band in Fig. 3 represents the parameter space consistent with the QCD axion from the original Peccei-Quinn theory.

#### IV. DARK PHOTONS AND CHAMELEONS

The conceptual setup we propose could also be adequate for research on paraphotons and chameleons, as we briefly comment in this section. In the case of paraphoton searches we might use the same source, same detector but no need of external magnetic field. In the case of chameleons, also the magnetic field in some region  $L$  is required, but the experiment is of the after-glow type, as described below.

**Paraphotons.** Paraphotons are hypothetical massive vectors of a hidden U(1) sector, as originally discussed in [15, 16]. For a more recent account, see for example [17–19]. The most general Lagrangian with two U(1) gauge groups, describing visible and hidden sector photons and their coupling to visible and hidden matter, can be written as

$$\mathcal{L} = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu} - \frac{1}{4}B^{\mu\nu}B_{\mu\nu} + eJ_{\text{em}}^\mu A_\mu + e_h J_h^\mu B_\mu - \frac{1}{2}\mu^2 B^\mu B_\mu \quad (14)$$

where  $F_{\mu\nu}$  is the field strength tensor for the electromagnetic gauge field,  $A^\mu$ , and  $B^{\mu\nu}$  that for the paraphoton,  $B^\mu$ . Visible and hidden sector matter currents are  $J_{\text{em}}^\mu$  and  $J_h^\mu$  and a mass term for the paraphotons breaks the  $U(1)_h$  symmetry explicitly. The fields  $A$  and  $B$  are rotated into  $B_1$  and  $B_2$  through a small mixing angle  $\chi$ .  $B_{1,2}$  get masses  $m_1 = \mu\chi$  and  $m_2 = \mu$  respectively. The value of  $\chi$  is expected to be  $\chi \lesssim 10^{-2}$  [20, 21] so that the following approximation  $k_1 \approx \omega$  is usually made to define the wave vector of  $B_1$ .

Since  $k_1 \neq k_2$ , the relative weight of  $B_1$  and  $B_2$  in the expression for  $A(r, t)$  will change with the traversed distance  $r$

$$A \propto e^{-i(\omega t - k_1 r)}(B_1 + \chi B_2 e^{-iqr}) \quad (15)$$

with  $q = k_1 - k_2$ . Expressing  $B_{1,2}$  in terms of  $A, B$  ( $B_1 \propto A - \chi B$  and  $B_2 \propto \chi A + B$ ) we can compute the photon( $A$ )-to-paraphoton( $B$ ) conversion probability as

$$P_{\gamma \rightarrow \gamma'}(r) = 4\chi^2 \sin^2\left(\frac{qr}{2}\right) \quad (16)$$

where

$$q \simeq \omega - \sqrt{\omega^2 - \mu^2} \quad (17)$$

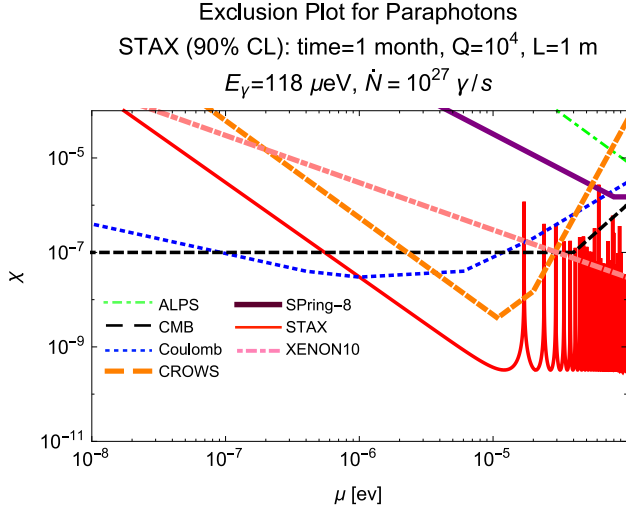

FIG. 4. 90% CL exclusion limits that STAX may achieve in case of a null result for paraphotons. An exposure time of one month and zero dark counts are considered. The STAX parameters are reported on top of the figure. The STAX limits are compared to those provided by ALPS [22], CROWS [23], SPring-8 [24] and XENON10 [25] Collaborations, to limits from searches of modifications of Coulomb’s law [26] and constraints on paraphotons from measurements of the CMB [27].

The conversion probability can be increased by using a cavity before the wall. If the photon beam is reflected  $N$  times, it will make  $(N + 1)/2$  “attempts” to cross the wall in a LSW experiment, enhancing the transmission probability by this same factor. If we define

$$P_{\text{trans}} = P_{\gamma \rightarrow \gamma'}(L_1) P_{\gamma' \rightarrow \gamma}(L_2) \quad (18)$$

$L_1$  and  $L_2$  being the effective traversed lengths of photons and paraphotons, the expected rate of LSW photons is

$$\dot{N} = \eta \dot{N}_\gamma \left[ \frac{N + 1}{2} \right] P_{\text{trans}} \quad (19)$$

where  $\eta$  is the detection efficiency.

In the STAX configuration described above, we take advantage of the very high  $\dot{N}_\gamma$  and quality factor of cavities at sub-THz frequencies. The single-photon detection with  $\eta \approx 1$  will still be assumed.

As discussed above, low-energy photons from the source might approach the values of the paraphoton masses, so that the approximation  $\mu \ll \omega$  is not given for granted. In this case,  $q \approx 0$  and the conversion probability is simply  $P = \chi^2 q^2 L^2$ , so that it is favorable to have large effective photon/paraphoton paths. Otherwise, as before, we will meet the onset of rapid oscillation at values of  $\mu$  approaching  $\omega$  – see Fig. 4. Other collaborations dedicated to the search for photon-paraphotons oscillations in LSW experiments are BMV [28], GammeV [29], LIPPS [30], ALPS [22], CROWS [23] and SPring-8 [24]. In particular, ALPS [22] and SPring-8 [24] provided the best experimental limits in the range

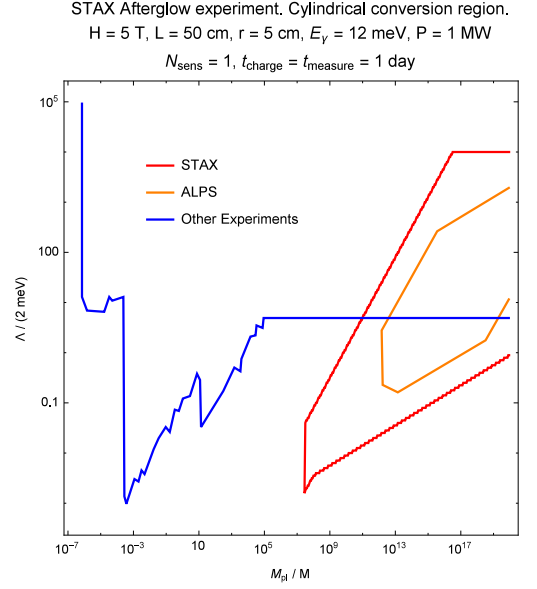

FIG. 5. Comparison of STAX with other experiments [33, 34] at digging exclusion regions for chameleons. The afterglow is considered on a one-day time scale. The STAX parameters and detector sensitivity are reported.  $M$  and  $\Lambda$  are two theoretical parameters characterizing the chameleons and  $M_{pl}$  is the Planck mass. The other parameter in chameleon theory is  $n$ , here fixed to  $n = 1$ .

$2 \cdot 10^{-4} < \mu \lesssim 10^{-3}$  eV and  $0.1 < \mu < 0.2$  meV, respectively. CROWS [23] has recently published updated results, which give the best experimental limit in the region  $3 \cdot 10^{-6} \lesssim \mu \lesssim 3 \cdot 10^{-5}$  eV. The second stage of ALPS, ALPS-II [9], is planning to extend the previous exclusion region of ALPS for paraphotons up to  $\chi \approx 10^{-9}$  for  $10^{-4} \lesssim \mu \lesssim 10^{-2}$  eV. See also Ref. [31].

**Chameleons.** Chameleons are scalar particles which might have a role at explaining dark energy [32, 33]. They couple with matter, the electromagnetic field and themselves, through a self-interaction potential. The peculiarity of these particles is the dependence of their mass value on the local mass-energy density.

Photons can convert into chameleons when traveling in an external magnetic field, but, differently from the case of axion-like particles, the conversion probability depends on the square of the energy  $\omega^2$  of the photon/chameleon (the dependence on  $H$  remains quadratic). This potentially makes the STAX configuration less suitable for the search of chameleons, for the LSW regenerated photons will have a production probability  $\propto \omega^4$  and STAX uses  $\sim 20$   $\mu\text{eV}$  photons.

Chameleons search experiments are based on a ‘afterglow’ technique [34, 35] different from axion LSW experiments. Light is injected in a cavity, where a transversal magnetic field is on. Chameleons are supposedly produced inside the cavity, with a certain value of their mass which depends on the density of matter in the hollow part of the cavity. As a result, chameleons might be trapped within the cavity if they miss the necessary amount of

energy needed for them to go through the cavity walls: in the denser cavity walls, chameleons are expected to have a larger mass. Low energy STAX photons are more likely producing trapped chameleons.

Light glows at  $\sim 20 \mu\text{eV}$  should then be detected *after* the source has been turned off. The number of chameleons produced in the cavity decreases with an exponential law  $\exp(-t/\tau)$  due to chameleon-photon conversion. The time-scale is  $\tau = L/P_{\gamma \rightarrow \mathcal{C}}$  where  $L$ , as usual, is the space extension of the magnetic field and

$$P_{\gamma \rightarrow \mathcal{C}} \approx 4 \left( \frac{\omega H}{m^2 M} \right)^2 \sin^2 \left( \frac{m^2 L}{4\omega} \right) \quad (20)$$

is the photon-chameleon conversion probability.  $M$  is a (free) parameter of the chameleon model and  $m, \omega$  are its mass and energy.

In the low energy regime, where gyrotrons work, the after-glow phenomenon might occur on quite long time scales so that the cavity is expected to thermalize. Black-body photons from a hot cavity ( $\gtrsim 300 \text{ K}$ ) are expected however to be of minimal impact on the background to 30 GHz afterglow photons.

In any case, the photons from source beam must be collimated in such a way to go through small size transmitting windows of the cavity to decrease the energy absorption on the body of cavity. If photon-chameleon conversion takes place within the magnetic field in the cavity, the role of the cavity will only be that of providing a cage to load chameleons in a closed region of space.

If engineering allows that only  $\approx 10^{-3}$  of the the source power heats the body of the cavity, using an hypothetical 1 MW source, we would have a photon background from the hot cavity peaked at  $\lambda \approx 80 \mu\text{m}$  – three orders of magnitude lower than the typical cm wavelength of afterglow photons at 30 GHz.

A detailed study on all background sources for the after-glow experiment and on the positioning of the light detector will be considered in future work.

We did not attempt here a full theoretical description of the photon-to-chameleon conversion rate, which is outside the scope of this paper and can be found in the literature [34–37]. We just report a plot showing the STAX potentiality at searching chameleons when compared to other experiments – see Fig. 5.

The other exclusion limits reported in Fig. 5 are those of the ALPS Collaboration, Alpenglw experiment [34] (orange line), and constraints arising from searches for violations of the weak equivalence principle, from searches for deviations from the  $1/r^2$  law of the gravitational force, and from bounds on the strength of any fifth force from measurements of the Casimir force (blue line) [33].

## V. SINGLE-PHOTON DETECTION OF SUB-THZ RADIATION

We argue that a suitably designed superconducting antenna connected to a nano-sized hot-electron calorimeter

read out by an ultra low noise superconducting quantum interference device (SQUID) amplifier can provide the desired sensitivity to detect even a single photon from an axion-to-photon conversion.

The calorimeter would consist of an absorbing metallic nano-wire made of a superconducting material operating near to the superconducting-to-normal state phase transition. The photon absorption will cause the temperature of the metal electrons to rise, thereby inducing an enhancement of the calorimeter resistance. This kind of detector is usually known as transition edge sensor (TES). Calorimeters based on TES have been successfully exploited as single-photon quantum detectors for X-ray spectroscopy [38] as well as for secure quantum communication applications using near-IR photons [39]. Nano-calorimeters are able to extend the ability of conventional calorimeters to detect both very tiny powers as well as small amounts of energy which potentially correspond to a single sub-THz or microwave photon event.

The TES calorimeter sensitivity is basically limited by the magnitude of the thermal energy fluctuations, due to the energy exchange between the sensor and the phonon bath. The RMS energy resolution  $\sigma_E$  can be written as  $\sigma_E \sim 0.3\sqrt{k_B T_c^2 C_e}$  [40, 41], where  $k_B$  is the Boltzmann constant,  $T_c$  the critical temperature of the TES superconductor and  $C_e$  the heat capacitance. In addition,  $C_e$  is given by  $\gamma V T_e$ , where  $\gamma$  is the Sommerfeld coefficient<sup>8</sup>,  $V$  is the sensor volume and  $T_e$  the electron temperature. The above expression suggests that low  $T_e$  and a reduced sensor volume are required to detect low-energy photons.

By using, for instance,  $\alpha$ -tungsten as TES material with a critical temperature of  $\sim 15 \text{ mK}$ ,  $\gamma \sim 136 \text{ J/K/m}^3$ , and  $V = 300 \times 40 \times 20 \text{ nm}^3$ , we expect a frequency resolution  $\sigma_E \sim 560 \text{ MHz}$  and therefore we predict a significant resolving power  $h\nu/\sigma_E \sim 50\text{--}180$  for 30–100 GHz photons [42]. In this picture, the dark count noise is well under control and the quantum efficiency of the device maximal.

The photon energy can be fed into the TES through a highly-efficient log-periodic spiral antenna, with a suitable size to match the photon wavelength, to be devised with superconductor materials which are in direct contact with the TES. The antenna will be designed to obtain the best possible impedance matching with the vacuum.

With a suitable choice of the TES material, a tiny but detectable current variation will be obtained. A temperature variation of the TES of several tens of mK might be achieved together with an electron-phonon coupling of the nano-wire of the order of few aW/K [42]. An expected signal of  $\sim 10^{-20} \text{ W}$  would translate into a current variation of some tens pA with a suitable bias volt-

<sup>8</sup> The Sommerfeld coefficient  $\gamma$  is the ratio of the electronic specific heat to temperature  $T$ . It is determined to be  $\gamma = n(\pi k_B)^2/(2\epsilon_F)$ , where  $n$  is the electron gas charge density,  $\epsilon_F$  is the Fermi energy, and  $k_B$  the Boltzmann constant.

age applied to the TES. Therefore, ultra low-noise DC SQUID readout amplifiers, inductively coupled to the TES circuit, are required. The best current sensitivity with SQUIDS reported to date ( $4 \text{ fA}/\sqrt{\text{Hz}}$ ) [43], together with a reduced bandwidth of few kHz, will result into a total current noise induced by the SQUID which is two orders of magnitude smaller than the expected current amplitude of the TES response.

This quantum sensor will be operated in a dilution refrigerator at a temperature of 10 mK properly coupled to the conversion magnetic field. Blackbody radiation in the refrigerator should induce a negligible background in the range of interest (30 GHz to 100 GHz): the peak of the blackbody spectrum is at a value of  $\approx 0.6 \text{ GHz}$ , much lower than the working frequency. In an energy range of  $\pm 10 \text{ GHz}$  around the central value of 30 GHz, the irradiance is calculated to be  $10^{-52} \text{ W/m}^2$  with  $10^{-30} \text{ m}^{-2}\text{s}^{-1}$  emitted photons. Other sources of energy deposit in the absorber – as cosmic ray radiation or radioactivity – should produce a very large signal: cosmic muons release about 10 eV in 10 nm of material. This would drastically increase the temperature of the detector and a dead-time would be needed to get back to the working temperature of 10 mK. We estimate this time scale to be much lower than the average time interval between two cosmic muon events hitting the detector.

## VI. CONCLUSIONS

We have presented the conceptual proposal of a different kind of Light-Shining-through-Wall experiment based on low energy, very intense photon sources (30 GHz) and very sensible ultra-cold single photon detectors.

We have discussed the photon-to-axion conversion probability in this photon frequency regime and showed the potentialities of the configuration we propose at digging the exclusion region for axion-like particles in a very competitive way with respect to other LSW experiments. We have briefly commented on the kind of detectors that could be devised for our purposes.

A brief analysis on the potentialities for the search of paraphotons and chameleons is also included.

The concept experiment proposed is found to be especially effective at axion-like particles searches whereas it has similar potentialities of other running or concept experiments in the case of paraphotons. As for chameleons, the exclusion region is extended in a sector of the parameter space which will not be covered by future space-based tests [34].

## Acknowledgements

We wish to thank Andreas Ringwald for comments on the manuscript and especially for pointing us about some studies we were not aware of on the use of gyrotrons

in LSW experiments. We thank Marcella Diemoz for encouraging this research activity at INFN Rome.

## APPENDIX

The Feynman rules to compute  $\Sigma(k)$  in Fig. 2 are the following. At each vertex attach (see (3))

$$(2\pi)^3 \delta(k_y - p_y) \delta(k_z - p_z) \delta(\mathcal{E}_\gamma - \mathcal{E}_a) (2\pi) \delta(k_x - p_x - q_x) \\ (2\pi)^3 \delta(p_y - k'_y) \delta(p_z - k'_z) \delta(\mathcal{E}_a - \mathcal{E}'_\gamma) (2\pi) \delta(p_x + q_x - k'_x)$$

where the last two delta-fuctions substitute the action of the external magnetic field. Integrate over both internal lines with the prescription

$$\frac{d^4 p}{(2\pi)^4} \frac{i dq_x}{2\pi} \quad (21)$$

considering that there are no transverse components. The first integration allows to factor out the term

$$(2\pi)^4 \delta^4(k - k') \quad (22)$$

thus, including the remaining terms in (3) we get

$$\Sigma(k_x) = -4 G^2 H^2 \mathcal{E}_\gamma^2 \int \frac{dq_x}{2\pi} \frac{\sin^2(q_x L_x/2)}{q_x^2 (p^2 - m_a^2 + i\epsilon)} \quad (23)$$

where we used the propagator for an axion of mass  $m_a$  as given by  $\Delta(p) = i/(p^2 - m_a^2 + i\epsilon)$ .

A factor of  $1/2!$  from the second perturbative order has been included, together with a factor of 2 coming from the fact that the two vertices can be interchanged. The overall  $(-1)$  factor in (23) reflects the fact that the photon is incoming at one vertex and outgoing at the other. From now on let us simplify the notation by setting  $L_x = L$ ,  $p_x = p$ ,  $k_x = k$ ,  $q_x = q$ .

The  $(p^2 - m_a^2 + i\epsilon)$  term in the denominator in (23) can be written as

$$(p^2 - m_a^2 + i\epsilon) = (\mathcal{E}_\gamma^2 - (k - q)^2 - m_a^2 + i\epsilon) = \\ = -(q - (q_1 + i\epsilon))(q - (q_2 - i\epsilon)) \quad (24)$$

where in the last term we redefined

$$i\epsilon \rightarrow i\epsilon p^* - \epsilon^2 \quad (25)$$

with  $\epsilon \rightarrow 0$ . To do this it is necessarily required that  $p^* \neq 0$ . We also assumed  $k = \mathcal{E}_\gamma > m_a$  and defined the two positive roots

$$q_1 = \mathcal{E}_\gamma + p^* \\ q_2 = \mathcal{E}_\gamma - p^* \quad (26)$$

in such a way that  $q_1 - q_2 > 0$ , and

$$p^* = \sqrt{\mathcal{E}_\gamma^2 - m_a^2} \quad (27)$$

The  $q_1 - q_2 > 0$  condition is essential to define the prescription to lift the  $q_{1,2}$  poles in the complex plane and is lost when  $p^* = 0$ .

Next we observe that taking a derivative of the integral in (23) with respect to  $L$  we obtain, leaving aside constant factors for the moment

$$\begin{aligned} & \frac{1}{2} \int dq \frac{\sin(qL)}{q(p^2 - m_a^2 + i\epsilon)} = \\ & = -\frac{1}{2} \int dq \frac{\sin(qL)}{q(q - (q_1 + i\epsilon))(q - (q_2 - i\epsilon))} \end{aligned} \quad (28)$$

The last integral can be evaluated as a contour integral in the complex plane and we find that

$$\begin{aligned} & \int_{-\infty}^{\infty} dx \frac{\sin(\alpha x)}{x(x - (a + i\epsilon))(x - (b - i\epsilon))} = \\ & = \frac{\pi}{ab} + \frac{\pi}{a - b} \left( \frac{e^{i\alpha a}}{a} - \frac{e^{-i\alpha b}}{b} \right) \end{aligned} \quad (29)$$

for  $a, b$  real parameters.

Comparing with (28) we have  $\alpha = L$ ,  $a = q_1$ ,  $b = q_2$ . Therefore the result of the integral in (28), upon integration over  $L$  is

$$-\frac{\pi L}{2q_1 q_2} + \frac{i\pi}{4p^*} \left( \frac{e^{iLq_1} - 1}{q_1^2} + \frac{e^{iLq_2} - 1}{q_2^2} \right) \quad (30)$$

where the integration constant of the indefinite integration has been fixed requiring the physical condition  $\Sigma \rightarrow 0$  as  $L \rightarrow 0$ .

The imaginary part of (30) is therefore

$$-\frac{\pi}{2p^*} \left( \frac{\sin^2(q_1 L/2)}{q_1^2} + \frac{\sin^2(q_2 L/2)}{q_2^2} \right) \quad (31)$$

From the unitarity of the S-matrix (cutting-equations) we conclude that the width of the unstable photon in the external magnetic field (conversion rate of a real photon into an axion) is twice the imaginary part of  $\Sigma$ .

From Eq. (6), (23) and (31), and including the appropriate wave function normalization  $1/(\sqrt{2\mathcal{E}_\gamma})^2$ , we have therefore, as long as  $p^* \neq 0$

$$P = G^2 H^2 \frac{\mathcal{E}_\gamma}{\sqrt{\mathcal{E}_\gamma^2 - m_a^2}} \left( \frac{\sin^2(q_2 L/2)}{q_2^2} + (2 \rightarrow 1) \right) \quad (32)$$

in agreement with Eq. (5). Notice that if we let  $\alpha \rightarrow \infty$  in the lhs of Eq. (29), the imaginary part will be zero in the  $\epsilon \rightarrow 0$  limit. This agrees with the discussion preceding Eq. (5).
