Abstract. We show that for any non-negative 4-ary quartic form \( f \) there exists a product of two non-negative quadrics \( q \) and \( q' \) so that \( qq'f \) is a sum of squares (s.o.s.) of quartics. As a step towards deciding whether just one \( q \) always suffices to make \( qf \) a s.o.s, we show that there exist non-s.o.s. non-negative 3-ary sextics \( ac - b^2 \), with \( a, b, c \) of degrees 2, 3, 4, respectively.

1. Introduction

Certifying global nonnegativity of a \( n \)-variate polynomial \( f \) of degree \( d \) by decomposing it as a sum of squares of “nice” functions is a classical topic. Hilbert proved in [14] that these “nice” functions cannot always be just polynomials, unless \( n = 1 \), or \( d = 2 \), or \( d = 4 \), \( n = 2 \) (see e.g. [20] for a modern exposition). In a less known paper [15] he has shown that for \( n = 2 \) one can decompose \( f \geq 0 \) as a sum of squares of rational functions, with degrees of denominators (and thus numerators) bounded from above by \( O(d^2) \). The tools at his disposal were insufficient to extend this to \( n > 2 \); this led to the 17-th Problem from Hilbert’s celebrated list [16], settled in the affirmative by Artin and Schrieier [1]. Namely, \( f \geq 0 \) is decomposable as a sum of squares of rational functions. However, first bounds on degrees of the corresponding denominators only appeared much later; the best presently known bound is a height 5 tower of exponents, involving \( n \) and \( d \), see [18]. Here we take on the first case without a nice bound, namely, \( n = 3 \), \( d = 4 \), and prove an almost sharp bound, by surprisingly elementary means.

Technically, it is more natural to work with \textit{forms}, i.e. homogeneous polynomials, as homogenisation does not change the s.o.s. decomposability. Consider \( \mathbb{R}[X_0, \ldots, X_n] := \mathbb{R}[X] \) and its homogeneous subspaces \( H_{n,d}(\mathbb{R}) \) of degree \( d \). Then the nonnegative on \( \mathbb{R}^{n+1} \) polynomials \( f \in H_{n,2d}(\mathbb{R}) \) form a convex cone, denoted by \( P_{n,2d} \). An \( g \in \mathbb{R}[X] \) is called s.o.s. polynomial if \( g = \sum_{k=1}^N h_k^2 \), for some \( h_k \in \mathbb{R}[X] \). The subcone of s.o.s. polynomials in \( P_{n,2d} \) is denoted by \( \Sigma_{n,2d} \); it is a proper subcone whenever \( d \geq 2 \), \( n \geq 2 \), unless \((d, n) = (2, 2)\). We use notation \( f \geq 0 \) to indicate global nonnegativity. Respectively, for inhomogeneous \( f \) we write \( f > 0 \) to indicate global positivity, and for homogeneous \( f \) we write \( f > 0 \) to indicate positivity away from the origin.

For \( f \in P_{n,2d} \) it is natural to consider a closely related problem of finding a “multiplier” \( q \in \Sigma_{n,2n} \) so that \( qf \in \Sigma_{n,2(d+1)} \) - indeed, we can use the fact that the product of a sum of squares is a sum of squares, and represent \( f \) as a s.o.s. of rational functions with common denominator \( q \). Finding multiplier may be cast as a s.o.s. \textit{polynomial optimisation} feasibility problem, which is equivalent to a \textit{semidefinite optimisation} problem (SDP), cf. [7 Sect. 3.1.7], along the lines of [9]. For the sake of completeness, we include a sketch of the corresponding setup in Appendix. In practice, these SDPs are (usually) efficiently solvable using interior point methods, see e.g. [2, 17]—this was an important reason for a lot of attention to s.o.s. representations in the past 20 years.

We show the following.
Theorem 1. Let \( f \in P_{3,4} \). Then \( f = p/(qq') \), where \( p \in \Sigma_{3,8} \) and \( q, q' \in \Sigma_{3,2} \).

Note that while \( q, q' \) might have some nontrivial real zeros, the identity \( f = p/(qq') \) will hold almost everywhere in the usual measure-theoretic sense.

In a nutshell, the proof is as follows. We start by explaining a folklore result that one can assume that \( f \) has a real zero. Then a linear change of variables allows to reduce to the case where \( f \) is a quadratic polynomial \( f = aX_0^2 + 2bX_0 + c \), w.r.t. \( X_0 \). This means that for any fixed values of the other variables (hidden in forms \( a, b, c \)), \( f \) is a nonnegative quadratic polynomial, and so it suffices to check that its minimum is nonnegative. Algebraically this amounts to “completing the square” i.e. writing \( af = (aX_0 + b)^2 + ac - b^2 \), and observing that the discriminant \( \Delta := ac - b^2 \in P_{3,6} \). As was shown by Hilbert in [15], there exists a \( q \in \Sigma_{3,2} \) so that \( q\Delta \in \Sigma_{3,8} \). Thus \( qaf \in \Sigma_{4,8} \), as claimed. The details are in Section 2.

In the remainder of the paper we investigate the sharpness of the degree bound in Theorem 1. Specifically, as \( \Delta \) lies in a proper subvariety of \( P_{3,6} \), for which no examples of non-s.o.s. nonnegative forms were known prior to this work, a priori \( \Delta \) could have always been a s.o.s., rendering the multiplier \( q \) obsolete. We construct non-s.o.s. \( \Delta \) in Section 3 using Blekherman’s approach from [3].

While the construction of Section 3 provides a supply of potential examples to show the sharpness of the bound, attempts to use them so far proved fruitless, see more on this in the concluding Section 3.1.

2. Reduction to a real zero case

We start by showing that one can assume that \( f \) has a real zero. In what follows, we denote \( X := (X_0, \ldots, X_n) \). First, we recall a well-known lemma (e.g. similar observations are made in [19]).

Lemma 2. Let \( f \in P_{n,2d} \), and \( S := \{ x \in \mathbb{R}^{n+1} | \sum_{k=0}^{n} x_k^2 = 1 \} \) be the unit sphere in \( \mathbb{R}^{n+1} \).

(i) Let \( f \) have a zero on \( S \). An orthogonal change of coordinates bringing the zero to \( (1 : 0 : \cdots : 0) \) transforms \( f \) into the form

\[
    f(X_0, X) = \sum_{k=2}^{2d} f_k(X)X_0^{2d-k}, \quad f_k \in \mathbb{R}[X_1, \ldots, X_n].
\]

(ii) Let \( f > 0 \), with a minimum on \( S \) reached at \( x^* \in S \). An orthogonal change of coordinates bringing \( x^* \) to \( (1 : 0 : \cdots : 0) \) transforms \( f \) into the form

\[
    f(X_0, X) = X_0^{2d} + \sum_{k=2}^{2d} f_k(X)X_0^{2d-k}, \quad f_k \in \mathbb{R}[X_1, \ldots, X_n],
\]

so that \( f(X_0, X) - X_0^{2d} \geq 0 \).

(iii) \( f_2 \geq 0 \) and \( f_{2d} \geq 0 \), and moreover, \( f_2 \in \Sigma_{n,2} \).

Proof. (i). After the transformation, \( f \) cannot have a term \( X_0^{2d} \), as otherwise it cannot vanish on \( (1 : 0 : \cdots : 0) \). It cannot have a term \( f_1(X)X_0^{2d-1} \), as it is nonnegative. Thus we have the required form.

(ii). We may assume without loss of generality that after the transformation we have

\[
    f(X_0, X) = X_0^{2d} + g(X_0, X), \quad g(X_0, X) = \sum_{k=1}^{2d} f_k(X)X_0^{2d-k}.
\]

1 Nontrivial lower bounds of the degrees of an s.o.s. multiplier to a form which make the product s.o.s. are known, e.g. [9], but they are not good enough for the case at hand.
Note that on $S$ one has $f(X_0, X) \geq 1$, as the minimum of $f$ on $S$ equals 1. Thus on $S$ one has $g(X_0, X) = f(X_0, X) - X_0^{2d} \geq f(X_0, X) - 1 \geq 0$. Hence $g(X_0, X) \geq 0$, as it is homogeneous. Moreover, it has a zero, $(1 : 0 : \cdots : 0)$, on $S$, and this (i) applies, ensuring $f_1 = 0$, as required.

(iii). $f_2 \geq 0$ and $f_{2d} \geq 0$ follows from $f \geq 0$ in the case (i), and from $f(X_0, X) - X_0^{2d} \geq 0$ in the case (ii). As $f_2$ is quadratic, it is an s.o.s.

Thus we may assume that $f$ has a real zero. From now on, consider the case $d = 2$. By Lemma \ref{lem:2} we have

$$g(X_0, X) := aX_0^2 + 2bX_0 + c \geq 0, \quad a := f_2(X) \geq 0, \quad c := f_3(X) \geq 0, \quad b := f_3(X)/2.$$  

Note that the nonnegativity of $g$ implies that $ac - b^2 \geq 0$. Indeed, if $(x_1 : \cdots : x_n)$ were a point where $ac - b^2 < 0$, then the univariate polynomial $g(X_0) = g(X_0, x_1, \ldots, x_n)$ would have two real roots, and would be negative on the interval between them, which is not possible. Write, omitting $X$ for brevity:

$$ag(X_0) = a^2X_0^2 + 2abX_0 + ac = (aX_0 + b)^2 - b^2 + ac. \tag{3}$$

The latter is the sum of a square and a polynomial $h(X) := ac - b^2 \in P_{n, 6}$.

In particular, for $n = 3$, by $\cite{13}$ (or by a recent $\cite{4}$ Sect. 5-6), cf. also $\cite{8}$, $h(X) = \frac{u(X)}{q(X)}$, with $u$ and $q$ s.o.s. polynomials of degrees 8 and 2, respectively. To summarise, we state

**Lemma 3.** Let $g(X_0, X) := f_2(X)X_0^2 + f_3(X)X_0 + f_4(X)$ be a nonnegative degree 4 homogeneous polynomial in $X_0, X$, with $X = (X_1, X_2, X_3)$. Then there exists $q(X)\Sigma_{3, 2}$ such that

$$q(X)f_2(X)g(X_0, X) = \sum_{k=1}^{N} r_k(X_0, X)^2, \tag{4}$$

i.e. it is an s.o.s. polynomial. \hfill $\square$

As an orthogonal change of coordinates (e.g. the inverse $G$ of the one in Lemma \ref{lem:2}i)) respects s.o.s. decompositions, and as $g(1, 0, 0, 0) = 0$, we obtain, applying $G$ to the both sizes of (4), the following.

**Lemma 4.** Let $f \in P_{4, 4}$ have a zero on $S$. Then there exist $q_t(X_0, \ldots, X_3) \in \Sigma_{4, 2}, t = 1, 2$, such that $q_1q_2f = s \in \Sigma_{4, 8}$, and $f = s/(q_1q_2)$. \hfill $\square$

To complete the proof of Theorem \ref{thm:1} it remains to observe that in the case of strictly positive $f(X_0) = X_0^4 + f_2X_0^2 + f_3X_0 + f_4$ in the form \ref{eq:2}, by Lemma \ref{lem:3} and Lemma \ref{lem:2}ii) we have $f(X_0) = X_0^4 + \sum_{i=2}^{N} \frac{r_i^2}{q_i^2}$, i.e.

$$q(X)f_2(X)f(X_0, X) = q(X)f_2(X)X_0^4 + \sum_{k=1}^{N} r_k(X)^2.$$  

The 1st term on the RHS of the latter is an s.o.s., and the argument used to establish Lemma \ref{lem:4} applies here, too. \hfill $\square$

**Remark.** Let $f = aX_0^2 + 2bX_0 + c \in P_{4, 4}$, as in Lemma \ref{thm:1}. If $a = \ell^2$, then $f \in \Sigma_{4, 4}$.

Indeed, as $\ell^2c \geq b^2$, one has that $\ell$ divides $b$. Thus one can write $b = b_1\ell$ and write down

$$f = \ell^2X_0^2 + 2b_1\ell X_0 + c = (\ell X_0 + b_1)^2 + c - b_1^2,$$

As any nonnegative ternary quartic is a s.o.s., $c - b_1^2$ is a s.o.s. Hence $f$ is a s.o.s. too. (cf. $\cite{19}$ Sect. 2.2).
3. ON SHARPNESS OF THE DEGREE BOUND FOR 4-ARY 4-ICS

Here we consider \( f(T, X, Y, Z) := aT^2 + 2bT + c \), where \( a, b, c \in \mathbb{R}[X, Y, Z] \), of degrees 2, 3, 4 respectively. As is readily seen from (3), if \( ac - b^2 \in \Sigma_{3, 6} \) then it suffices to multiply \( f \) by \( a \) to obtain \( af \in \Sigma_{4, 6} \). Therefore it is necessary, for non-existence of a quadratic multiplier to \( f \) making \( af \) s.o.s., that \( ac - b^2 \in P_{3, 6} \backslash \Sigma_{3, 6} \). Whether such sextics exist is a nontrivial question, not answered in the literature. We answer it here in the affirmative.

Note that not every polynomial in \( P_{3, 6} \) can be written in the form \( ac - b^2 \), as can be observed by the following dimension-counting argument, or extracted from a sheaf-theoretic argument from \([2]\). Write \( ac - b^2 = \begin{vmatrix} a & b \\ b & c \end{vmatrix} \) and observe that for any 3-ary linear form \( \ell \) and a nonzero \( r \in \mathbb{R} \) one has

\[
\begin{vmatrix} a & b \\ b & c \end{vmatrix} = \begin{vmatrix} r & 0 \\ \ell & 1/r \end{vmatrix} \begin{vmatrix} a & b \\ b & c \end{vmatrix} \begin{vmatrix} \ell & 1/r \end{vmatrix}^{-1} = \begin{vmatrix} r^2a + r\ell a + b & r\ell a + b \\ \ell^2a + 2b\ell/r + c/r^2 \end{vmatrix}.
\] (5)

Thus the variety of nonnegative 3-ary sextics of the form \( ac - b^2 \) has dimension at most \( 6 + 10 + 15 - 3 - 1 = 27 < 28 \), where 28 is the dimension of \( P_{3, 6} \).

**Theorem 5.** There exist positive 3-ary sextics of the form \( ac - b^2 \notin \Sigma_{3, 6} \), with \( a, b, c \in \mathbb{R}[X, Y, Z] \), of degrees 2, 3, 4, respectively.

The proof is based on the approach pioneered in \([3]\). We start by constructing an extremal s.o.s. \( p := ac - q_3^2 > 0 \), so that \( b := (1 + \epsilon)q_3 \) gives a non-s.o.s. \( ac - b^2 > 0 \), for a small \( \epsilon > 0 \). Any such \( p \) is the sum \( p = q_0^2 + q_1^2 + q_2^2 \) of exactly 3 squares, \( p \) is irreducible over \( \mathbb{C} \), and such that \( V_C(q_0, q_1, q_2) = \{ 0 \} \) and \( V_C(q_0, q_1) \) has exactly 9 points, at least 7 of them real, cf. \([3]\). We proceed by seeking \( q_0, \ldots, q_3 \) so that \( ac = p + q_3^2 = uu^* + vv^* \), where \( u := q_0 + iq_1 \), \( v := q_2 + iq_3 \), \( i = \sqrt{-1} \).

The following existence proof, cf. \([12]\), may be replaced by an explicit example—however we provide it for the sake of completeness. Start off from 8 sufficiently generic real points \( V' := \{ V_1, \ldots, V_6 \} \subset \mathbb{P}^2 \). We may assume that no 3 points of \( V' \) are collinear, and there is no conic through any 6 points of \( V' \). Take a basis \( \{ q_0, q_1 \} \) in the 2-dimensional space \( B_{V'} \) of real cubics vanishing on \( V' \). By Chasles Theorem \([11]\) each cubic in \( B_{V'} \) will also vanish in the 9-th point \( V_6 \), also real, as \( q_0 \) and \( q_1 \) are real. Then \( u = q_0 + iq_1 \) will vanish at exactly 9 real points \( V := V' \cup \{ V_6 \} \). Moreover, \( u \) is irreducible, for otherwise \( u \) either contains a real quadric or a line, or has less than 9 real points, contradicting our choice of \( V' \).

Let \( C := V_{22}(a) \) be defined over \( \mathbb{R} \) and smooth; without loss in generality we can assume \( a = X^2 + Y^2 + Z^2 \). The cubic curve \( U := V_{22}(u) \) intersects \( C \) in 6 not necessarily distinct points \( T := \{ T_1, \ldots, T_6 \} \), and \( T_i^* \neq T_j^* \)—otherwise \( U \) and \( U^* \) intersect in such a \( T_i^* \) and \( T_j^* \), which is impossible, as they already intersect in \( V \). To construct \( v \), we partition \( T \) into two parts \( T_1 \) and \( T_2 \), \( |T_1| \geq |T_2| \geq 1 \), and let \( v \) to be a cubic vanishing on \( T_1 \cup T_2^* \). For clarity, we can assume that the latter set of six points is partitioned into three pairs, and that \( v \) is the product of three linear forms defined by these pairs of points.

Next, we need to make sure that \( a \) divides \( uu^* + vv^* \). To this end, let \( W \in C \setminus (T \cup T^*) \). We claim that \( uu^* \) and \( vv^* \) take nonzero values on \( W \) so we can scale \( vv^* \) by \( \gamma := \frac{u(W)u^*(W)}{v(W)v^*(W)} < 0 \), so that \( \gamma v(W)v^*(W) = u(W)u^*(W) \mod (a) \). This gives 13th point of intersection of degree 6 curve \( V_{22}(uu^* - \gamma vv^*) \) and degree 2 curve \( C \), implying, by Bézout Theorem, that \( C \) is a component of this curve, i.e. our latest claim.

\2Often called Cayley-Bacharach.\
We need to check that $\mathbb{R} \ni \gamma < 0$, otherwise the signs of $q_2^r$ and $q_3^r$ in the decomposition of $ac$ would be wrong. We prove the following result, suggested to us, along with a technique to prove it, by Alex Degtyarev.

**Lemma 6.** The constant $\gamma$ is real, and negative whenever $|T_1|$ is odd.

**Proof.** Before starting the proof, we develop necessary tools. We observe that $C$ may be parametrised by

$$ \rho: \mathbb{P}^1 \to \mathbb{P}^2 $$

$$(v : \nu) \mapsto (2i\nu : i(\nu^2 - \nu^2) : \nu^2 + \nu^2) \quad \text{(6)}$$

and the pullback on $C$ of the complex conjugation map

$$ \tau: \mathbb{P}^2 \to \mathbb{P}^2 $$

$$(x : y : z) \mapsto (\overline{x} : \overline{y} : \overline{z})$$

becomes, in homogeneous coordinates, an order 4 (projectively, order 2) map

$$ c: \mathbb{P}^1 \to \mathbb{P}^1 $$

$$(v : \nu) \mapsto (-\nu: \nu).$$

The map $\rho$ defined in (6) induces the map $\hat{\rho}: \mathbb{C}[U, V] \to \mathbb{C}[X, Y, Z]/(u)$ defined on polynomials of even degree, via

$$ UV \mapsto X/2i, \quad U^2 \mapsto (Y + iZ)/2i, \quad V^2 \mapsto (-Y + iZ)/2i. \quad \text{(7)}$$

Obviously, $\hat{\rho}$ is the inverse of the restriction mapping of $\mathbb{C}[X, Y, Z]$ to $C$, and as such is one-to-many, in general. We make it one-to-one by writing a homogeneous $p \in \mathbb{C}[U, V]$ of degree $2k$ as a product of linear factors $\ell_1 \ldots \ell_{2k}$, and rewrite each $\ell_{2j-1}\ell_{2j}$ using (6); thus $\hat{\rho}(p)$ is always a particular, depending on the matching of linear factor we chose, product of $k$ linear forms.

The linear form $\ell := \ell_{(v, \nu)}(U, V) := \nu U - \nu V$ vanishes at $(v : \nu) \in \mathbb{P}^1$, and the form $\ell^* := -\ell_{c((v, \nu))}(U, V) = -\overline{\nu} U - \nu V$ vanishes at $(-\nu : \nu) = c((v : \nu))$. It is more convenient to write $\ell^*$ as

$$ \ell^*(U, V) = \ell(c(U : V)) \quad (= -\overline{\nu} U - \nu V = -\nu U + \nu V = \ell^* \text{- to check}),$$

implying

$$ \ell^{**}(U, V) = \ell^*(c(U : V)) \equiv \ell^*(-\nu U + \nu V) = \nu V - \nu U = -\ell(U, V). \quad \text{(8)}$$

As a homogeneous degree $d$ form $p \in \mathbb{C}[U, V]$ factors into linear forms as $p = \ell_1 \ldots \ell_d$, we can define $p^* = \ell_1^* \ldots \ell_d^*$, and conclude that

$$ p^{**} = (-1)^d p. \quad \text{(8)}$$

Now, let $s, t, u \in \mathbb{C}[U, V]$ be the restrictions of $u, v$ to $C$. Then $s$ is a scalar multiple of $\ell_1 s_2$, say, $s = \alpha s_1 s_2$, for $s_j = \prod_{r \in T_1} \ell_r$, and $t$ is a scalar multiple of $s_1 s_2^*$, say, $t = \beta s_1 s_2^*$. Finally, we compute, using (7), that

$$ \frac{s s^*}{\ell^*} = \frac{\alpha \overline{\nu} s_1 s_2^* s_2 s_1^*}{\beta \beta \nu s_1 s_2^* s_2 s_1^*} = (-1)^{|T_1|} \gamma = \gamma, \quad \text{where} \quad \gamma = -\frac{\alpha \nu}{\beta \beta} < 0.$$

This completes the proof of the Lemma. \hfill \Box

We still need to make sure that $q_2^2$ does not vanish on any $V_j \in \mathcal{V}$. To this end, we use the fact that for any $\ell := \ell_2 + i\ell_3$, with $\ell_j \in H_{3,1}$ the form $v + \ell a$ will cut on $C$ the same points as $v$, i.e. $uu^* + (v + \ell a)(v + \ell a)^*$ equals $uu^* + vv^*$ in the coordinate ring of $C$.

As $C \cap \mathcal{V} = \emptyset$, we can choose $\ell_2$, with $V(\ell_2) \cap \mathcal{V} = \emptyset$, so that $|\ell_2(V_j)a(V_j)|$ is small enough not to cause vanishing of $q_2^2 := q_2 + \ell_2 a$ on $V_j$. Thus $V(q_2^2) \cap \mathcal{V} = \emptyset$, as required. Now [3] implies the following.
Lemma 7. The forms $q_0$, $q_1$, $q'_2$ form a basis of the kernel of a p.s.d. quadratic form $Q \in \Sigma_{3,8}$. There exists a linear functional $\mathcal{L} \in H_{3,6}^*$ such that for any $f \in H_{3,3}$ one has $Q(f) = \mathcal{L}(f^2) \geq 0$, and $Q$ spans an extreme ray of $H_{3,6}^*$. Moreover,

$$\mathcal{L}(h) = \sum_{V \in \mathcal{V}} \mu_V h(V) \quad \text{for any } h \in H_{3,6}, \text{ and } \mathcal{L}(q_0^2) = \mathcal{L}(q_1^2) = \mathcal{L}((q'_2)^2) = 0.$$  

One can choose $\mu_V > 0$ for $1 \leq j \leq 8$, and $\mu_V < 0$.

It remains to show that $\ell_3$ in $q'_3 := q_3 + \ell_3 a$ can be chosen so that $p = ac - (1 + \epsilon)(q'_3)^2 = q_0^2 + q_1^2 + (q'_2)^2 - \epsilon(q'_3)^2$ is not s.o.s. Note that by Lemma 7 one has $\mathcal{L}(p) = -\epsilon \mathcal{L}((q'_3)^2)$, that is, to certify that $p$ is not s.o.s., by linearity of $\mathcal{L}$ it suffices to show that $\mathcal{L}((q'_3)^2) \neq 0$.

To this end, we show that $\ell_3$ may be chosen so that $q'_3(V_0) = 0$, yet $\mathcal{V} \setminus \mathcal{V}(q'_3) \neq \emptyset$, and so the positivity of $\mu_V$ gives the desired. If $q_3$ vanishes on a nonempty proper subset of $\mathcal{V}$, then it can be arranged that is vanishes on $V_0$, and so we are done in this case. If $q_3$ vanishes on $\mathcal{V}$, we can replace it with $q_3 + \ell' a$, with $V(\ell') \cap \mathcal{V} = \emptyset$, reducing to the case where $q_3$ vanishes on no point of $\mathcal{V}$. Finally, choose $\ell_3$ through $V_0$ so that it $\ell_3(V_0) a(V_0) = -q_3(V_0)$. Then $q'_3(V_0) \neq 0$, but $q'_3(V_0) = 0$, and have $\mathcal{L}(p) < 0$, completing the proof of Theorem 7.

3.1. Remarks. Particular examples of $a$, $b$, $c$ obtained following the construction of Theorem 5 are too “complicated” to be fed in an off the shelf SDP solver, in order to test whether the resulting $f(T)$ is an s.o.s. or admits a quadratic multiplier making it an s.o.s. It is a delicate exercise in computer algebra to construct them, as we do not know in advance a good $T$ on the conic $C$, but need to construct it, starting from $a$ with exactly 9 real points $\mathcal{V}$, and this brings in high degree irrationalities. To work around the latter, we take a rational approximation of $T$ in terms of a parametrisation of $C$, of sufficiently high precision as to leave $\mathcal{V}$ real. This results in $b$ and $c$ having large rational coefficients, not approximated well by machine-precision floating point numbers using by SDP solvers—and even the arbitrary precision SDP solver SDPA-GMP [13] has problems with there inputs.

Thus the question whether our degree bound is sharp remains open, for the time being. One possible way out might be to use an arbitrary precision SDP solver with controlled precision, e.g. implementing an algorithm outlined in [10].

It might be interesting to investigate a possibility to obtain a non-s.o.s. $ac - b^2$ with a high number of real zeros (from Theorem 5) is it not clear how to get more than one real zero, whereas a theoretical bound is 10—this is how many zeroes ternary non-s.o.s. nonnegative sextics can have, see e.g. [5].

Acknowledgement. We thank Alex Degtyarev for help with constructing sextics in Theorem 5 and Greg Blekherman for explaining details of 8 and other helpful discussions.

References

Here we use multinomial notation for monomials $X_1^{K_1}X_2^{K_2}\ldots X_n^{K_n} := X^K$ of degree $|K| := \sum_j K_j$, and the matrix scalar product $\langle A, B \rangle := \text{Tr}(A^\top B) = \sum_{i,j} A_{ij}B_{ij}$.

Let $f(X) = \sum_{|K|=2d} c_K X^K = \sum_{t=1}^{t^*} \left( \sum_{|M|=d} \ell_{t,M} X^M \right)^2 \in \Sigma_{n,2d}$ be a sum of $t^*$ squares. It is convenient to introduce a matrix $L$ by $L_{t,M} := \ell_{t,M}$ and a vector $X := (X^M \mid |M| = d)$, allowing one to write $f(X) = X^\top L^\top L X$. The matrix $G := L^\top L$ is called a Gram matrix for $f$. By definition, $G$ is positive semidefinite (p.s.d., for short), and finding an s.o.s. decomposition for $f$ amounts to finding a $G$. By comparing the coefficients of $X^K$ on the left- and the right-hand sides of $f(x) = X^\top G X$ we see that the latter is equivalent to the system of equations

$$\langle G, M_K \rangle = c_K, \quad \text{for each } K \text{ with } |K| = 2d, \tag{9}$$

where each $M_K$ is an explicit matrix which depends only on $K$; it is usually called moment matrix.

Note that (9) together with the constraint saying that $G$ is p.s.d., written as $G \succ 0$, is a particular case of the feasibility problem for the semidefinite programming in primal form, cf. e.g. [2] Chapter 2).

In a greater generality, where we only know that $f \geq 0$, we need to find a multiplier $a \in \Sigma_{n,2m}$, so that $af \in \Sigma_{n,2(m+d)}$. We put the Gram matrices for $af$ and $a$ into the block-diagonal p.s.d. matrix variable $\text{diag}(S,T)$. Now the right-hand sides of (9) become variables, on which the condition that $a$ divides $af$ imposes linear constraints, and this is how the SDP formulation for the problem at hand is
usually stated in the literature. However, these extra variables can be eliminated completely. Namely, the following holds.

**Proposition 8.** Let \( f \in P_{n,2d} \). Then there exists \( a \in \Sigma_{n,2m} \) satisfying \( af \in \Sigma_{n,2(d+m)} \), if and only if the linear system of equations

\[
\langle \text{diag}(S,T), \text{diag}(M_I, - \sum_{K+J=I} c_K M_J) \rangle = 0, \quad \text{for } |I| = 2(d+m), \quad \text{(10)}
\]

has a solution with \( \text{Tr} T = 1 \) and \( T \succeq 0, S \succeq 0 \).

**Proof.** As \( S \) is a Gram matrix for \( af \), for every \( I \) it must satisfy

\[
\langle S, M_I \rangle = \sum_{K+J=I} a_J c_K, \quad \text{where } a(X) = \sum_J X^J.
\]

On the other hand, \( T \) is a Gram matrix for \( a \), thus \( a_J = \langle T, M_K \rangle \). Therefore, by bi-linearity of \( (,)_n \) we obtain

\[
\langle S, M_I \rangle = \sum_{K+J=I} c_K \langle T, M_J \rangle = \langle T, \sum_{K+J=I} c_K M_J \rangle,
\]

implying \((10)\). The condition \( \text{Tr} T = 1 \) makes sure that \( a \) is not identically 0. \( \Box \)
