Abstract—Anonymized social network graphs published for academic or advertisement purposes are subject to de-anonymization attacks by leveraging side information in the form of a second, public social network graph correlated with the anonymized graph. This is because the two are from the same underlying graph of true social relationships. In this paper, the maximum a posteriori (MAP) estimates of user identities for the anonymized graph are characterized and sufficient conditions for successful de-anonymization for underlying graphs with community structure are provided. The results generalize prior work that assumed underlying graphs of Erdős-Rényi type, and prove the optimality of the attack strategy adopted in the literature.

I. INTRODUCTION

Privacy of users in social networking sites is an important concern, especially with the rising popularity of social networks. Social network data is often intentionally (and sometimes accidentally) revealed for academic and advertisement purposes. Before such revelations, names and other identifying information about users are usually omitted (or randomized) in an effort to preserve the anonymity of the users. However, removing user names from published data may not in itself be sufficient to preserve privacy. This is because an attacker might be able to use publicly available side information correlated with the anonymized data to recover user identities. For instance, anonymized Netflix data of user viewing preferences was de-anonymized using a publicly available IMDB database [1].

In this work, we focus on the problem of privacy in social networks when the data published by the networking site is an anonymized graph of user connectivity. That is, each vertex in the graph is a user, and users that are connected (for instance, friends) share an undirected edge. The graph is anonymized by removing or randomizing the labels corresponding to each vertex. However, as in the Netflix/IMDB example above, an attacker might be able to recover some or all of the user identities using data from a second social network whose graph of user connectivity is publicly available. For example, Narayanan and Shmatikov demonstrated an attack in which anonymized Twitter users were identified using Flickr data [2].

The success of social network de-anonymization is premised on the observation that data from two social networks can be reasonably expected to be correlated assuming that the two graphs, \( g_1 \) and \( g_2 \), are independently sampled (with probability \( s \)) from the same underlying graph, \( g \), which represents the true relationships between all users. In recent work [3], Pedarsani and Grossglauser have theoretically analyzed the social network de-anonymization by assuming that the underlying graph, \( g \), is an Erdős-Rényi graph with edge probability \( p \). In particular, [3] establishes sufficient conditions on the edge probability, \( p \), and sampling probability, \( s \), that guarantee perfect de-anonymization, that is, each user in the anonymized network is correctly identified.

There are several important directions in which the prior work can be extended. First, in obtaining their results, Pedarsani and Grossglauser [3] and succeeding work [4], [5] assume that the attacker matches nodes in the anonymized graph to those in the public graph so as to minimize a certain cost function, which is the number of mismatched edges. However, the authors do not provide a rationale for this choice of cost function, or prove the optimality of the attacker’s strategy. Second, it has been empirically shown that graphs of social interaction are not, in fact, Erdős-Rényi and instead have community structure [6]. A natural question, therefore, is what are the attacker’s capabilities when the statistics of the underlying graph reflect community structure? The goal of our work is to address these questions.

Specifically, in this paper, we make the following contributions. First, we derive the maximum a posteriori (MAP) matching of nodes in the anonymized graph to those in the public graph assuming an underlying graph \( g \) with community structure. For the special case of a graph with a single community, which is simply an Erdős-Rényi graph and community structure. For the special case of a graph with a single community, which is simply an Erdős-Rényi graph, we establish the equivalence between the MAP matching and the matching that minimizes Pedarsani and Grossglauser’s cost function, establishing the optimality of the attacker’s strategy in that and several succeeding works. Second, we determine conditions on the parameters of the underlying graph and the sampling probability that guarantee perfect de-anonymization for the general case of graphs with community structure.

We note that when \( g \) has community structure, the de-anonymization problem has some relation to the well known community detection problem [7]. Hence the problem can be viewed as community detection with side information, although we note that recovering the community labels in \( g_2 \) is only a necessary, but not sufficient, condition for de-anonymization. In the rest of this paper, we will focus on an attack setting in which the attacker’s goal is to determine user identities only, assuming that the community labels in \( g_1 \) and
edges are known.

II. SYSTEM MODEL

Let \( g = (V, E_g) \) be an undirected graph of true relationships between \( n \) users. The number of users is \( |V| = n \), and the edge set is \( E_g \subseteq V \times V \). We assume nodes of \( g \) are partitioned into disjoint subsets of \( k \geq 1 \) communities, \( C_1, C_2, \ldots, C_k \). The number of nodes in community \( C_i \) is \( |C_i| = n_i \). An example of \( g \) for the two community case is shown in Figure 1.

Edges in \( E_g \) are drawn independently at random as follows: nodes \( u \in C_i \) and \( v \in C_j \) are connected with probability \( p_{ij} \). In literature, this model is referred to as the stochastic block model \( 6 \), and is simply the Erdős-Rényi graph model for \( k = 1 \).

From underlying graph of true relationships between users, \( g \), we obtain two independent samples \( g_1 = (V, E_{g_1}) \) and \( g_2 = (V, E_{g_2}) \), as shown with an example in Figure 1 that represent the connectivity graphs of two different social network platforms. As in \( 3 \), we assume that only edges are known in both \( g_1 \) and \( g_2 \). In particular:

\[
\mathbb{P}( (u, v) \in E_{g_i} ) = \begin{cases} s & \text{if } (u, v) \in E_g \\ 0 & \text{otherwise} \end{cases}
\]

for \( i = 1, 2 \) where we further assume that each edge is sampled independently.

In the context of the de-anonymization problem, we assume that all the labels of the nodes of \( g_1 \) are given and the attacker's goal is to recover the labels of \( g_2 \) given \( g_1 \). However, as noted in Section I, we will assume that the community assignments are known in both \( g_1 \) and \( g_2 \). This problem is equivalent to finding a matching between the node sets of two graphs. A matching of \( g_1 \)'s nodes to \( g_2 \)'s nodes, which is also a permutation over \( [n] \), will be denoted as \( \pi : V \rightarrow V \), where \( \Pi \) is the set of all possible permutations that is compatible with the community assignments.

With some abuse of notation, for an edge \( e \in E_{g_1}, \) we will allow \( \pi(e) \) to denote the image of \( e \) in \( E_{g_2} \). That is, for \( (u, v) \in E_{g_2}, \pi((u, v)) = (\pi(u), \pi(v)) \). Given community labels, \( E_{g_k}^{ij} \) refers to the subset of edges in \( g_k (k \in \{1, 2\}) \) that lie between nodes in community \( C_i \) and \( C_j \) and similar definition follows for \( E_{g_2}^{ij} \).

III. MAXIMUM A POSTERIORI DE-ANONYMIZATION

In this section, we derive the MAP estimate of \( \pi \) (the labeling of nodes in \( g_2 \)), assuming an a priori uniform distribution over \( \pi \), given realizations of \( g_1 \) and \( g_2 \). In particular, we will show that the the MAP estimate corresponds to the matching that minimizes the cost function, \( \Delta_\pi \) that we define below.

**Definition 1.**

\[
\Delta_\pi = \sum_{i \leq j} \omega_{ij} \left( \sum_{e \in E_{g_2}^{ij}} 1 \{ \pi(e) \notin E_{g_1}^{ij} \} + \sum_{e \in E_{g_1}^{ij}} 1 \{ \pi^{-1}(e) \notin E_{g_2}^{ij} \} \right)
\]

(1)

where

\[
\omega_{ij} = \log \left( \frac{1 - p_{ij}s(2 - s)}{p_{ij}(1 - s)^2} \right),
\]

and \( \sum_{i \leq j} \) is the short-hand notation for \( \sum_{1 \leq i \leq j \leq k} \).

By virtue of being the MAP estimate, minimizing \( \Delta_\pi \) corresponds to the attacker's optimal strategy that minimizes error probability \( 8 \), i.e., the probability of obtaining an incorrect matching. On the other hand, if we set all the weights \( \omega_{ij} \) in Equation 1 to 1, \( \Delta_\pi \) above would correspond to the "edge mismatch" cost function that \( 3 \) and subsequent works \( 5 \), \( 4 \) minimize. This strategy is sub-optimal, in general, for community structured graphs.

Now, we define the MAP estimate of \( \pi \) given \( g_1 \) and \( g_2 \) as:

\[
\text{MAP}(g_1, g_2) = \arg \max_{\pi \in \Pi} p(\pi | g_1, g_2),
\]

which can be further written as:

\[
\text{MAP}(g_1, g_2) = \arg \max_{\pi \in \Pi} \sum_{g \in G_\pi} p(g, \pi | g_1, g_2),
\]

where \( G_\pi \) is the set of all underlying graphs that are consistent with \( g_1 \) and \( g_2 \) given \( \pi \).

**Theorem 1.** Assuming \( p_{ij} < 1/2 \) for all \( i, j \in [1, k] \),

\[
\text{MAP}(g_1, g_2) = \arg \min_{\pi \in \Pi} \Delta_\pi
\]

**Proof:** Let us start with elaborating \( \text{MAP}(g_1, g_2) \).

\[
\begin{align*}
\text{MAP}(g_1, g_2) &= \arg \max_{\pi \in \Pi} \sum_{g \in G_\pi} p(g_1 | g) \cdot p(g_2 | g, \pi) \cdot p(g) \\
&= \arg \max_{\pi \in \Pi} \sum_{g \in G_\pi} p(g_1 | g) \cdot \prod_{i \leq j} (1 - s)^{|E_{g_1}^{ij}| - |E_{g_1}^{ij}|} |E_{g_1}^{ij}| \\
&\quad \cdot \prod_{i \leq j} (1 - s)^{|E_{g_2}^{ij}| - |E_{g_2}^{ij}|} |E_{g_2}^{ij}| \\
&\quad \cdot \prod_{i \leq j} p_{ij}^{k} (1 - p_{ij})^{N - k - |E_{g}^{ij}|} \\
&= \arg \max_{\pi \in \Pi} \sum_{g \in G_\pi} p(g_1 | g) \cdot p(g_2 | g, \pi) \cdot p(g)
\end{align*}
\]

(2)

(3)
Noting that sum in (5) is a binomial sum, we can further write
\[ \sum_{g \in \mathcal{G}_g} \prod_{i \leq j} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{|E^{ij}_p|} \]
\[ = \arg \max_{\pi \in \Pi} \left( \prod_{i \leq j} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{|E^{ij}_p|} \right) \]
\[ = \arg \max_{\pi \in \Pi} \sum_{g \in \mathcal{G}_g} \prod_{i \leq j} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{|E^{ij}_p|} \quad (4) \]

In (2) we used the facts that distribution of \( g_1 \) given \( g \) is independent of the labeling of \( g_2 \), and \( \pi \) has uniform prior distribution. In (3), \( N^{ij} \) is the number of node pairs from communities \( C_i \) and \( C_j \), and while writing (4) we used the observation that
\[ \sum_{i \leq j} \left( |E^{ij}_g| + |E^{ij}_{g_2}| \right) = |E_g| + |E_{g_2}| \]
is constant given \( g_1 \) and \( g_2 \).

Now let \( g_2^* \) denote the graph having the smallest number of edges in \( \mathcal{G}_g \), i.e., \( g_2^* = \min \{ V, E_g, \pi(E_g) \} \). Note that \( \mathcal{G}_g \) consists of all graphs whose edge sets are supersets of \( g_2^* \). Summing over all graphs in \( \mathcal{G}_g \), we get:
\[ \text{MAP}(g_1, g_2) = \arg \max_{\pi \in \Pi} \left( \prod_{i \leq j} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{|E^{ij}_p|} \right) \]
\[ \prod_{i \leq j} \sum_{a_{ij}=0}^{N_{ij}-|E^{ij}_g|} \left( N_{ij} - |E^{ij}_g| \right)^{a_{ij}} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{a_{ij}} \quad (5) \]

Noting that sum in (5) is a binomial sum, we can further write (5) as:
\[ \arg \max_{\pi \in \Pi} \prod_{i \leq j} \left( \frac{p_{ij}(1-s)^2}{1-p_{ij}} \right)^{|E^{ij}_p|} \]
\[ = \arg \min_{\pi \in \Pi} \sum_{i \leq j} |E^{ij}_g| \log \left( \frac{1-p_{ij}(1-s)^2}{1-p_{ij}} \right) \quad (6) \]

Now we observe that
\[ |E^{ij}_g| = \frac{1}{2} \left( |E^{ij}_g| + |E^{ij}_{g_2}| \right) \]
\[ + \sum_{e \in E^{ij}_{g_2}} \mathbb{1}\{\pi(e) \notin E^{ij}_{g_2}\} + \sum_{e \in E^{ij}_{g_1}} \mathbb{1}\{\pi^{-1}(e) \notin E^{ij}_{g_1}\} \]

which allows us to write (6) as
\[ \arg \min_{\pi \in \Pi} \sum_{i \leq j} \omega_{ij} \left( \sum_{e \in E^{ij}_g} \mathbb{1}\{\pi(e) \notin E^{ij}_g\} + \sum_{e \in E^{ij}_{g_2}} \mathbb{1}\{\pi^{-1}(e) \notin E^{ij}_{g_2}\} \right) \]
\[ = \arg \min_{\pi \in \Pi} \Delta_{\pi} \]

since \( |E^{ij}_g| + |E^{ij}_{g_2}| \) does not depend on \( \pi \).

**Corollary 1.1.** If \( g \) is an Erdős-Rényi graph with edge probability \( p < 1/2 \)
\[ \text{MAP}(g_1, g_2) = \]
\[ \arg \min_{\pi \in \Pi} \left( \sum_{e \in E_{g_1}} \mathbb{1}\{\pi(e) \notin E_{g_2}\} + \sum_{e \in E_{g_2}} \mathbb{1}\{\pi^{-1}(e) \notin E_{g_1}\} \right) \quad (7) \]

**Proof:** Set \( k = 1 \) in Theorem 1 and note that for \( p_{11} < 1/2, \omega_{11} > 0 \).

**Remark 1.** The cost function in (7) is the same as the “edge mismatch” cost function that [3] and subsequent works [4] minimize, but without proof of optimality. Corollary 1.1 establishes that when \( q \) is an Erdős-Rényi graph, minimizing the edge mismatch cost function as defined by [3] indeed corresponds to the attacker’s optimal strategy. This optimality result for the special case of Erdős-Rényi graphs is also presented in a concurrent work [9]. For the general case with two or more communities on the other hand, Theorem 1 shows that inter-community and intra-community edge mismatches must be weighted differently.

**IV. Probability of Error**

In the previous section, we characterized the attacker’s optimal de-anonymization strategy for finite \( n \). In this section, we derive sufficient conditions for which the attacker can find *asymptotically almost surely* the correct matching for the two community case. For notational simplicity let \( p = p_{11} = p_{22} \) and \( q = p_{12} \). The corresponding result in the classical Erdős-Rényi model follows as a special case.

**Theorem 2.** Given \( g_1, g_2 \) and \( p, q \to 0 \) where \( q \leq p \), if
\[ s \left( 1 - \sqrt{1-s^2} \right) \left( p + 2 \cdot \frac{n_2}{n_1} q \right) = \frac{3 \log n_1}{n_1} + \omega(n_1^{-1}) \],
\[ s \left( 1 - \sqrt{1-s^2} \right) \left( p + 2 \cdot \frac{n_1}{n_2} q \right) = \frac{3 \log n_2}{n_2} + \omega(n_2^{-1}) \],
then the probability of error of the attacker can approach zero asymptotically, i.e., \( \arg \min_{\pi} \Delta_{\pi} = \pi_0 \) a.a.s. as \( n_1, n_2 \to \infty \) where \( \pi_0 \) is the correct matching.

**Proof:** Note that in \( \Delta_{\pi} \), as \( p, q \to 0, \frac{n_1}{n_2} \to 1 \) if \( p = \Theta(q) \). For tractability of our proof, we will assume that the attacker uses a sub-optimal cost function \( \Delta' \) where \( \omega_{12} = 1 \). Since the error probability with \( \Delta' \) upper bounds that with \( \Delta_{\pi} \), we still obtain sufficient conditions for correct de-anonymization.

Let
\[ S_{k_1,k_2} = \sum_{\pi \in \Pi_{k_1,k_2}} \mathbb{1}\{\Delta'_{\pi} \leq \Delta'_0\} \]
where \( \Delta'_0 \) is the cost corresponding to \( \pi_0 \). Here \( \Pi_{k_1,k_2} \) denotes the set of label assignments for nodes in \( g_2 \) that is compatible with the given community assignment and where \( k_1 \) of the nodes in \( C_1 \) and \( k_2 \) of those in \( C_2 \) are mismatched. Note \( S_{k_1,k_2} \) denotes the number of node matchings with \( k_1 \) mismatches in \( C_1 \) that has mismatch cost not greater than that of true matching. Let us denote the number of labelings with at least one mismatch and edge cost not greater than \( \Delta'_0 \) with \( S \), that is
\[ S = \sum_{k_1=0}^{n_1} \sum_{k_2=0,k_1+k_2 \neq 0}^{n_2} S_{k_1,k_2} \quad (8) \]

Our proof is based on showing the expected value of \( S \), a non-negative random variable, is asymptotically 0 if the conditions
stated in the theorem are satisfied, therefore guaranteeing that an attacker using the $\Delta_\pi$ cost function would be able to recover the true matching. We have
\[
E[S] = \sum_{k_1} \sum_{k_2} \sum_{\pi \in \Pi_{k_1,k_2}} \mathbb{P}\{\Delta_\pi' - \Delta_\pi' \leq 0\}
\leq \sum_{k_1} \sum_{k_2} |\Pi_{k_1,k_2}| \cdot \max_{\pi \in \Pi_{k_1,k_2}} \mathbb{P}\{\Delta_\pi - \Delta_\pi' \geq 0\}
\tag{9}
\]
where the summations still have the same restrictions of (8) and [3].

By similar arguments
\[
u_2 \triangleq \mathbb{P}\{A_e = -1\} = ps(s + 1 - 2ps)
\]
\[
u_1 \triangleq \mathbb{P}\{B_e = 1\} = qs(1 - s)
\]
\[
u_3 \triangleq \mathbb{P}\{B_e = -1\} = qs(s + 1 - 2qs)
\]
and define $u_2 \triangleq 1 - u_1 - u_3$, $v_2 \triangleq 1 - v_1 - v_3$. If we denote $Z = \sum_{e \in \mathcal{E}_{\text{intra}}} A_e$ and $T = \sum_{e \in \mathcal{E}_{\text{inter}}} B_e$, we get
\[
\mathbb{P}\{\Delta_0 - \Delta_\pi' \geq 0\} = \mathbb{P}\{Y_\pi - Y_\pi' \geq 0\} = \mathbb{P}\{Z + T \geq 0\}
\tag{11}
\]
Terms of the sum in $Z$ can be dependent due to cycles in the mapping $\pi$, and so are those of $T$, but each term in $Z$ is independent of all terms in $T$. Next we decompose $Z$ and $T$ into three sums such that each sum consists of only independent terms.

**Proposition 1.** There exists a partition $\mathcal{E}_{\text{intra}} = \cup_{i=1}^3 \mathcal{E}_{\text{intra},i}$ such that
\[
\left( \bigcup_{e \in \mathcal{E}_{\text{intra},i}} \{\pi(e)\} \right) \cap \mathcal{E}_{\text{intra},i} = \emptyset \quad \text{and}
\]
\[
|\mathcal{E}_{\text{intra},i}| \geq \frac{|\mathcal{E}_{\text{intra}}|}{3} \quad \text{for all } i = 1, 2, 3.
\tag{13}
\]

**Proof:** For any mapping $\pi$, we define a dependency graph $D_{\pi}$ such that every node pair in $\mathcal{E}_{\text{intra}}$ corresponds to a vertex in $D_{\pi}$. An edge exists between $e$ and $e'$ of $D_{\pi}$ if and only if $\pi(e) = e'$ or $\pi(e') = e$. Any partitioning of $\mathcal{E}_{\text{intra}}$ that meets (12) corresponds to a vertex coloring in $D_{\pi}$. Note that $D_{\pi}$ consists of a finite number of disjoint cycles. Thus, we can color $D_{\pi}$ using three colors (since an odd cycle would require three colors [10]). The second condition of the Proposition (13) follows from induction on the number of cycles in $D_{\pi}$.

Accordingly we let
\[
Z_i = \sum_{e \in \mathcal{E}_{\text{intra},i}} A_e \quad \text{and} \quad T_i = \sum_{e \in \mathcal{E}_{\text{inter},i}} B_e
\]
Continuing from (11),
\[
\mathbb{P}\{Z + T \geq 0\} = \mathbb{P}\{\sum_{i=1}^3 (Z_i + T_i) \geq 0\}
\leq \sum_{i=1}^3 \mathbb{P}\{Z_i + T_i \geq 0\} \leq 3 \max_i \mathbb{P}\{Z_i + T_i \geq 0\}
\tag{14}
\]
For $i = 1, 2, 3$
\[
\mathbb{P}\{Z_i + T_i \geq 0\} = \mathbb{P}\{e^{\varphi(Z_i + T_i)} \geq 1\} \quad \varphi > 0
\leq \mathbb{E}[e^{\varphi(Z_i + T_i)}]
\tag{15}
= (u_1 e^{\varphi} + u_2 + u_3 e^{-\varphi})^{n_{Z_i}} (v_1 e^{\varphi} + v_2 + v_3 e^{-\varphi})^{n_{T_i}}
\leq \exp \left[ n_{Z_i} (u_3 - e^{-\varphi} u_1) (e^{\varphi} - 1) + n_{T_i} (v_3 - e^{-\varphi} v_2) (e^{\varphi} - 1) \right]
\tag{16}
\]
where $n_{Z_i} = |\mathcal{E}_{\text{intra},i}|$ and $n_{T_i} = |\mathcal{E}_{\text{inter},i}|$. (16) is due to Markov’s inequality and we use the inequality $x \leq e^{x-1}$ in (16). To find the smallest upper bound, we find the $\varphi^*$ that
sets the derivative of the exponent in (16), which is a convex function of \( \varphi \), to 0. Inserting \( \varphi^* \) in the expression we get

\[
P\{Z_i + T_i \geq 0\} \leq e^{-\left(\sqrt{n_z u_3 + n_r v_3} - \sqrt{n_z u_1 + n_r v_1}\right)^2} \tag{17}
\]

Now we find lower bounds on \( n_{Z_i} \) and \( n_{T_i} \):

\[
n_{Z_i} \geq \left| E_{\text{inter}} \right| / 3 \geq 1 / 3 \sum_{i=1,2} \left[ \frac{k_i}{2} + k_i(n_i - k_i) \right] - \left| E_{\text{intr}} \right| / 3 - 1
\]

\[
\geq 1 / 3 \sum_{i=1,2} k_i (n_i - k_i^2 - 1) - 1 \quad \text{and} \quad \tag{18}
\]

\[
n_{T_i} \geq \left| E_{\text{inter}} \right| / 3 \geq k_1 n_2 + k_2 n_1 - k_1 k_2 - 1
\]

\[
\geq k_1 n_2 + k_2 n_1 - 1
\]

(18) is due to the bound \( \left| E_{\text{intr}} \right| \leq (k_1 + k_2^2) / 2 \). It can be checked that the derivative of the exponent in (17) with respect to both \( n_{Z_i} \) and \( n_{T_i} \) is negative for sufficiently small \( p \) and \( q \). Therefore from (17) and the lower bounds over \( n_{Z_i} \) and \( n_{T_i} \) found above,

\[
P\{Z_i + T_i \geq 0\} \leq e^{-\frac{3}{2}(1 - \sqrt{1 - s^2})(k_1 n_1 p + k_2 n_2 q + k_2 n_2 q + k_2 n_2 q + k_2 n_2 q)} \tag{19}
\]

From (11), (14) and (19),

\[
P\{\Delta'_0 - \Delta'_1 \geq 0\} \leq 3e^{-\frac{3}{2}(1 - \sqrt{1 - s^2})(k_1 n_1 p + k_1 n_2 q + k_2 n_2 q + k_2 n_2 q)}
\]

Let us now upper bound the other term in the summand of (9).

\[
|\Pi_{k_1, k_2}| \leq n_1 k_1 n_2 k_2 \exp[k_1 \log n_1 + k_2 \log n_2] \tag{20}
\]

Using (19) and (20) in (9) we get,

\[
\mathbb{E}[S] \leq 3 \sum_{k_1} \sum_{k_2} \exp[k_1 \log n_1 - s(1 - \sqrt{1 - s^2})(n_1 p + n_2 q) / 3]
\]

\[
+ k_2 \left[ \log n_2 - s(1 - \sqrt{1 - s^2})(n_2 p + n_1 q) / 3 \right]
\]

The sum goes to 0 and thus we guarantee successful MAP de-anonymization if

\[
s \left( 1 - \sqrt{1 - s^2} \right) \left( p + \frac{n_2 q}{n_1} \right) = \frac{3 \log n_1}{n_1} + \omega(n_1^{-1}) \quad \text{and} \quad
\]

\[
s \left( 1 - \sqrt{1 - s^2} \right) \left( p + \frac{q n_1}{n_2} \right) = \frac{3 \log n_2}{n_2} + \omega(n_2^{-1})
\]

Corollary 2.1. In the case of single community (regular Erdős-Rényi graph with \( n_1 \) nodes), a sufficient condition for de-anonymization is

\[
ps \left( 1 - \sqrt{1 - s^2} \right) = \frac{3 \log n_1}{n_1} + \omega(n_1^{-1}).
\]

Proof: The result can be obtained by setting \( q = 0 \), \( n_1 = n_2 \) in Theorem 2. Note that in this case there are no inter-community edges and the setting is equivalent to de-anonymization in each community separately.

Remar 2. For the case of symmetric communities, \( n_1 = n_2 \) and non-zero inter-community edge probability \( q \), conditions given in Theorem 2 are less strict than the result in Corollary 2.1 suggesting that inter-community edges help in the de-anonymization of nodes within a community.

Remark 3. Concurrent work on the matching of regular (single-community) correlated Erdős-Rényi graphs [9] proposes a proof based on combinatorial methods and obtains a sufficient condition for successful de-anonymization that is stronger than Corollary 2.1 for the single community case. However our result in Theorem 2 is more general since it handles graphs with community structure.

Remark 4. Setting \( s = 1 \) in Corollary 2.1 provides the following sufficient condition for successful de-anonymization:

\[
p = 3 \log n_1 / n_1 + \omega(n_1^{-1}) \tag{21}
\]

Note for this special case, a necessary and sufficient condition for successful de-anonymization is the graph \( g \) not having any automorphisms (other than itself). The condition for this, found in [11], is tighter than (21) by a factor of 3, showing that there is room for improvement in the calculation of probability of error.

V. Conclusion

In this work we have investigated the de-anonymization problem in social networks for graphs with community structure. We have characterized the optimal attack strategy for this setting by determining the MAP estimate of the matching \( \pi \), and determined sufficient conditions for successful de-anonymization, asymptotically, for large graphs. For the special case of a single community, our results have proved the optimality of the de-anonymization strategy adopted in prior work.
