Abstract

Traditional inconsistency-tolerant query answering in ontology-based data access relies on selecting maximal components of an ABox/database which are consistent with the ontology. However, some rules in ontologies might be unreliable if they are extracted from ontology learning or written by unskilled knowledge engineers. In this paper we present a framework of handling inconsistent existential rules under stable model semantics, which is defined by a notion called rule repairs to select maximal components of the existential rules. Surprisingly, for R-acyclic existential rules with R-stratified or guarded existential rules with stratified negations, both the data complexity and combined complexity of query answering under the rule repair semantics remain the same as that under the conventional query answering semantics. This leads us to propose several approaches to handle the rule repair semantics by calling answer set programming solvers. An experimental evaluation shows that these approaches have good scalability of query answering under rule repairs on realistic cases.

Introduction

Querying inconsistent ontologies is an intriguing new problem that gives rise to a flourishing research activity in the description logic (DL) and existential rules community. Consistent query answering, first developed for relational databases (Arenas, Bertossi, and Chomicki 1999; Chomicki 2007) and then generalized as the AR and IAR semantics for several DLs (Lembo et al. 2010), is the most widely recognized semantics for inconsistency-tolerant query answering. These two traditional semantics are based upon the notion of repair, defined as an inclusion-maximal subset of the ABox consistent with the TBox. Du, Qi, and Shen (2013) studied query answering under weight-based AR semantics for DL SHIQ. Bienvenu, Bourgaux, and Gossiaux (2014) studied variants of AR and IAR semantics for DL-Lite\textsubscript{R} obtained by replacing classical repairs with various preferred repairs. Existential rules (also known as Datalog\textsuperscript{\pm}) are set to play a central role in the context of query answering and information extraction for the Semantic Web. Lukasiewicz et al. (2012, 2013, 2015) studied the data complexity and combined complexity of AR semantics under the main decidable classes of existential rules enriched with negative constraints.

However, observe that some rules might be unreliable if they are extracted from ontology learning or written by unskilled knowledge engineer (Lehmann et al. 2011). Meyer et al. (2009) proposed a tableau-like algorithm which yields EXP\textsc{time} as upper bound for finding maximally concept-satisfiable terminologies represented in ALC. Kalyanpur et al. (2006) provided solutions on repairing unsatisfiable concepts in a consistent OWL ontology. Furthermore, usually there exist preferences between rules, and rules with negation are often considered less preferred than rules without negation. Scharrenbach et al. (2010) proposed that the original axioms must be preserved in the knowledge base under certain conditions and requires changing the underlying logics for repair. Wang et al. (2014) proposed that when new facts are added that contradict to the ontology, it is often desirable to revise the ontology according to the added data. Therefore, this motivates us to consider another repair that selects maximal components of the existential rules. We illustrate the motivation via the following example.

Example 1. Let $D = \{\text{Bat}(a), \text{Mammal}(a)\}$ be a database and let $\Sigma$ be the following rule set expressing that each bat can fly and has at least one cave to live in; and if one creature lives in cave then it is a trogloxene; and if we do not know one mammal can fly, then it can not fly; if one creature can fly then it is a bird; additionally a bird can not be a trogloxene at the same time; similarly a bird can not be a mammal meanwhile.

\begin{align*}
\text{Bat}(x) \rightarrow \text{CanFly}(x),
\text{Bat}(x) \rightarrow \exists y \text{LiveIn}(x, y), \text{Cave}(y),
\text{LiveIn}(x, y), \text{Cave}(y) \rightarrow \text{Trogloxene}(x),
\text{Mammal}(x), \not \exists \text{CanFly}(x) \rightarrow \text{CanNotFly}(x),
\text{CanFly}(x) \rightarrow \text{Bird}(x),
\text{Bird}(x), \text{Trogloxene}(x) \rightarrow \bot,
\text{Bird}(x), \text{Mammal}(x) \rightarrow \bot.
\end{align*}

Clearly $\langle \Sigma, D \rangle$ is inconsistent under stable model semantics. We assume $P_1 = \{(1), (2), (3)\}$ is more reliable (or preferred) than $P_2 = \{(4), (5), (6), (7)\}$. Then we can delete (6) and (7), or (5) in $P_2$ to restore the consistency, and get...
inclusion-maximal preferred consistent rule sets w.r.t. $D$: 
\{(1), (2), (3), (4), (6), (7)\}, \{(1), (2), (3), (4), (5)\}.

We will focus on the case where the database is reliable but rules are not. Our main goal is to present a framework of handling inconsistent existential rules under stable model semantics. We define a notion called rule repairs to select maximal components of the rules, the philosophy behind that is to trust the rules as many as possible. Our second goal is to perform an in-depth analysis of the data and combined complexity of inconsistency-tolerant query answering under rule repair semantics. Let us recall some previous work on existential rules under stable model semantics. [Magka, Krötzbach, and Horrocks (2013) presented R-acyclic and R-stratified normal rule sets each of which always admits at most one finite stable models. Zhang, Zhang, and You (2015) implicitly showed that the R-acyclicity is enough to capture all negation-free rule sets with finite stable models. Alviano and Piers 2015 extended the stickiness notion to normal rule sets and showed that it assures the decidability for well-founded semantics rather than stable model semantics. We will focus on R-acyclic rule sets with R-stratified or full negations and guarded existential rules with stratified or full negations.

Our main contributions are briefly summarized as follows. We define rule repair semantics to handle inconsistent existential rules under stable model semantics. We consider rule repairs w.r.t. inclusion-maximal subset or cardinality, and that with preference. We obtain a (nearly) complete picture of the data and combined complexity of inconsistency-tolerant query answering under rule repair semantics (Table 1). Surprisingly, for R-acyclic existential rules with R-stratified or guarded existential rules with stratified negations, both the data complexity and combined complexity of query answering under the rule repair semantics remain the same as that under the conventional query answering semantics. Interestingly, the data complexity based upon weak-acyclic or guarded existential rules with stratified negation is PTIME-complete. This leads us to propose several approaches to handle the rule repair semantics by calling answer set programming (ASP) solvers. An experimental evaluation shows that these approaches have good scalability of query answering rule repairs on realistic cases.

Preliminaries

We consider a standard first-order language. We use $\text{Vax}(\varepsilon)$ to denote the variables appearing in an expression $\varepsilon$.

**Databases.** We assume an infinite set $\Delta$ of (data) constants, an infinite set $\Delta_0$ of (labeled) nulls (used as fresh Skolem terms), and an infinite set $\Delta_v$ of variables. A term $t$ is a constant, a null, or a variable. We denote by $x$ a sequence of variables $x_1, \ldots, x_k$ with $k \geq 0$. An atom $\alpha$ has the form $R(t_1, \ldots, t_n)$, where $R$ is an $n$-ary relation symbol, and $t_1, \ldots, t_n$ are terms. A conjunction of atoms is often identified with the set of all its atoms. We assume a relational schema $\mathcal{R}$, which is a finite set of relation symbols. An instance $I$ is a (possibly infinite) set of facts $p(t)$, i.e., atoms without involving variables, where $t$ is a tuple of constants and nulls. A database $D$ over a relational schema $\mathcal{R}$ is a finite instance with relation symbols from $\mathcal{R}$ and with arguments only from $\Delta$ (i.e., without involving nulls).

**Normal Logic Programs and Stable Models.** Each normal (logic) program is a finite set of NLP rules of the form
\[
\alpha \leftarrow \beta_1, \ldots, \beta_n, \text{not } \beta_{n+1}, \ldots, \text{not } \beta_m
\]
where $\alpha, \beta_1, \ldots, \beta_m$ are atoms and $m \geq n \geq 0$. Given a rule $r$ of the above form, let $\text{head}(r) = \alpha$, let $\text{body}^+(r) = \{\beta_1, \ldots, \beta_n\}$, and let $\text{body}^-(r) = \{\beta_{n+1}, \ldots, \beta_m\}$.

Let $\Pi$ be a normal program. The Herbrand universe and Herbrand base of $\Pi$ are denoted by $HU(\Pi)$ and $HB(\Pi)$, respectively. A variable-free rule $r'$ is called an instance of some rule $r \in \Pi$ if there is a substitution $\theta : \Delta_r \rightarrow HU(\Pi)$ such that $r\theta = r'$. Let $\text{ground}(\Pi)$, the grounding of $\Pi$, be the set of all instances of $r$ for all $r \in \Pi$.

The Gelfond-Lifschitz reduct of a normal program $\Pi$ w.r.t. a set $M \subseteq HB(\Pi)$, denoted $\Pi^M$, is the (possibly infinite) ground positive program obtained from $\text{ground}(\Pi)$ by
- deleting every rule $r$ such that $\text{body}^-(r) \cap M \neq \emptyset$, and
- deleting all negative literals from each remaining rule.

A subset $M$ of $HB(\Pi)$ is called a stable model of $\Pi$ if it is the least model of $\text{ground}(\Pi^M)$. For more about stable model semantics, refer to (Gelfond and Lifschitz 1988; Ferraris, Lee, and Lifschitz 2011).

**Normal Existential Rules.** Every normal (existential) rule is a first-order sentence of the form $\forall x \forall y \forall \varphi(x, y) \rightarrow \exists \psi(x, z)$, where $\varphi$ is a conjunction of literals, i.e., atoms or negated atoms (of the form $\neg \alpha$ where $\alpha$ is atomic), $\psi$ is a conjunction of atoms, and each universally quantified variable appears in at least one positive conjunct of $\varphi$. In the above normal rule, $\varphi$ is called its body, and $\psi$ its head. A normal rule is called a constraint if its head is the “false” $\bot$. For simplicity, when writing a rule, we often omit the universal quantifiers; by a normal rule set, we always mean a finite number of normal existential rules.

Let $r$ be a normal rule $\varphi(x, y) \rightarrow \exists \psi(x, z)$. For each variable $z \in z$, we introduce an $n$-ary fresh function symbol $f^n_z$ where $n = |x|$. The skolemization of $r$, denoted $sk(r)$, is the rule obtained from $r$ by substituting $f^n_z(x)$ for $z \in z$, followed by substituting “not” for $\neg$. Let $\Sigma$ be a normal rule set. We define $sk(\Sigma)$ to be the set of rules $sk(r)$ for all $r \in \Sigma$. Clearly, $sk(\Sigma)$ can be regarded as a normal program in an obvious way. Given any database $D$, an instance is called a stable model of $D \cup \Sigma$ if it is a stable model of $D \cup sk(\Sigma)$.

A normal rule $r$ is called guarded if there is a positive conjunct in the body of $r$ that contains all the universally quantified variable of $r$, and a normal rule set is called guarded if every rule in it is guarded.

A normal rule set $\Sigma$ is stratified if there is a function $\ell$ that maps relation symbols to integers such that for all $r \in \Sigma$:
- for all relation symbols $R$ occurring in the head and $S$ positively occurring in the body, $\ell(R) \geq \ell(S)$, and
- for all relation symbols $R$ occurring in the head and $S$ negatively occurring in the body, $\ell(R) > \ell(S)$.
Sometimes, the negations that occur in a stratified normal rule set are called stratified negations, and those in a non-stratified normal rule set are called full negations.

Let \( r_1 \) and \( r_2 \) be two normal rules, and let \( B_1^+ \) (resp., \( B_1^- \) and \( H_1 \)) be the set of atoms positively (resp., negatively and positively) occurring in the body (resp., body and head) of \( r_1 \). W.l.o.g., assume that no variable occurs in both \( r_1 \) and \( r_2 \).

Rule \( r_2 \) positively relies on \( r_1 \), written \( r_1 \rightarrow^+ r_2 \), if there exist a database \( D \) and a substitution \( \theta \) such that \( B_1^+ \theta \subseteq D \) and \( B_2^- \theta \cap \{ r_1 \theta \} = \emptyset \). Rule \( r_2 \) negatively relies on \( r_1 \), written \( r_1 \rightarrow^- r_2 \), if there exist a database \( D \) and a substitution \( \theta \) such that \( B_1^- \theta \subseteq D \) and \( B_2^+ \theta \cap \{ r_1 \theta \} = \emptyset \) and \( B_2^- \theta \cap \{ r_1 \theta \} = \emptyset \).

\( \text{Classical Boolean Query Answering.} \) A normal Boolean conjunctive query (NBCQ) \( Q \) is an existentially closed conjunction of atoms and negated atoms involving no null. Let \( Q^- \) (respectively, \( Q^- \)) be the set of atoms positively (respectively, negatively) occurring in \( Q \). An NBCQ is called safe if every variable in an atom from \( Q^- \) has at least one occurrence in \( Q^+ \); it is covered if for every atom \( x \) in \( Q^- \), there is an atom in \( Q^+ \) that contains all arguments of \( x \).

Given a database \( D \) and an NBCQ \( Q \), we write \( D \models Q \) if there exists an assignment \( h \) (that is, a function that maps each variable to a variable-free term) such that \( h(Q^-) \subseteq D \) and \( h(Q^+) \cap \{ r_1 \theta \} = \emptyset \). Furthermore, given a database \( D \), a normal rule set \( \Sigma \), and an NBCQ \( Q \), we write \( D \models \Sigma \models Q \) if, for each stable model \( M \) of \( D \cup \Sigma \), we have that \( M \models Q \).

\( \text{Complexity Classes.} \) We assume that the reader is familiar with the complexity theory. Given a unary function \( T \) on natural numbers, by \( \text{DTIME}(T(n)) \) (\( \text{NTIME}(T(n)) \), respectively) we mean the class of languages decidable in time \( T(n) \) by a deterministic (nondeterministic, respectively) Turing machine. Besides the well-known complexity classes such as \( \text{(co)NP} \), \( \text{(co)NP} \), we will also use several unusual classes as follows. By notation \( \text{ExpTime} \) we mean the class of all languages decidable in exponential time by a deterministic Turing machine with an oracle for some \( \text{NExpTime} \)-complete problem. The Boolean hierarchy (BH) is defined as follows: BH(1) is \( \text{PTime} \); for \( k \geq 1 \), BH(2k) (BH(2k + 1)) is the class of languages each of which is the intersection (union, respectively) of a language in \( \text{BH}(2k - 1) \) (BH(2k), respectively) and a language in \( \text{coPTime} \) (\( \text{NP} \), respectively); BH is then the union of BH(n) for all \( n \geq 1 \). Note that DP, the class for \( \text{difference polynomial time} \), is exactly the class BH(2); BH(2k) is actually the class of languages each of which is the union of \( k \) languages in DP; and BH is closed under complement. It was shown by \( \text{[Chang and Kadin 1996]} \) that a collapse of the Boolean hierarchy implies a collapse of the polynomial hierarchy; thus it seems impossible to find a BH-complete problem.

\( \text{Existential Rule Repair Semantics.} \) In this section, we propose several semantics to handle inconsistency in ontological knowledge base. Different from many existing works, we will focus on the case where the database is reliable but rules are not. Similar to the data repair semantics, see \( \text{[Lembo et al. 2010]} \), our inconsistency-tolerant semantics will rely on a notion called rule repairs.

**Definition 1.** Each preference-based ontology is an ordered pair \( (\Sigma, \preceq) \), where \( \Sigma \) is a normal rule set, and \( \preceq \) is a preorder (i.e., a reflexive and transitive binary relation) on \( \mathcal{P}(\Sigma) \) (i.e., the power set of \( \Sigma \)). We call \( \preceq \) a preference.

Now, we are in the position to define rule repairs.

**Definition 2.** Let \( O \) be a preference-based ontology \( (\Sigma, \preceq) \) and \( D \) a database. A subset \( S \) of \( \Sigma \) is called a (preferred) repair of \( \Sigma \) w.r.t. \( O \) and \( D \) (or simply a repair w.r.t. \( D \) if \( \Sigma \) and \( D \) are clear from the context) if \( S \cup D \) has at least one stable model, and for all subsets \( S' \) of \( \Sigma \) with \( S \preceq S' \) (i.e., \( S' \) and \( S' \) have a stable model).

Intuitively, a preferred rule repair is a maximal component of the rule set which is consistent with the current database. The philosophy behind it is to trust the rules as many as possible. Note that the number of repairs are normally more than one. To avoid a choice among them, we follow the spirit of “certain” query answering. The semantics is then as follows.

**Definition 3.** Let \( O \) be a preference-based ontology \( (\Sigma, \preceq) \) where \( \Sigma \) is a normal rule set, and let \( D \) be a database and \( Q \) an NBCQ. Then we write \( \langle D, O \rangle \models Q \) if, for all preferred repair \( S \subseteq \Sigma \) w.r.t. \( \preceq \) and \( D \), we have \( D \cup S \models Q \).

The following proposition shows us that our semantics for inconsistency-tolerant query answering will coincide with the classical semantics for query answering if the ontological knowledge base is consistent, which is clearly important.

**Proposition 1.** Let \( O \) be a preference-based ontology \( (\Sigma, \preceq) \) and let \( D \) be a database. If \( \Sigma \cup D \) has a stable model, then \( \langle D, O \rangle \models Q \) iff \( \Sigma \cup D \models Q \), for any NBCQ \( Q \).

With the above definitions, we then have a framework to define semantics for rule-based inconsistency-tolerant query answering. To define concrete semantics, we need to find preferences which will be useful in real-world applications. Besides the preference based on the set inclusion \( \subseteq \), similar to \( \text{[Bienvenu, Bourgaux, and Ong 2014]} \), we will consider other four kinds of preferences over subsets, which were first proposed by \( \text{[Eiter and Gottlob 1995]} \) to study logic-based abduction.

**Cardinality (\( \preceq \)).** Given any \( S, S' \subseteq \Sigma \), we write \( S \preceq S' \) if \( |S| \leq |S'| \). The intuition of using this preference is that we always prefer the rule set with the maximum number of rules which are most likely to be correct.

**Priority Levels (\( \preceq_p \)).** Every prioritization \( P \) of \( \Sigma \) is a tuple \( \langle P_1, \ldots, P_n \rangle \) where \( \langle P_1, \ldots, P_n \rangle \) is a partition of \( \Sigma \). Given a prioritization \( P \), the preferences \( \preceq_p \) and \( \preceq_p \) can be defined as follows:
• Prioritized set inclusion ($\subseteq_P$): Given $S, S' \subseteq \Sigma$, we write $S \subseteq_P S'$ if $S \cap P_i = S' \cap P_i$ for every $1 \leq i \leq n$, or there is some $1 \leq i \leq n$ such that $S \cap P_i \subseteq S' \cap P_i$ and for all $1 \leq j < i$, $S \cap P_j = S' \cap P_j$.

• Prioritized cardinality ($\subseteq_P$): Given $S, S' \subseteq \Sigma$, we write $S \subseteq_P S'$ if $|S \cap P_i| = |S' \cap P_i|$ for every $1 \leq i \leq n$, or there is some $1 \leq i \leq n$ such that $|S \cap P_i| < |S' \cap P_i|$ and for all $1 \leq j < i$, $|S \cap P_j| = |S' \cap P_j|$.

Weights ($\leq_w$). A weight assignment is a function $w: \Sigma \to \mathbb{N}$. Given two sets $S, S' \subseteq \Sigma$ and a weight assignment $w$, we write $S \leq_w S'$ if $\sum_{r \in S} w(r) \leq \sum_{r \in S'} w(r)$.

In the rest of this paper, we will fix $P$ as a prioritization and $w$ as a weight assignment unless otherwise noted.

Example 2 (Example 1 continued). Let $\Sigma$ and $D$ be the same as in Example 1. Then the repairs w.r.t. $\subseteq$ and $D$ are:
\[
\{(1), (3), (4), (5), (6), (7)\}, \quad \{(1), (2), (3), (4), (5)\}, \quad \{(1), (2), (4), (5), (6), (7)\},
\]
\[
\{(2), (3), (4), (5), (6), (7)\}.
\]
The repairs w.r.t. $\leq$ and $D$ include:
\[
\{(1), (2), (3), (4), (6), (7)\}, \quad \{(2), (3), (4), (5), (6), (7)\}.
\]
Let $P = (P_1, P_2)$ where $P_1, P_2$ are the same as in Example 1. Then the repairs w.r.t. $\subseteq_P$ and $D$ are shown in Example 1 and the repairs w.r.t. $\leq_P$ and $D$ are:
\[
\{(1), (2), (3), (4), (6), (7)\}, \quad \{(2), (3), (4), (5), (6), (7)\}.
\]
Let $w$ be the weight assignment which maps each rule to its index. Then the only repair w.r.t. $\leq_w$ and $D$ is:
\[
\{(2), (3), (4), (5), (6), (7)\}.
\]

We find that repairs under $\leq_P, \leq_w, \leq_P$ and $\leq_w$ are the subset of the inclusion-maximal repairs.

Theorem 1. The repairs under $\leq_P, \leq_w$ are the subset of the repairs under $\subseteq$.

Proof. Let $S$ be the set of repairs under $\leq_P, S_P$ be the set of repairs under $\subseteq_P$, we prove that $S_P \subseteq S$. Suppose for contradiction that $S_P \not\subseteq S$, then there exists a repair $R, R \in S_P$ and $R \not\in S$. Because the repairs in $S_P$ are inclusion-maximal, we have $R \supseteq R'$ for some $R' \in S$. It is clear that $R \subseteq P, R'$, then $R$ is not a $\subseteq_P$ repair which contradict our assumption.

The rest semantics can be proved similarly.

Complexity Results

In this section, we study the data and combined complexity for query entailment under our rule repair semantics. In particular, we focus on the following decision problems:

• Data complexity: Fixing a preference-based ontology $O$ and an NBCQ $Q$, given any database $D$ as input, deciding whether $\langle D, O \rangle \models Q$.

• Combined complexity: Given any preference-based ontology $O$, any NBCQ $Q$ and any database $D$ as input, deciding whether $\langle D, O \rangle \models Q$.

To measure the size of input, we fix a natural way to represent a database $D$, a normal rule set $\Sigma$, an NBCQ $Q$, a prioritization $P$ and a weight assigning function $w$, and let $|D|, |\Sigma|, |Q|, |P|, |w|$ denote the sizes of $D, \Sigma, Q, P, w$, respectively, w.r.t. the fixed representing approach. Given a preference-based ontology $O = (\Sigma, \leq)$, we define
\[
|O| := \begin{cases} |\Sigma| & \text{if } \leq \in \{\subseteq, \leq\}, \\ |\Sigma| + |P| & \text{if } \leq \in \{\subseteq_P, \leq_P\}, \\ |\Sigma| + |w| & \text{if } \leq = \leq_w. 
\end{cases}
\]

By properly representing, we can have that $|O| = |\Sigma|^{O(1)}$.

The following result is obvious.

Proposition 2. Let $O$ be a preference-based ontology $(\Sigma, \leq)$, where $\leq \in \{\subseteq, \leq_P, \leq_P, \leq_w\}$. Then, given any subsets $S, S' \subseteq \Sigma$, deciding whether $S \preceq S'$ is in DTIME($|O|^{O(1)}$).

Now, let us consider the complexity of query answering for R-acyclic and R-stratified rule sets under our semantics.

Algorithm 1: PRQA($D, O, Q$)

Input : a database $D$, a preference-based ontology $O = (\Sigma, \leq)$, and a Boolean query $Q$.

Output: true if $\langle D, O \rangle \models Q$, and false otherwise.

1 foreach $S \subseteq \Sigma$ do
2 if $D \cup S$ has at least one stable model then
3 isRepair := true;
4 foreach $S' \subseteq \Sigma$ with $S \preceq S'$ do
5 if $D \cup S'$ has at least one stable model then
6 isRepair := false;
7 break;
8 if isRepair and $D \cup S \not\models Q$ then
9 return false;
10 return true;

Theorem 2. Let $O$ be a preference-based ontology $(\Sigma, \leq)$, where $\Sigma$ is R-acyclic and R-stratified, and $\leq \in \{\subseteq_P, \leq_P, \leq_P, \leq_w\}$. Given a database $D$ and a safe NBCQ $Q$, deciding whether $\langle D, O \rangle \models Q$ is PTIME-complete for data complexity, and 2EXPTime-complete for combined complexity.

Proof. Let $D$ be a database and $Q$ be a safe NBCQ. By the definition of semantics, it is easy to verify that the problem of deciding whether $\langle D, O \rangle \models Q$ can be solved by Alg. 1.

First, we consider the data complexity. In Alg. 1 let us fix a preference-based ontology $O = (\Sigma, \leq)$ as defined in this theorem, fix a safe NBCQ $Q$, and let $D$ be the only input. As $\Sigma$ is R-acyclic and R-stratified, by Theorem 5 in [Magka, Krötzsch, and Horrocks, 2013], it is clear that the body of the second loop (the inside one) in Alg. 1 is computable in PTIME w.r.t. $D$. (Note that the existence of stable models can be reduced to the query answering problem in a routine way.) Since the second loop will be repeated a constant times, and by Proposition 2 the loop condition can be checked in a constant time. (Note that the rule set $\Sigma$ is fixed now.) Thus, the second loop can be computed in PTIME w.r.t. the size of $D$. By a similar argument, we can show that Alg. 1 can be implemented in PTIME w.r.t. $D$. This then
completes the proof of membership. The hardness follows from the PTIME-hardness of Datalog for data complexity, see, e.g., (Dantsin et al. 2001).

Next, we prove the combined complexity. Again, first address the membership. Let \( n \) be the number of rules in \( \Sigma \). Clearly, the body of the second loop will be repeated at most \( 2^n \) times. By Theorem 9 in (Magka, Krötzsch, and Horrocks 2013), it is computable in \( \text{DTIME}(2^{2O(|\Sigma|^2)}) \). By Proposition 2 it is also clear that the loop condition can be checked in \( \text{DTIME}(|\Sigma|O(1)) \). So, the second loop is computable in \( \text{DTIME}(2^{2O(|\Sigma|^2)}) \) since \( n \leq |\Sigma| \leq |\Omega| \). By a similar evaluation, we know that the algorithm is implementable in \( \text{DTIME}(2^{2O(|\Sigma|^2)}) \). Thus, the combined complexity is in \( 2\text{EXPTime} \). And the hardness follows from the \( 2\text{EXPTime}-\)hardness of query answering of the R-acyclic language (Magka, Krötzsch, and Horrocks 2013) and the fact that \( D \cup \Sigma \models_s Q \) iff \( \langle D, \{s^*, \Sigma\} \rangle \models q \), where \( \Sigma^* \) is \( \Sigma \cup \{Q \rightarrow q\} \) and \( q \) a fresh 0-ary relational symbol.

Theorem 3. Let \( O \) be a preference-based ontology \( \langle \Sigma, \preceq \rangle \), where \( \Sigma \) is R-acyclic with full negations and \( \preceq \in \{\leq, \preceq_p, \preceq, \preceq_{\Sigma}, \leq_w\} \). Given a database \( D \) and a safe NBCQ \( Q \), deciding whether \( \langle D, O \rangle \models Q \) is in \( \text{BH} \) for data complexity and in \( \Delta_2-2\text{EXPTime} \) for combined complexity.

Proof. We first prove the data complexity. To do this, we need to define some notations. Let \( \mathcal{R} \) be the schema of \( \Sigma \). Given any subset \( X \) of \( \Sigma \), let \( L^X \) be the set of all \( \mathcal{R} \)-databases \( D \) such that

1. \( D \cup X \) has at least one stable model, and
2. \( D \cup X \models_s Q \) does not hold, and
3. for all \( Y \subseteq \Sigma \) with \( X \prec Y \), \( D \cup Y \) has no stable model.

Let \( L \) denote the union of \( L^X \) for all subsets \( X \) of \( \Sigma \). By the definition of the rule repair semantics, it is easy to see that \( \langle D, O \rangle \models Q \) iff there is no \( X \subseteq \Sigma \) such that \( D \in L^X \), iff \( D \) does not belong to \( L \). Thus, if the following claim is true, by the definition of BH we then have the desired result. Notice that the complexity class BH is closed under complement.

Claim. Given any subset \( X \) of \( \Sigma \), it is in \( \text{DP} \) (w.r.t. the size of input database \( D \)) to determine whether \( D \in L^X \).

Now, it remains to show the claim. Fix a subset \( X \subseteq \Sigma \). Let \( L_1 \) denote the set of all \( \mathcal{R} \)-databases such that conditions 1 and 2 hold, and let \( L_2 \) denote the set of all \( \mathcal{R} \)-databases such that the condition 3 holds. According to Theorem 2 in (Magka, Krötzsch, and Horrocks 2013), \( L_1 \) is in \( \text{NPTIME} \) and \( L_2 \) in \( \text{coNPTime} \). (Note that, as \( \Sigma \) and \( X \) are fixed, the number of subsets \( Y \) is independent on the size of input database; thus \( L_2 \) should be in \( \text{coNPTime} \).) By definition, \( L^X = L_1 \cap L_2 \) is in \( \text{DP} \). This proves the data complexity.

Next, we show the combined complexity. It is clear that \( \langle D, O \rangle \models Q \) holds iff there does not exist \( S \subseteq \Sigma \) such that

1. \( D \cup S \) has at least one stable model, and
2. \( D \cup S \models_s Q \) does not hold, and
3. for all \( S' \subseteq \Sigma \) with \( S \prec S' \), \( D \cup S' \) has no stable models.

By Theorem 2 in (Magka, Krötzsch, and Horrocks 2013) and an analysis similar to that in Theorem 2 for (combined complexity), it is not difficult to see that, fixing \( S \subseteq \Sigma \), both conditions 1 and 2 are in \( \text{coNPTime} \), and condition 3 is in \( \text{NPTime} \). For “there does not exist \( S \subseteq \Sigma \)”, we can simply enumerate all subsets \( S \), which can be done in \( 2^{2|\Sigma|} \) times. Therefore, query answering under the mentioned semantics must be in \( \Delta_2-2\text{EXPTime} \) for combined complexity, which is as desired.

Now let us focus on guarded rules. The proof of the following is similar to that of Theorem 2 but employs the complexity results in (Call, Gottlob, and Lukasiewicz 2012). The only thing we should be careful about is the constraints.

Theorem 4. Let \( O \) be a preference-based ontology \( \langle \Sigma, \preceq \rangle \), where \( \Sigma \) is guarded and stratified, and \( \preceq \in \{\leq, \preceq_p, \leq_p, \leq_w\} \). Given a database \( D \) and a covered NBCQ \( Q \), deciding whether \( \langle D, O \rangle \models Q \) is \( \text{PTIME}-\)complete for data complexity, and \( 2\text{EXPTime}-\)complete for combined complexity.

For guarded rules with full negations, we have some results as below, where the proof for data complexity is similar to that in Theorem 5 and the proof for combined complexity is similar to that in Theorem 2. Both results rely on the corresponding complexity results in (Gottlob et al. 2014).

Theorem 5. Let \( O \) be a preference-based ontology \( \langle \Sigma, \preceq \rangle \), where \( \Sigma \) is guarded, and \( \preceq \in \{\leq, \preceq, \preceq_{\Sigma}, \leq_w\} \). Then, given a database \( D \) and a covered NBCQ \( Q \), deciding whether \( \langle D, O \rangle \models Q \) is in \( \text{BH} \) for data complexity and \( 2\text{EXPTime}-\)complete for combined complexity.

Finally, we conclude the results of this section as follows:

<table>
<thead>
<tr>
<th>Data complexity</th>
<th>Combined complexity</th>
</tr>
</thead>
<tbody>
<tr>
<td>RA + RS</td>
<td>\text{PTIME}-complete in ( \text{BH} )</td>
</tr>
<tr>
<td>RA + Full</td>
<td>\text{PTIME}-complete in ( \text{BH} )</td>
</tr>
<tr>
<td>G + Stra</td>
<td>\text{PTIME}-complete in ( \Delta_2-2\text{EXPTime} )</td>
</tr>
<tr>
<td>G + Full</td>
<td>\text{PTIME}-complete in ( \text{BH} )</td>
</tr>
</tbody>
</table>

Table 1: The data and combined complexity of Boolean query answering over normal rule sets under preference-based semantics for 5 types of preferred rule repairs, including \( \leq, \leq_p, \leq, \leq_{\Sigma}, \leq_w \). Here, “RA” means “R-acyclic rule sets”, “G” means “guarded rule sets”, “RS” means “with R-stratified negations”, “Stra” means “with stratified negations”, and “Full” means “with full negations”.

Experimental Evaluation

To demonstrate the effectiveness, we have implemented a prototype system for query answering of R-acyclic rule languages under the rule-repair semantics w.r.t. \( \leq, \leq_p, \leq, \) and \( \leq_w \), by calling a state-of-the-art ASP solver.

From Query Answering to ASP

To improve the efficiency, we adopt particular algorithm for each rule-repair semantics. The algorithms are all based on breadth-first search. Finding rule repairs w.r.t. \( \leq \) uses the basic principle illustrated in Alg. 1 and exponential checking will be conducted during the process. For rule repairs w.r.t. \( \leq_w \), though it works better than \( \leq \) for the reason that there no need to search the rest levels once it finds consistent sets. As for rule repairs w.r.t. \( \leq_p \), we design an algorithm...
which iterates over the rules from low to high prioritization. Once finding consistent results in the rules with lower prioritization, the searching stops. It’s known that $\leq P$ can be translated into $\leq w$, but not vice versa. As for $\leq w$, we search by deleting rules from the lowest weight to the greatest.

As a whole, the algorithms for situations with prioritization or weights will be much more efficient if the rule set satisfies the following two conditions:

- The size of rules with lower prioritization (less weights) is very small, even though the whole rule set is large;
- The rule set can be consistent by only deleting rules with lower prioritization (less weights).

These conditions can be easily found in real applications because incorrectness are mostly caused by the rules newly added and the amount of these rules is normally small.

### Experiments

We developed a prototype system QAIEI\(^3\) (Query Answering with Inconsistent Existential Rules) in C++. QAIEI can answer queries with inconsistent R-acyclic rule sets. When it needs to check the existence of stable models, QAIEI invokes an ASP solver clingo-4.4.\(^4\).

### Related Work and Conclusions

In terms of changing the rule set, Box for repair, Meyer et al.\(^5\) (2006) proposed an algorithm running in \textsc{Exptime} that finds maximally consistent - satisfiable terminologies in \textsc{ALC}. Scharrenbach et al.\(^6\) (2010) showed that probabilistic description logics can be used to resolve conflicts and receive a consistent knowledge base from which inferences can be drawn again. Also Qi and Du\(^7\) (2009) proposed model-based revision operators for terminologies in \textsc{DL}, and Wang et al.\(^8\) (2014) introduced a model-theoretic approach to ontology revision. In order to address uncertainty arising from inconsistency, Gottlob et al.\(^9\) (2013) extended the Datalog\(^\pm\) language with probabilistic uncertainty based on Markov logic networks. More generally, several works have focused on reasoning with inconsistent ontologies, see (Huang, van Harmelen, and ten Teije 2005) and references therein. Surprisingly, this paper shows that for R-acyclic existential rules with R-stratified or guarded existential rules with stratified negations both the data complexity and combined complexity of query answering under the rule repair semantics do not increase.

We have developed a general framework to handle inconsistent existential rules with default negations. Within this framework, we analyzed the data and combined complexity of inconsistency-tolerant query answering under rule repair semantics. We proposed approaches simulating queries answering under rule repairs with calling ASP solvers and developed a prototype system called QAIEI. Our experiments show that for R-acyclic existential rules with R-stratified or guarded existential rules with stratified negations both the data complexity and combined complexity of query answering under the rule repair semantics do not increase.

\(^3\)EUDG: http://www.informatik.uni-bremen.de/~clu/combined/

\(^5\)All experiments run in Linux Ubuntu 14.04.1 LTS on a HP compaq 8200 elite with a 3.4GHz Intel Core i7 processor and 4G 1333 MHz memory. Real numbers in the tables figure the run time (in seconds) of query answering. If the time exceeds 1800 seconds, we write it as “-”.
