

On the uncomputability of the spectral gap

Seth Lloyd

Department of Mechanical Engineering, MIT

Abstract: This paper reviews the 1994 proof that the spectral gap of Hamiltonian quantum systems capable of universal computation is uncomputable.

In a recent set of papers [1] Cubitt *et al.* prove that the spectral gap of a Hamiltonian system capable of universal computation is undecidable: in the subspace of Hilbert space corresponding to computations that halt, the Hamiltonian has a discrete spectrum and a finite spectral gap, while in the sector corresponding to computations that fail to halt, the spectrum is continuous and there is no gap. The authors exhibit an elegant planar system based on aperiodic tilings and show that the spectral gap of this system is undecidable/uncomputable. The uncomputability of the spectral gap is not a new result, however. In two papers from 1993 [2] and 1994 [3] I showed that the spectral gap of Hamiltonian systems capable of universal computation is uncomputable. (See also [4].)

The purpose of the current paper is to review the proof of the uncomputability of the gap. The systems investigated in [2-3] are the Benioff [5-8], Deutsch [11], Feynman [9-10], and Margolus [12] models for quantum computation: they are less ‘physicsy’ than the system investigated in [1]. Consequently, the proof of the uncomputability of the gap is straightforward, as will now be seen.

The fundamental mechanism for the undecidability/uncomputability of the spectral gap proved in [2-3] is the same as in the more recent work [1]. The basic intuition is simple. In computations that halt, the dynamics explores only a finite region of physical space. Accordingly, the Hilbert space explored by the system is finite-dimensional, the spectrum is discrete and the gap is finite. In computations that fail to halt, the dynamics explores an infinite region of physical space. The Hilbert space is infinite dimensional, the spectrum

is continuous, and there is no gap.

References [2-3] belong to the medieval era of quantum information theory, pre-Shor and pre-arXiv: the contemporary reader may compare them to illuminated manuscripts. I now redescribe their results in contemporary language. [2-3] investigated what were then the only known models of quantum computation [5-12]. In particular, [2] showed that in such models the spectral decomposition of a computational state is uncomputable, while [3] constructed the spectrum and eigenstates for both unitary [5-8,11] and Hamiltonian [9-10,12] models for quantum computation, and shows the uncomputability of the answer to the question of whether the spectrum in the eigenspace explored by a computation is discrete and gapped, or continuous and gapless.

First, [3] considered unitary models as in Benioff's original model for quantum computation [5-8] and as in Deutsch's quantum Turing machine [11]. Let U be the unitary transformation that advances the operation of the computer by a single time step, and let $|b_0\rangle$ be the initial state of the qubits in the computer. As in Feynman's quantum computer [9-10] the computer possesses a clock register with states $|\ell\rangle$. The clock register starts in the state $|\ell = 0\rangle$ and is incremented by one for each step of the computation. The computation proceeds through a set of orthonormal states,

$$U^\ell |b_0\rangle |\ell = 0\rangle = U_\ell U_{\ell-1} \dots U_1 |b_0\rangle |\ell\rangle, \quad (1)$$

where U_ℓ is the unitary operator that performs the ℓ 'th quantum logic operation. We can write

$$U = \sum_{\ell} U_\ell \otimes |\ell + 1\rangle \langle \ell|. \quad (2)$$

To ensure unitarity of U we allow ℓ to vary from $-\infty$ to ∞ , and define $U_{-\ell} = U_\ell^\dagger$, so that for negative values of ℓ the computation proceeds 'backwards.'

If the computation halts, we can always set up the computer so that the time evolution is cyclic [3]. The sign of the clock state ℓ is represented by qubit with states $|\pm\rangle$. To make halting computations cyclic, when the halt flag is raised, the sign bit switches from $|+\rangle$ to $|-\rangle$ and the subsequent evolution of the computer undoes the computation, returning it to its initial state. If the computation halts after $m/2$ steps, then we have

$$U^m |b_0\rangle |0\rangle = |b_0\rangle |0\rangle. \quad (3)$$

Consequently, the eigenvalues of U are m 'th roots of unity $e^{2\pi i k/m}$ and the corresponding

eigenstates are

$$|k, b_0\rangle = \frac{1}{\sqrt{m}} \sum_{\ell=0}^{m-1} e^{-2\pi i k \ell / m} U^\ell |b_0\rangle |0\rangle. \quad (4)$$

Halting computations correspond to eigenspaces of U with a discrete spectrum. The eigenstates are ‘plane waves,’ uniform superpositions of all the states in the computation.

By contrast, if the computation specified by b_0 does not halt, then the eigenvalues of U are of the form $e^{2\pi i a}$, where a can be any real number greater than or equal to 0 and less than 1. The corresponding (unnormalized) eigenstates are

$$|a, b_0\rangle = \sum_{\ell=-\infty}^{\infty} e^{-2\pi i a \ell} U^\ell |b_0\rangle |0\rangle. \quad (5)$$

Non-halting computations correspond to eigenspaces of U with a continuous spectrum.

Feynman transformed the discrete unitary time evolution of quantum computers into a continuous Hamiltonian time evolution by a simple trick [9-10]. He added a clock register as above, and looked at the the Hamiltonian

$$H = U + U^\dagger. \quad (6)$$

Feynman represented his clock in a ‘unary’ fashion, where ℓ represents the position of a single 1 propagating along a line of 0’s. With such a clock the Feynman Hamiltonian can be written as a sum of terms that are at most four-local.

In Feynman’s Hamiltonian formulation, when the computer is prepared in the initial state $|b_0\rangle|\ell=0\rangle$, the subsequent dynamics governed by the unitary transformation e^{-iHt} causes the clock to perform a quantum walk, propagating the computation both forward and backward in ℓ . Because we have assumed $U_{-\ell} = U_\ell^\dagger$, both forward and backward propagations perform the same computation. Feynman did not treat the distinction between halting and non-halting programs. Once one adds the innovation of reference [3] described above, however, so that halting problems correspond to computational dynamics that ‘bounce’ back and forth, while non-halting problems correspond to dynamics that go on forever, the spectrum of the Feynman Hamiltonian is uncomputable.

In particular, the eigenvectors of Feynman’s Hamiltonian H are the same as those of U . They take the form the form of equation (4) for halting computations and of equation (5) for non-halting computations. The eigenvalues of H are twice the real part of the eigenvalues of U : they take the form $2\cos(2\pi k/m)$ for halting computations, and $2\cos(2\pi a)$ for non-halting computations. Halting computations correspond to eigenspaces with a discrete

spectrum which has an energy gap. Non-halting computations correspond to eigenspaces with a continuous spectrum which is gapless. Since the answer to the question of whether a particular computation halts or not is uncomputable, so is the answer to the question of whether an initial state lies in an eigenspace of H with discrete or continuous spectrum. The gap of H is uncomputable.

The fact that the ground state of the Feynman Hamiltonian contains all the states in the computation in quantum superposition underlies the theory of QMA completeness [13] and the equivalence of adiabatic and conventional quantum computation [14].

In summary, the innovation of Cubitt *et al.* [1] is not to show that Hamiltonian quantum systems capable of universal computation have an uncomputable gap. This result was proved in [2-3]. Rather, the contribution of [1] is to present an elegant, two-dimensional, planar, ‘physics-like’ Hamiltonian system whose overall gap is uncomputable (as opposed to uncomputable within the eigenspaces corresponding to different computations, as shown here). This is a significant accomplishment and as the authors note, suggests that the gap of other physics-based Hamiltonians might also be uncomputable. Meanwhile, the contemporary reader can return to [2-3, 5-12] for the original proof and for a reminder of what life was like in the medieval era of quantum information theory.
