Abstract

We study the problem of computing shortest paths in so-called dense distance graphs. Every planar graph \( G \) on \( n \) vertices can be partitioned into a set of \( O(n/r) \) edge-disjoint regions (called an \( r \)-division) with \( O(r) \) vertices each, such that each region has \( O(\sqrt{r}) \) vertices (called boundary vertices) in common with other regions. A dense distance graph of a region is a complete graph containing all-pairs distances between its boundary nodes. A dense distance graph of an \( r \)-division is the union of the \( O(n/r) \) dense distance graphs of the individual pieces. Since the introduction of dense distance graphs by Fakcharoenphol and Rao [6], computing single-source shortest paths in dense distance graphs has found numerous applications in fundamental planar graph algorithms.

Fakcharoenphol and Rao [6] proposed an algorithm (later called FR-Dijkstra) for computing single-source shortest paths in a dense distance graph in \( O(n \sqrt{r} \log n \log \log r) \) time. We show an \( O(n^{\frac{3\log 2}{3\log 2 - 1}} \sqrt{r} \left( \frac{\log^2 r}{\log \log r} + \log n \log^{\frac{1}{2}} r \right)) \) time algorithm for this problem, which is the first improvement to date over FR-Dijkstra for the important case when \( r \) is polynomial in \( n \). In this case, our algorithm is faster by a factor of \( O(\log^{\frac{1}{2}} \log n) \) and implies improved upper bounds for such planar graph problems as multiple-source multiple-sink maximum flow, single-source all-sinks maximum flow, and (dynamic) exact distance oracles.

1 Introduction

Computing shortest paths and finding maximum flows are among the most basic graph optimization problems. Still, even though a lot of effort has been made to construct efficient algorithms for these problems, the known bounds for the most general versions are not known to be tight yet. For general digraphs with real edge lengths, Bellman–Ford algorithm computes the shortest path tree from a given vertex in \( O(nm) \) time, where \( n \) denotes the number of vertices and \( m \) is the number of edges. This simple methods remains to be the best known strongly-polynomial time bound, although some optimizations in the constant factor are known [2]. For the case of non-negative edge lengths, Fredman and Tarjan’s [7] implementation of Dijkstra’s algorithm achieves \( O(m + n \log n) \) time. The maximum flow problem with real edge capacities can be solved in \( O(nm) \) time as well [18], but here the algorithm is much more complex.

Finding a truly subquadratic algorithm assuming \( m = O(n) \) for either the single-source shortest paths or the maximum flow seems to be very difficult. However, the situation changes significantly if we restrict ourselves to planar digraphs, which constitute an important class of

*Supported by the grant NCN2014/13/B/ST6/01811 of the Polish Science Center.
sparse graphs. In this regime the goal is to obtain linear or almost linear time complexity. A linear time algorithm for the single-source shortest path problem with non-negative edge lengths was proposed by Henzinger et al. [9]. In their breakthrough paper, Fakcharoenphol and Rao gave the first nearly-linear time algorithm for the case of real edge lengths [10]. Their algorithm had $O(n \log^3 n)$ time complexity. Although their upper bounds for single-source shortest paths were eventually improved to $O \left( \frac{n \log^2 n}{\log \log n} \right)$ by Mozes and Wulff-Nilsen [17], the techniques introduced in [9] proved very useful in obtaining not only nearly-linear time algorithms for other static planar graph problems, but also first sublinear dynamic algorithms for shortest paths and maximum flows.

A major contribution of Fakcharoenphol and Rao was introducing the dense distance graph. For a planar digraph $G$ partitioned into edge-disjoint regions $G_1, \ldots, G_r$, define a boundary of a region $\partial G_i$ to be the vertices of $G_i$ shared with other regions. Let $\partial G = \bigcup_i \partial G_i$. The boundary of each weakly connected component of $G$ can be assumed to lie on a constant number of faces of $G_i$. A partition is called an $r$-division, if additionally $g = O(n/r)$, $|V(G_i)| = O(r)$ and $|\partial G_i| = O(\sqrt{r})$. The dense distance graph of a region is a complete digraph on $\partial G_i$ with the length of edge $(u, v)$ equal to the length of the shortest path $u \rightarrow v$ in $G_i$. The dense distance graph of $G$ is the union of dense distance graphs of individual regions. Fakcharoenphol and Rao showed how to compute the lengths of the shortest paths from $s \in \partial G$ to all other vertices of $\partial G$ in $O(\sum_i |\partial G_i| \log |\partial G_i| \log |\partial G|)$ time, which is nearly-linear in the number of vertices of this graph, as opposed to the number of edges, i.e., $O(\sum_i |\partial G_i|^2)$. Their method is often called the FR-Dijkstra. For an $r$-division, FR-Dijkstra runs in $O \left( \frac{n}{\sqrt{r}} \log n \log r \right)$ time. Based on FR-Dijkstra, they also showed how to compute the dense distance graph itself in nearly-linear time.

Following the work of Fakcharoenphol and Rao, dense distance graphs and FR-Dijkstra have become important planar graph primitives and have been used to obtain faster algorithms for numerous problems related to cuts (e.g. [5, 3, 10]), flows ([4, 14]), and computing exact point-to-point distances ([6, 16]) in planar digraphs. FR-Dijkstra has also found applications in algorithms for bounded-genus graphs, e.g., [3].

Although better algorithms (running in $O(\sum_i |\partial G_i| \log |\partial G_i|)$ time) have been proposed for computing the dense distance graph itself ([10, 12]), the only improvement over FR-Dijkstra to date is due to Mozes et al. ([15], manuscript). Using the methods of [9], they show that for an $r$-division, the shortest paths in a dense distance graph can be found in $O \left( \frac{n}{\sqrt{r}} \log^2 r \right)$ time. However, this does not improve over FR-Dijkstra in the case when $r$ is polynomial in $n$, a case which emerges in many applications.

In this paper we show an algorithm for computing single-source shortest paths in a dense distance graph in $O \left( \sum_i |\partial(G_i)| \left( \frac{\log^2 |\partial G|}{\log^2 \log |\partial G|} + \log |\partial G| \log^2 \log |\partial G_i| \right) \right)$ time (for any $\epsilon \in (0, 1)$), which is faster than FR-Dijkstra in all cases. Specifically, in the case of an $r$-division with $r = \text{poly}(n)$, the algorithm runs in $O \left( \frac{n}{\sqrt{r}} \log^2 \log n \right)$ time. Our algorithm implies an improvement by a factor of $O(\log^2 \log n)$ in the time complexity for a number of planar digraph problems such as multiple-source multiple-sink maximum flows, maximum bipartite matching [4], single-source all-sinks maximum flows [14], exact distance oracles [16]. It also yields polylog-logarithmic improvements to dynamic algorithms for both shortest paths and maximum flows [10, 11, 12].

However, for small values of $r$, such as $r = \text{polylog}(n)$, our algorithm does not improve on [15], as the $O \left( \frac{n}{\sqrt{r}} \log n \log^2 r \right)$ term starts to dominate the overall complexity of our algorithm. Dense distance graphs for $r$-divisions with $r = \text{polylog}(n)$ have also found applications, most notably in the $O(n \log \log n)$ algorithm for minimum $s,t$-cut in undirected planar graphs [10]. However, computing shortest paths in a DDG is not a bottleneck in this case. For other
Overview of the Result  In order to obtain the speedup we use a subtle combination of techniques. The problem of computing the single-source shortest paths in a dense distance graphs is solved with an optimized implementation of Dijkstra’s algorithm. Since the vertices of \( \partial G_i \) lie on \( O(1) \) faces of a planar digraph \( G_i \), we can exploit the fact that many of the shortest paths represented by the dense distance graph have to cross. Consequently, there is no point in relaxing most of the edges of the dense distance graph of \( G_i \). The edge-length matrix of a dense distance graph on \( G_i \) can be partitioned into a constant number of so-called staircase Monge matrices. A natural approach to restricting the number of edges of the dense distance graph to be relaxed is to design a data structure reporting the column minima of a certain staircase Monge matrix \( M \) in an online fashion. Specifically, the data structure has to handle row activations intermixed with extractions of the column minima in non-decreasing order. Once Dijkstra’s algorithm establishes the distance \( d(v) \) to some vertex \( v \), the row of \( M \) corresponding to \( v \) is activated and becomes available to the data structure. This row contains values \( d(v) + \ell(v,w) \), where \( \ell(v,w) \) is the length of the edge \( (v,w) \) of the DDG. Alternatively, a minimum in some column corresponding to \( v \) (in the revealed part of \( M \)) may be used by Dijkstra’s algorithm to establish a new distance label \( d(v) \), even though not all rows of \( M \) have been revealed so far. In this case, we can guarantee that all the inactive rows of \( M \) contain entries not smaller than \( d(v) \) and hence we can safely extract the column minimum of \( M \).

We show how to use such a data structure to obtain an improved single-source shortest path algorithm in Section 6. Such an approach was also used by Fakcharoenphol and Rao [6] and Mozes et al. [15], who both dealt with staircase Monge matrices by using a recursive partition into square Monge matrices, which are easier to handle. In particular, Fakcharoenphol and Rao showed that a sequence of row activations and column minima extractions can be performed on a \( m \times m \) square Monge matrix in \( O(m \log m) \) time. The recursive partition assigns each row and column to \( O(\log (|\partial G_i|)) \) square Monge matrices. As a result, the total time for handling all the square matrices is \( O(|\partial G_i| \log^2 |\partial G_i|) \).

Our first component is a refined data structure for handling row activations and column minima extractions on a rectangular Monge matrix, described in Section 3. We show a data structure supporting any sequence of operations on a \( k \times l \) matrix in \( O(k \frac{\log m}{\log \log m} + l \log m) \) total time, where \( m = \max(k,l) \). In comparison to [6], we do not map all the columns to active rows containing the current minima. Instead, the columns are assigned potential row sets of bounded size that are guaranteed to contain the “currently optimal” rows. This relaxed notion allows to remove the seemingly unavoidable binary search at the heart of [6] and instead use the SMAWK algorithm [4] to split the potential row sets once they become too large. The maintenance of a priority queue used for reporting the column minima in order is possible with the recent efficient data structure supporting subrow minimum queries in Monge matrices [8] and the usage of priority queues with \( O(1) \) time \texttt{Decrease-Key} operation [7].

The second step is to relax the requirements posed on a data structure handling rectangular \( k \times l \) Monge matrices. It is motivated by the following observation. Let \( \Delta > 0 \) be an integer. Imagine we have found the minima of \( l/\Delta \) evenly spread, pivot columns \( c_1, \ldots, c_{l/\Delta} \). Denote by \( r_1, \ldots, r_{l/\Delta} \) the rows containing the corresponding minima. A well-known property of Monge matrices implies that for any column \( c' \) lying between \( c_i \) and \( c_{i+1} \), we only have to look for a minimum of \( c' \) in rows \( r_i, \ldots, r_{i+1} \). Thus, the minima in the remaining columns can be found in \( O(k\Delta + l) \) total time. In Section 4 we show how to adapt this idea to an online setting that fits our needs. The columns are partitioned into \( O(l/\Delta) \) blocks of size at most \( \Delta \). Each block is conceptually contracted to a single column: an entry in row \( r \) is defined as the minimum in row \( r \) over the contracted columns. For sufficiently small values of \( \Delta \), such a minimum can be
computed in $O(1)$ time using the data structure of [8]. Locating a block minimum can be seen as an introduction of a new pivot column. We handle the block matrix with the data structure of Section 3 and prove that the total time needed to correctly report all the column minima is $O\left(k \frac{\log m}{\log \log m} + k\Delta + l + \frac{\epsilon}{\Delta} \log m\right)$. In particular, for $\Delta = \log^{1-\varepsilon} m$, this bound becomes $O\left(k \frac{\log m}{\log \log m} + l \log^c m\right)$.

Finally, in Section 5 we exploit the asymmetry of per-row and per-column costs of the developed block data structure for rectangular matrices by using a different partition of a staircase Monge matrix. Our partition is biased towards columns, i.e., the matrix is split into rectangular (as opposed to square) Monge matrices, each with roughly poly-logarithmically more columns than rows. Consequently, the total number of rows in these matrices is $O\left(|\partial G_i| \frac{\log |\partial G_i|}{\log \log |\partial G_i|}\right)$, whereas the total number of columns is only slightly larger, i.e., $O\left(|\partial G_i| \log^{1+\varepsilon} |\partial G_i|\right)$. This yields a data structure handling staircase Monge matrices in $O\left(|\partial G_i| \frac{\log^2 |\partial G_i|}{\log \log |\partial G_i|}\right)$ total time.

**Model of Computation**  We assume the standard word-RAM model with word size $\Omega(\log n)$. However, we stress that our algorithm works in the very general case of real edge lengths, i.e., we are only allowed to perform arithmetical operations on lengths and compare them.

**Outline of the Paper** We present our algorithm in a bottom-up manner: in Section 2 we introduce the terminology, while in Sections 3, 4 and 5 we develop the increasingly more powerful data structures for reporting column minima in online Monge matrices. Each of these data structures is used in a black-box manner in the following section. The improved algorithm for computing single-source shortest paths in dense distance graph is discussed in detail in Section 6. We describe the most important implications in Section 7.

## 2 Preliminaries

### 2.1 Partitions of Planar Graphs and Dense Distance Graphs

Let $G = (V, E)$ be a planar weighted digraph. Let $E_1, \ldots, E_g$ be a partition of $E$ into non-empty, disjoint subsets. We define regions of $G$ to be the induced subgraphs $G_i = G[E_i]$. The boundary $\partial G_i$ of a region $G_i$ is defined to be the set of vertices of $G_i$ that also belong to other regions, i.e., $\partial G_i = V(G_i) \cap V(G[E \setminus E_i])$. Let $\partial G = \bigcup_{i=1}^{g} \partial G_i$.

A partition of $G$ into regions $G_1, \ldots, G_g$ is called a partition with few holes if for each $i$ and for each weakly connected component $G_i^j$ of $G_i$, the vertices of $\partial G_i^j$ lie on $O(1)$ faces of $G_i^j$. A hole is thus defined to be a face of $G_i$ containing at least one vertex of $\partial G_i$.

For a partition of $G$ with few holes, we denote by $\text{DDG}(G_i)$ the dense distance graph of a region $G_i$, which is defined to be a complete directed graph on vertices $\partial G_i$, such that the weight of an edge $(u, v)$ is equal to the length of the shortest path $u \rightarrow v$ in $G_i$. If the edge lengths are non-negative, the dense distance graphs are typically computed using the **multiple-source shortest paths** data structure of Klein [12]. This data structure allows us to preprocess a plane graph $G = (V, E)$ with a distinguished face $F$ in $O(n \log n)$ time so that we can find in $O(\log n)$ time the length of the shortest path $u \rightarrow v$ for any $u \in F$ and $v \in V$. As the boundary vertices in each component of $G_i$ lie on $O(1)$ faces, we can compute $\text{DDG}(G_i)$ in $O(|V(G_i)| + |\partial G_i|^2) \log |V(G_i)|)$ time. $\text{DDG}(G)$ is defined as $\bigcup_{i=1}^{g} \text{DDG}(G_i)$.

For $r < n$, an $r$-division of a planar graph $G$ is a partition $G_1, \ldots, G_g$ with few holes such that $g = O(n/r)$ while $|V(G_i)| = O(r)$ and $|\partial G_i| = O(\sqrt{r})$ for any $i = 1, \ldots, g$. Klein et al. [13] proved that for any triangulated and biconnected planar graph $G$ and any $r < n$, an $r$-division
can be computed in linear time. Given an \( r \)-division \( G_1, \ldots, G_g \), \( \text{DDG}(G) \) can be thus computed by computing the dense distance graph for each region separately in \( O(n \log r) \) total time.

2.2 Matrices and Their Minima

In this paper we define a matrix to be a partial function \( \mathcal{M} : R \times C \to \mathbb{R} \), where \( R \) (called rows) and \( C \) (called columns) are some totally ordered finite sets. Set \( R = \{r_1, \ldots, r_k\} \) and \( C = \{c_1, \ldots, c_l\} \), where \( r_1 \leq \cdots \leq r_k \) and \( c_1 \leq \cdots \leq c_l \). If for \( r_i, r_j \in R \) we have \( r_i \leq r_j \), we also say that \( r_i \) is (weakly) above \( r_j \) and \( r_j \) is (weakly) below \( r_i \). Similarly, when \( c_i, c_j \) have \( c_i < c_j \), we say that \( c_i \) is to the left of \( c_j \) and \( c_j \) is to the right of \( c_i \).

For some matrix \( \mathcal{M} \) defined on rows \( R \) and columns \( C \), for \( r \in R \) and \( c \in C \) we denote by \( \mathcal{M}_{r,c} \) an element of \( \mathcal{M} \). An element is the value of \( \mathcal{M} \) on pair \((r,c)\), if defined.

For \( R' \subseteq R \) and \( C' \subseteq C \) we define \( \mathcal{M}(R', C') \) to be a submatrix of \( \mathcal{M} \). \( \mathcal{M}(R', C') \) is a partial function on \( R' \times C' \) satisfying \( \mathcal{M}(R', C')_{r,c} = \mathcal{M}_{r,c} \) for any \((r,c) \in R' \times C' \) such that \( \mathcal{M}_{r,c} \) is defined.

The minimum of a matrix \( \min\{\mathcal{M}\} \) is defined as the minimum value of the partial function \( \mathcal{M} \). The column minimum of \( \mathcal{M} \) in column \( c \) is defined as \( \min\{\mathcal{M}(R, \{c\})\} \).

We call a matrix \( \mathcal{M} \) rectangular if \( \mathcal{M}_{r,c} \) is defined for every \( r \in R \) and \( c \in C \). A matrix is called staircase (flipped staircase) if \(|R| = |C| \) and \( \mathcal{M}_{r,c} \) is defined if and only if \( i \leq j \) (\( i \geq j \) respectively).

Finally, a subrectangle of \( \mathcal{M} \) is a rectangular matrix \( \mathcal{M}(\{r_{a_1}, \ldots, r_{a_l}\}, \{c_{b_1}, \ldots, c_{b_l}\}) \) for \( 1 \leq a \leq b \leq k, 1 \leq x \leq y \leq l \). We define a subrow to be a subrectangle with a single row.

Given a matrix \( \mathcal{M} \) and a function \( d : R \to \mathbb{R} \), we define the offset matrix \( \text{off}(\mathcal{M}, d) \) to be a matrix \( \mathcal{M}' \) such that for all \( r \in R \), \( c \in C \) for which \( \mathcal{M}_{r,c} \) is defined, we have \( \mathcal{M}'_{r,c} = \mathcal{M}_{r,c} + d(r) \).

2.3 Monge Matrices

We say that a matrix \( \mathcal{M} \) with rows \( R \) and columns \( C \) is a Monge matrix, if for each \( r_1, r_2 \in R, r_1 \leq r_2 \) and \( c_1, c_2 \in C, c_1 \leq c_2 \) such that all elements \( \mathcal{M}_{r_1,c_1}, \mathcal{M}_{r_1,c_2}, \mathcal{M}_{r_2,c_1}, \mathcal{M}_{r_2,c_2} \) are defined, the following Monge property holds

\[
\mathcal{M}_{r_2,c_1} + \mathcal{M}_{r_1,c_2} \leq \mathcal{M}_{r_1,c_1} + \mathcal{M}_{r_2,c_2}.
\]

**Fact 1.** Let \( \mathcal{M} \) be a Monge matrix. For any \( R' \subseteq R \) and \( C' \subseteq C \), \( \mathcal{M}(R', C') \) is also a Monge matrix.

**Fact 2.** Let \( \mathcal{M} \) be a rectangular Monge matrix and assume \( R \) is partitioned into disjoint blocks \( R = R_1, \ldots, R_t \) such that each \( R_i \) is a contiguous group of subsequent rows and each \( R_i \) is above \( R_{i+1} \). Assume also that the set \( C \) is partitioned into blocks \( C = C_1, \ldots, C_b \) so that \( C_i \) is to the left of \( C_{i+1} \). Then, a matrix \( \mathcal{M}' \) with rows \( R \) and columns \( C \) defined as

\[
\mathcal{M}'_{R_i,C_j} = \min\{\mathcal{M}(R_i, C_j)\},
\]

is also a Monge matrix.

**Fact 3.** Let \( \mathcal{M} \) be a rectangular Monge matrix. Assume that for some \( c \in C \) and \( r \in R \), \( \mathcal{M}_{r,c} \) is a column minimum of \( c \). Then, for each column \( c^- \) to the left of \( c \), there exists a row \( r^- \) (weakly) below \( r \), such that \( \mathcal{M}_{r^-,c^-} \) is a column minimum of \( c^- \). Similarly, for each column \( c^+ \) to the right of \( c \), there exists a row \( r^+ \) (weakly) above \( r \), such that \( \mathcal{M}_{r^+,c^+} \) is a column minimum of \( c^+ \).
Figure 1: Example 10 × 10 Monge matrices: a rectangular one to the left and a staircase one to the right. The grey cells contain the column minima of the respective columns.

**Fact 4.** Let \( M \) be a rectangular Monge matrix. Let \( r \in R \) and \( C = \{c_1, \ldots, c_l\} \). The set of columns \( C_r \in C \) having one of their column minima in row \( r \) is contiguous, that is either \( C_r = \emptyset \) or \( C_r = \{c_a, \ldots, c_b\} \) for some \( 1 \leq a \leq b \leq l \).

**Remark 1.** The statements of facts 3 and 4 could be simplified if we either assumed that the column minima in the considered Monge matrices are unique or introduced some tie-breaking rule. However, this would lead to a number of similar assumptions in terms of priority queue keys and path lengths in the following sections which in turn would complicate the description. Thus, we do not use any simplifying assumptions about the column minima.

**Fact 5.** Let \( M \) be a Monge matrix with rows \( R \) and let \( d : R \to \mathbb{R} \). Then \( \text{off}(M, d) \) is also a Monge matrix.

### 2.4 Data-Structural Prerequisites

**Priority Queues** We assume that priority queues store elements with real keys. A priority queue \( H \) supports the following set of operations:

- **INSERT\((e, k)\)** – insert an element \( e \) with key \( k \) into \( H \).
- **EXTRACT-MIN\()\)** – delete an element \( e \in H \) with the smallest key and return \( e \).
- **DECREASE-KEY\((e, k)\)** – given an element \( e \in H \), decrease key of \( e \) to \( k \). If the current key of \( e \) is smaller than \( k \), do nothing.
- **MIN-KEY\()\)** – return the smallest key in \( H \).

Formally, we assume that each call **INSERT\((e, k)\)** also produces a “handle”, which can be later used to point the call **DECREASE-KEY** to a place inside \( H \), where \( e \) is being kept. In our applications, the elements stored in a priority queue are always distinct and thus for brevity we skip the details of using handles later on.

Fredman and Tarjan [7] showed a data structure called the Fibonacci heap, which can perform **EXTRACT-MIN** in amortized \( O(\log n) \) time and all the remaining operations in amortized \( O(1) \) time. Here \( n \) is the current size of the queue. In the following sections, we assume that each priority queue is implemented as a Fibonacci heap.
Predecessor Searching  Let $S$ be some totally ordered set such that for any $s \in S$ we can compute the rank of $s$, i.e., the number $|\{y \leq s : y \in S\}|$, in constant time. A dynamic predecessor/successor data structure maintains a subset $R$ of $S$ and supports the following operations:

- Insertion of some $s \in S$ into $R$.
- Deletion of some $s \in R$.
- $\text{Pred}(s)$ ($\text{Succ}(s)$) – for some $s \in S$, return the largest (smallest respectively) element $r$ of $R$ such that $r \leq s$ ($r \geq s$ resp.).

Van Emde Boas [19] showed that using $O(\log \log |S|)$ space we can perform each of these operations in $O(\log \log |S|)$ time. Whenever we use a dynamic predecessor/successor data structure in the following sections, we assume the above bounds to hold.

3 Online Column Minima of a Rectangular Offset Monge Matrix

Let $M_0$ be a rectangular $k \times l$ Monge matrix. Let $R = \{r_1, \ldots, r_k\}$ and $C = \{c_1, \ldots, c_l\}$ be the sets of rows and columns of $M_0$, respectively. Set $m = \max(k, l)$.

Let $d : R \rightarrow \mathbb{R}$ be an offset function and set $M = \text{off}(M_0, d)$. By Fact 5, $M$ is also a Monge matrix. Our goal is to design a data structure capable of reporting the column minima of $M$ in increasing order of their values. However, the function $d$ is not entirely revealed beforehand, as opposed to the matrix $M_0$. There is an initially empty, growing set $\bar{R} \subseteq R$ containing the rows for which $d(r)$ is known. Alternatively, $\bar{R}$ can be seen as a set of “active” rows of $M$ which can be accessed by the data structure. There is also a set $\bar{C} \subseteq C$ containing the remaining columns for which we have not reported the minima yet. Initially, $\bar{C} = C$ and the set $\bar{C}$ shrinks over time. We also provide a mechanism to guarantee that the rows that have not been revealed do not influence the smallest of the column minima of $\bar{C}$.

The exact set of operations we support is the following:

- $\text{Init}(R, C)$ – initialize the data structure and set $\bar{R} = \emptyset, \bar{C} = C$.
- $\text{Activate-Row}(r)$, where $r \in R \setminus \bar{R}$ – add $r$ to the set $\bar{R}$.
- $\text{Lower-Bound}()$ – compute the number $\min\{M(\bar{R}, \bar{C})\}$. If $\bar{R} = \emptyset$ or $\bar{C} = \emptyset$, return $\infty$.
- $\text{Ensure-Bound-And-Get}()$ – inform the data structure that we have

$$\min\{M(R \setminus \bar{R}, C)\} \geq \min\{M(\bar{R}, \bar{C})\} = \text{Lower-Bound}(),$$

that is, the smallest element of $M(R, \bar{C})$ does not depend on the values of $M$ located in rows $R \setminus \bar{R}$. It is the responsibility of the user to guarantee that this condition is in fact satisfied.

Such claim implies that for some column $c \in \bar{C}$ we have $\min\{M(R, \{c\})\} = \min\{M(\bar{R}, \bar{C})\}$, which in turn means that we are able to find the minimum element in column $c$. The function returns any such $c$ and removes it from the set $\bar{C}$.

- $\text{Current-Min-Row}(c)$, where $c \in C – \text{compute } r$, where $r \in \bar{R}$ is a row such that $\min\{M(\bar{R}, \{c\})\} = M_{r,c}$. If $\bar{R} = \emptyset$, return nil. Note that $c$ is not necessarily in $\bar{C}$.
Additionally, we require CURRENT-MIN-ROW to have the following property: once the column $c$ is moved out of $\bar{C}$, CURRENT-MIN-ROW($c$) always returns the same row. Moreover, for $c_1, c_2 \in C$ such that $c_1 < c_2$ we require

$$\text{CURRENT-MIN-ROW}(c_1) \geq \text{CURRENT-MIN-ROW}(c_2).$$

Note that ACTIVATE-ROW increases the size of $\bar{R}$ and thus cannot be called more than $k$ times. Analogously, ENSURE-BOUND-AND-GET decreases the size of $\bar{C}$ so it cannot be called more than $l$ times. Actually, in order to reveal all the column minima with this data structure, the operation ENSURE-BOUND-AND-GET has to be called exactly $l$ times.

### 3.1 The Components

#### The Subrow Minimum Query Data Structure

Given $r \in \bar{R}$ and $a, b$, $1 \leq a \leq b \leq l$, a subrow minimum query $S(r, a, b)$ computes a column $c \in \{c_a, \ldots, c_b\}$ such that

$$\min\{\mathcal{M}\{r\}, \{c_a, \ldots, c_b\}\} = \mathcal{M}_{r,c}.$$  

We use the following theorem of Gawrychowski et al. \[8\].

**Theorem 1** (Theorem 3. of \[8\]). *Given a $k \times l$ rectangular Monge matrix $\mathcal{M}$, a data structure of size $O(l)$ can be constructed in $O(l \log k)$ time to answer subrow minimum queries in $O((\log \log (k+l))$ time.*

Recall that $\mathcal{M} = \text{off}(\mathcal{M}_0, d)$. Adding the offset $d(r)$ to all the elements in row $r$ of $\mathcal{M}_0$ does not change the relative order of elements in row $r$. Hence, the answer to a subrow minimum query $S(r, a, b)$ in $\mathcal{M}$ is the same as the answer to $S(r, a, b)$ in $\mathcal{M}_0$.

We build a data structure of Theorem 1 for $\mathcal{M}_0$ and assume that any subrow minimum query in $\mathcal{M}$ can be answered in $O((\log \log m)$ time.

#### The Column Groups

The set $C$ is internally partitioned into disjoint, contiguous *column groups* $C_1, \ldots, C_q$ (where $C_1$ is the leftmost group and $C_q$ is the rightmost), so that $\bigcup_i C_i = C$.

As the groups constitute contiguous segments of columns, we can represent the partition with a subset $F \subseteq C$ containing the first columns of individual groups. Each group can be identified with its leftmost column. We use a dynamic predecessor data structure for maintaining the set $F$. The first column of the group containing column $c$ can be thus found by calling $F.PRED(c)$ in $O((\log \log m)$ time. Such representation also allows to split groups and merge neighboring groups in $O((\log \log m)$ time.

#### The Potential Row Sets

For each $C_i$ we store a set $P(C_i) \subseteq \bar{R}$, called a *potential row set*. Between consecutive operations, the potential row sets satisfy the following invariants:

- **P.1** For any $c \in C_i$ there exists a row $r \in P(C_i)$ such that $\min\{\mathcal{M}(\bar{R}, \{c\})\} = \mathcal{M}_{r,c}$.

- **P.2** The size of any set $P(C_i)$ is less than $2\alpha$, where $\alpha$ is a parameter to be fixed later.

- **P.3** For any $i < j$ and any $r_i \in P(C_i)$, $r_j \in P(C_j)$, we have $r_i \geq r_j$.

As by Fact 1 $\mathcal{M}(\bar{R}, C)$ is a Monge matrix, from Fact 3 it follows that invariant P.3 can be indeed satisfied. By invariant P.2 we also have $|P(C_i) \cap P(C_{i+1})| \leq 1$ and thus the sum of sizes of sets $P(C_i)$ is $O(k+l)$. The sets $P(C_i)$ are stored as balanced binary search trees, sorted bottom to top. Additionally, the union of sets $P(C_i)$ is stored in a dynamic predecessor/successor data structure $U$. We also have an auxiliary array last mapping each row $r \in \bar{R}$ to the rightmost column group $C_i$ such that $r \in P(C_i)$ (if such group exists).
Lemma 1. An insertion or deletion of some $r$ to $P(C_i)$ (along with the update of the auxiliary structures) can be performed in $O(\log \alpha + \log \log m)$ time.

Proof. The cost of updating the binary search tree is $O(\log |P(C_i)|) = O(\log \alpha)$, whereas updating the predecessor structure $U$ takes $O(\log \log m)$ time. Updating the array $\text{last}$ upon insertion is trivial. When a row $r$ is deleted and $\text{last}[r] \neq C_i$, $\text{last}[r]$ does not have to be updated. Otherwise, we check if $r \in P(C_{i-1})$ and set $\text{last}[r]$ to either $C_{i-1}$ or $\text{nil}$. 

Special Handling of Columns with Known Minima We require that for each column $c$ being moved out of $\bar{C}$, a row $y_c$ such that $\text{min}\{M(R, c)\} = M_{y_c,c}$ is computed. In order to ensure that CURRENT-MIN-ROW has the described deterministic behavior, we guarantee that at the moment of deletion of $c$ from $\bar{C}$, there exists a group $C$ consisting of a single element $c$, such that $P(C) = \{y_c\}$. Such groups are called done.

The Priority Queue A priority queue $H$ contains an element $c$ for each $c \in \bar{C}$. The queue $H$ satisfies the following invariants.

H.1 For each $c \in \bar{C}$, the key of $c$ in $H$ is greater than or equal to $\text{min}\{M(\bar{R}, \{c\})\}$.

H.2 For each group $C_j$ that is not done, there exists such column $c_j \in C_j$ that the key of $c_j$ in $H$ is equal to

$$\text{min}\{M(\bar{R}, \{c_j\})\} = \text{min} \{\{M(\bar{R}, C_j)\}\}.$$

Lemma 2. We can ensure that invariant [H.2] is satisfied for a single group $C_j$ in $O(\alpha \log \log m)$ time.

Proof. We perform $O(|P(C_j)|) = O(\alpha)$ subrow minimum queries on $M$ to compute for each $r \in P(C_j)$ some column $c \in C_j$ such that $M_{r,c} = \text{min}\{M(\{r\}, C_j)\}$. As each subrow minimum query takes $O(\log \log m)$ time, this takes $O(\alpha \log \log m)$ in total. For each computed $c$, we decrease the key of $c$ in $H$ to $M_{r,c}$ in $O(1)$ time. Note that by invariant [P.1] some $M_{r,c}$ is in fact equal to $\text{min}\{M(\bar{R}, C_j)\}$.

We will maintain invariant [H.1] implicitly, each time setting the key of a column $c$ to either $\infty$ or some value $M_{r,c}$, where $r \in \bar{R}$. Note that invariant [H.2] guarantees that the key of the top element of $H$ is equal to $\text{min}\{M(\bar{R}, C)\}$.

3.2 Implementing the Operations

Initialization First, we build the data structure of Theorem 1 in $O(l \log m)$ time. Then, an element $c$ with key $\infty$ is inserted into $H$ for each $c \in C$. When the first row $r$ is activated, we create a single group $C = C$ with $P(C) = \{r\}$. Using Lemma 2 we ensure that invariant [H.2] is satisfied.

Current-Min-Row The data structure $F$ is used to identify the group $C$ containing the column $c$. If $c \in C \setminus \bar{C}$, then the group $c$ is done and we return the only element of $P(C)$. Otherwise, we spend $O(|P(C)|) = O(\alpha)$ time to find the topmost row of $P(C)$ that contains a minimum of $c$. By Fact 3 and invariant [P.3] returning the topmost row of $P(C)$ guarantees that for $c_1 \leq c_2$, CURRENT-MIN-ROW($c_1$) $\geq$ CURRENT-MIN-ROW($c_2$). The total running time is thus $O(\alpha + \log \log m)$. 

9
Lower-Bound, Ensure-Bound-And-Get  Invariant $\text{H.2}$ guarantees that we have $\min\{\mathcal{M}(\vec{R}, \vec{C})\} = \min\{\mathcal{M}(\vec{R}, \{c_i\})\} = \mathcal{M}_{r^*, c_i} = \text{H.Min-Key}()$, where $c_i$ is the top element of $H$ and $r^*$ is a row returned by CURRENT-MIN-ROW($c_i$). Thus, the operation LOWER-BOUND() can be executed in $O(1)$ time.

Let us now implement ENSURE-BOUND-AND-GET. By the precondition of this call, we conclude that $\mathcal{M}_{r^*, c_i} = \min\{\mathcal{M}(\vec{R}, \vec{C})\}$. By invariant $\text{H.2}$, $\mathcal{H}.\text{Extract-Min}()$ returns the column $c_i$. With a single query to $F$, we find the current group of $c_i$, $\mathcal{C} = \{c_a, \ldots, c_i, \ldots, c_b\}$. First, we need to create a single-column group $\mathcal{C}^* = \{c_i\}$ and mark it done, with $P(\mathcal{C}^*) = \{r^*\}$. We thus split $\mathcal{C}$ into at most three groups $\mathcal{C}^- = \{c_a, \ldots, c_{i-1}\}$, $\mathcal{C}^* = \{c_{i+1}, \ldots, c_b\}$ and mark $\mathcal{C}^*$ done. By Fact $[3]$ we can safely set $P(\mathcal{C}^-) = \{r \in P(\mathcal{C}) : r \geq r^*\}$ and $P(\mathcal{C}^+) = \{r \in P(\mathcal{C}) : r \leq r^*\}$. The split of $\mathcal{C}$ requires $O(1)$ operations on $F$, whereas by Lemma $[1]$ replacing the set $P(\mathcal{C})$ with the sets $P(\mathcal{C}^-), P(\mathcal{C}^+)$ takes $O(\alpha(\log \log m + \log \alpha))$ time.

The last step is to fix the invariant $\text{H.2}$ for the newly created groups. This takes $O(\alpha \log \log m)$, by Lemma $[2]$. Thus, taking into account the $O(\log m)$ cost of performing $\text{H.Extract-Min, Ensure-Bound-And-Get}$ takes $O(\log m + \alpha(\log \alpha + \log \log m))$ time.

Before we describe how ACTIVATE-ROW is implemented, we need the following lemma.

Lemma 3. Let $\mathcal{M}$ be a $u \times v$ rectangular Monge matrix with rows $R = \{r_1, \ldots, r_u\}$ and columns $C = \{c_1, \ldots, c_v\}$. For any $i \in [1, u)$, in $O\left(u \frac{\log v}{\log u}\right)$ time we can find such column $c_s \in C$ that:

1. Some minima of columns $c_1, \ldots, c_s$ lie in rows $r_1, \ldots, r_i$.

2. Some minima of columns $c_{s+1}, \ldots, c_v$ lie in rows $r_{i+1}, \ldots, r_u$.

Proof. Aggarwal et al. $[1]$ proved the following theorem. The algorithm they found was nicknamed the SMAWK algorithm.

Theorem 2. One can compute the bottommost column minima of a rectangular $k \times l$ Monge matrix in $O(k + l)$ time.

If $u \geq v$, we can find the column minima for each column of matrix $\mathcal{M}$ using the SMAWK algorithm in $O(u)$ time. Picking the right $c_s$ is straightforward in this case.

Assume $u < v$. We first pick a set $\mathcal{C}' = \{c'_1, \ldots, c'_u\}$ of $u$ evenly spread columns of $\mathcal{C}$, including the leftmost and the rightmost column. By Fact $[1]$, $\mathcal{M}(\vec{R}, \mathcal{C}')$ is also a Monge matrix. The SMAWK algorithm is then used to obtain the bottommost rows $r'_1, \ldots, r'_u$ containing the column minima of $c'_1, \ldots, c'_u$ in $O(u)$ time. By Fact $[3]$ we have $r'_1 \geq \ldots \geq r'_u$. We then find some $j$ such that $r'_j \geq r_i$. The sought column $c_s$ can now be found by proceeding recursively on the matrix

$$\mathcal{M}' = \mathcal{M}(\vec{R}, \{c'_j, \ldots, c'_{j+1}\}).$$

The matrix $\mathcal{M}'$ has still $u$ rows, but it has only $O(v/u)$ columns.

At each recursive step we divide the size of the column set by $\Omega(u)$, so there are at most $\log_u v = \frac{\log v}{\log u}$ steps. Each step takes $O(u)$ time and hence we obtain the desired bound. $\Box$

Activate-Row  Assume we activate row $r$. At that point $r \notin P(\mathcal{C}_i)$ for any group $\mathcal{C}_i$. Our goal is to reorganize the column groups and their potential row sets so that the conditions $[P.1]$ $[P.2]$ $[P.3]$ and $[H.2]$ are again satisfied.

Consider some group $\mathcal{C}_i$. $\mathcal{C}_i$ can fall into three categories.

C.1 For each $c \in \mathcal{C}_i$ we have $\mathcal{M}_{r, c} \leq \min\{\mathcal{M}(P(\mathcal{C}_i), \{c\})\}$.

C.2 For some two columns $c_1, c_2 \in \mathcal{C}_i$ we have $\mathcal{M}_{r, c_1} < \min\{\mathcal{M}(P(\mathcal{C}_i), \{c_1\})\}$ and $\mathcal{M}_{r, c_2} > \min\{\mathcal{M}(P(\mathcal{C}_i), \{c_2\})\}$. 

\[10\]
C.3 For each \( c \in C_i \) we have \( M_{r,c} \geq \min \{ M(P(C_i), \{ c \}) \} \).

Fact 4 guarantees that row \( r \) contains column minima for a (possibly empty) interval of columns of \( M(R \cup \{ r \}, C) \). As the groups do not overlap, this implies that the groups in category C.1 form a (possibly empty) interval of groups \( c_a, \ldots, c_b \), while there are at most two category C.2 groups \( -c_{a-1} \) and \( c_{b+1} \), if they exist. The groups that are done, clearly fall into category C.3.

We can decide if \( C_i \) falls into category C.1 in \( O(|P(C_i)|) = O(\alpha) \) time by looking only at the leftmost and rightmost columns \( c_-, c_+ \) of \( C_i \). Clearly, if for some \( r' \in P(C_i) \) we have \( M_{r',c_-} < M_{r,c_-} \) or \( M_{r',c_+} < M_{r,c_+} \), \( C_i \) does not belong to C.1. Otherwise, by invariant P.1, the row \( r \) contains some column minima for all columns of \( C_i \) and hence by Fact 4 it contains column minima for all columns of \( C_i \). Moreover, if \( r \) is below all the rows of \( P(C_i) \) or above all the rows of \( P(C_i) \), by looking only at the border columns of \( C_i \), we can precisely detect the category of \( C_i \). As invariant P.3 holds before the activation of \( r \), there is at most one group \( C_i^+ \) such that \( P(C_i^+) \) contains rows both above and below \( r \).

We first find the rightmost group \( C_i \) such that for all \( r' \in P(C_i) \) we have \( r' > r \). This can be done in \( O(\log \log m) \) time by setting \( C_i = \text{l} \text{a} \text{s} \text{t} \{ U. \text{S} \text{u} \text{c} \text{c} \text{(} r \text{)} \} \). By Fact 4, if there is any group \( C' \) in categories C.1 or C.2 then one of the groups \( C_i, C_{i+1} \) also falls into C.1 or C.2. We may thus find all groups \( C_a, \ldots, C_b \) in category C.1 by moving both to the left and to the right of \( C_i \). The groups \( C_a, \ldots, C_b \) are replaced with a single group \( C' \) spanning all their columns and \( P(C') \) is set to \( \{ r \} \). If the group \( C_{a-1} \) (\( C_{b+1} \) resp.) exists, we insert \( r \) into \( P(C_{a-1}) \) (\( P(C_{b+1}) \)) only if this group is either in fact \( C_+ \) or is in category C.2. After such insertions, both invariants P.2 and P.3 may become violated.

Invariant P.3 can only be violated if the group existed \( C_i^+ \) and was not in category C.1 and also there exists some other group with \( r \) in its potential row set. Since it is impossible that \( r \) was inserted into potential row sets of groups both to the left and to the right of \( C_i^+ \), suppose wlog. that some \( C' \) is to the right of \( C_i^+ \) and \( r \in P(C') \). In \( O(\alpha) \) time we can check if \( r \) contains the column minimum of the rightmost column of \( C_i^+ \) of \( M(R \cup \{ r \}, C_i^+) \). If so, by Facts 3 and 4, we can delete from \( P(C_i^+) \) all the rows above \( r \) (recall that \( r \) contains a column minimum for the leftmost column of \( C' \)). Otherwise, by Fact 4, we can safely delete \( r \) from \( P(C_i^+) \). Hence, we fix invariant P.3 in \( O(\alpha(\log \log m + \log \alpha)) \) time.

Invariant P.2 is violated if \( |P(C_{a-1})| = 2\alpha \) or \( |P(C_{b+1})| = 2\alpha \). In that case algorithm of Lemma 3 is used to split group \( C_z \), for \( z \in \{ a-1, b+1 \} \) into groups \( C_z', C_z'' \) such that \( |P(C'_z)| = |P(C''_z)| = \alpha \).

We spend \( O(\alpha(\log \log m + \log \alpha)) \) time on identifying, accessing and updating each group that falls into categories C.2 or C.3. There are \( O(1) \) such groups, as discussed above. Also, by Lemma 2, it takes \( O(\alpha \log \log m) \) time to fix the invariant P.1 for (possibly split) groups \( C_{a-1}, C_{b+1} \) and \( C' \).

In order to bound the running time of the remaining steps, i.e., handling the groups of category C.1 and splitting the groups that break the invariant P.2, we introduce two types of credits for each element inserted into sets \( P(C_i) \):

- an \( O(\log \log m + \log \alpha) \) identification credit,
- an \( O \left( \frac{\log m}{\log \alpha} \right) \) splitting credit.

The identification credit is used to pay for successfully verifying that some group \( C_i \) falls into category C.1 and deleting all the elements of \( P(C_i) \). Indeed, as discussed above, we spend \( O(|P(C_i)||\log \log m + \log \alpha)| \) time on this. As \( P(C_i) \) is not empty, we can charge the cost of merging \( C_i \) with some other group to some arbitrary element of \( P(C_i) \). Recall that merging and splitting groups takes \( O(\log \log m) \) time.
Figure 2: Updating the column groups and the corresponding potential row sets after activating row \( r \). The rectangles conceptually show the potential row sets. The rows of \( \bar{R} \) that are not contained in any potential row set are omitted in the picture. The dots represent the column minima. Note that it might happen that \( P(C_i) \) contains rows both above and below \( r \).

Finally, consider performing a split of \( P(C_i) \) of size \( 2\alpha \). As the sets \( P(C_i) \) only grow by inserting single elements, there exist at least \( \alpha \) elements of \( P(C_i) \) that never took part in any split. We use the total \( O\left( \frac{\alpha \log m}{\log \alpha} \right) \) total credit of those elements to pay for the split.

To sum up, the time needed to perform \( k \) operations Activate-Row is \( O\left( k\alpha \left( \log \log m + \log \alpha \right) + I \left( \log \log m + \log \alpha + \frac{\log m}{\log \alpha} \right) \) \), where \( I \) is the total number of insertions to the sets \( P(C_i) \). As Ensure-Bound-And-Get incurs \( O(l) \) insertions in total, \( I = O(k + l) \). Setting \( \alpha = \sqrt{\log m} \), we obtain the following lemma.

**Lemma 4.** Let \( M \) be a \( k \times l \) offset Monge matrix. There exists a data structure supporting Init in \( O(k + l \log m) \) time, Lower-Bound in \( O(1) \) time and both Current-Min-Row and Ensure-Bound-And-Get in \( O(\log m) \) time. Additionally, any sequence of Activate-Row operations is performed in \( O\left( (k + l) \frac{\log m}{\log \log m} \right) \) total time, where \( m = \max(k, l) \).

### 4 Online Column Minima of a Block Monge Matrix

Let \( \mathcal{M} = \text{off}(\mathcal{M}_0, d) \), \( R \), \( C \), \( l \), \( k \), \( m \) be defined as in Section 3. In this section we consider the problem of reporting the column minima of a rectangular offset Monge matrix, but in a slightly different setting.

Again, we are given a fixed rectangular Monge matrix \( \mathcal{M}_0 \) and we also have an initially empty, growing set of rows \( \bar{R} \subseteq R \) for which the offsets \( d(\ast) \) are known. Let \( \Delta > 0 \) be an integral parameter not larger than \( l \). We partition \( C \) into a set \( \mathcal{B} = \{B_1, \ldots, B_b\} \) of at most \( \lfloor l/\Delta \rfloor \) blocks, each of size at most \( \Delta \). The columns in each \( B_i \) constitute a contiguous fragment of \( c_1, \ldots, c_l \), and each block \( B_i \) is to the left of \( B_{i+1} \). We also maintain a shrinking subset \( \bar{\mathcal{B}} \subseteq \mathcal{B} \) containing the blocks \( B_i \), such that the minima \( \min\{\mathcal{M}(R, B_i)\} \) are not yet known. More formally, for each \( B_i \in \mathcal{B} \setminus \bar{\mathcal{B}} \), we have \( \min\{\mathcal{M}(R, B_i)\} = \min\{\mathcal{M}(\bar{R}, \{c\})\} \). Initially \( \bar{\mathcal{B}} = \mathcal{B} \).

For each column \( c \) not contained in any of the blocks of \( \bar{\mathcal{B}} \), the data structure explicitly maintains the current minimum, i.e., the value \( \min\{\mathcal{M}(\bar{R}, \{c\})\} \). Moreover, when some new
row is activated, the user is notified for which columns of $\bigcup (B \setminus \bar{B})$ the current minima have changed.

For blocks $\bar{B}$, the data structure only maintains the value $\min \{ \mathcal{M}(\bar{R}, \bigcup \bar{B}) \}$. Once the user can guarantee that the value $\min \{ \mathcal{M}(R, \bigcup \bar{B}) \}$ does not depend on the “hidden” rows $R \setminus \bar{R}$, the data structure can move a block $B_i \in \bar{B}$ such that $\min \{ \mathcal{M}(R, \bigcup \bar{B}) \} = \min \{ \mathcal{M}(\bar{R}, B_i) \}$ out of $\bar{B}$ and make it possible to access the current minima in the columns of $B_i$.

More formally, we support the following set of operations:

- **Init($R, C$)** – initialize the data structure.
- **Activate-Row($r$)**, where $r \in R \setminus \bar{R}$ – add $r$ to the set $\bar{R}$.
- **Block-Lower-Bound()** – return $\min \{ \mathcal{M}(\bar{R}, \bigcup \bar{B}) \}$. If $\bar{R} = \emptyset$ or $\bar{B} = \emptyset$, return $\infty$.
- **Block-Ensure-Bound()** – tell the data structure that indeed
  \[ \min \{ \mathcal{M}(R \setminus \bar{R}, C) \} \geq \text{Block-Lower-Bound()} = \min \{ \mathcal{M}(\bar{R}, B_i) \}, \]
  for some $B_i \in \bar{B}$, i.e., the smallest element of $\mathcal{M}(R, \bigcup \bar{B})$ does not depend on the entries of $\mathcal{M}$ located in rows $R \setminus \bar{R}$. Again, it is the responsibility of the user to guarantee that this condition is in fact satisfied.

As the minimum of $\mathcal{M}(R, B_i)$ can now be computed, $B_i$ is removed from $\bar{B}$.

- **Current-Min($c$)**, where $c \in C$ – for $c \in \bigcup (B \setminus \bar{B})$, return the explicitly maintained $\min \{ \mathcal{M}(\bar{R}, \{c\}) \}$. For $c \in \bigcup \bar{B}$, set Current-Min($c$) = $\infty$.

Additionally, the data structure provides an access to the queue Updates containing the columns $c \in \bigcup (B \setminus \bar{B})$ such that the most recent call to either Activate-Row or Block-Ensure-Bound resulted in a change (or an initialization, if $c \in B_i$ and the last update was Block-Ensure-Bound, which moved $B_i$ out of $\bar{B}$) of the value Current-Min($c$).

Note that there can be at most $k$ calls to Activate-Row and no more than $\lceil l/\Delta \rceil$ calls to Block-Ensure-Bound.

### 4.1 The Components

**An Infrastructure for Short Subrow Minimum Queries** In this section we assume that for any $r \in R$ and $1 \leq a, b \leq l$, $b - a + 1 \leq \Delta$, it is possible to compute an answer to a subrow minimum query $S(r, a, b)$ (see Section 3) on matrix $\mathcal{M}_0$ (equivalently: $\mathcal{M}$) in constant time. We call such a subrow minimum query short.

**The Block Minima Matrix** Define a $k \times b$ matrix $\mathcal{M}'$ with rows $R$ and columns $B$, such that
\[ \mathcal{M'}_{r_i, B_j} = \min \{ \mathcal{M}(\{r_i\}, B_j) \}. \]
As we assume that we can perform short subrow minima queries in $O(1)$ time, and every block spans at most $\Delta$ columns, we can access the elements of $\mathcal{M}'$ in constant time. Fact 2 implies that $\mathcal{M}'$ is also a rectangular Monge matrix.

We build the data structure of Section 3 for matrix $\mathcal{M}'$. For brevity we identify the matrix $\mathcal{M}'$ with this data structure and write e.g. $\mathcal{M}'$.Init() to denote the call to Init of the data structure built upon $\mathcal{M}'$. This data structure handles the blocks contained in $\bar{B}$.
The Exact Minima Array  For each column \( c \in \bigcup (B \setminus \overline{B}) \), the value
\[
c\text{min}(c) = \min \{ \mathcal{M}(\overline{R}, \{c\}) \}
\]
is stored explicitly. The operation \text{CURRENT-MIN}(c)\ returns \( c\text{min}(c) \).

Rows Containing the Block Minima  For each \( B_j \in (B \setminus \overline{B}) \) we store the value
\[
y_j = \mathcal{M}'(\text{CURRENT-MIN-ROW}(B_j)).
\]
Note that the data structure of Section 3 guarantees that for \( B_i, B_j \in (B \setminus \overline{B}) \) such that \( i < j \), we have \( y_i \geq y_j \).

The set of defined \( y_j \)'s grows over time. We store this set in a dynamic predecessor/successor data structure \( Y \). We can thus perform insertions/deletions and \textsc{Pred}/\textsc{Succ} queries on a subset of \( \{1, 2, \ldots, k\} \) in \( O(\log \log k) = O(\log \log m) \) time.

We also have two auxiliary arrays \texttt{first} and \texttt{last} indexed with the rows of \( R \). \texttt{first}(r) (\texttt{last}(r)) contains the leftmost (rightmost respectively) block \( B_j \) such that \( y_j = r \). Updating these arrays when \( \overline{B} \) shrinks is straightforward.

The Row Candidate Sets  Two subsets \( D_0 \) and \( D_1 \) of \( \overline{R} \) are maintained. The set \( D_q \) for \( q = 0, 1 \) contains the rows of \( \overline{R} \) that may still prove useful when computing the initial value of \( c\text{min}(c) \) for \( c \in \bigcup \{ B_i : B_i \in B \land i \mod 2 = q \} \). For each such \( c \), \( D_q \) contains a row \( r \) such that \( \min \{ \mathcal{M}(\overline{R}, \{c\}) \} = \mathcal{M}_{r,c} \). Note that adding any row from \( \overline{R} \) to \( D_q \) does not break this invariant. The call \text{ACTIVATE-ROW}(r)\ always adds the row \( r \) to both \( D_0 \) and \( D_1 \). The sets \( D_q \) are stored in dynamic predecessor/successor data structures as well.

Remark 2. There is a subtle reason why we keep two row candidate sets \( D_0, D_1 \) responsible for even and odd blocks respectively, instead of one. Being able to separate two neighboring blocks of each group with a block from the other group will prove useful in an amortized analysis of the operation \text{BLOCK-ENSURE-BOUND}.

4.2 Implementing the Operations

\textbf{Block-Ensure-Bound}  The preconditions of this operation ensure that it is valid to call \( \mathcal{M}'(\text{ENSURE-BOUND-AND-GET}()) \), which in response returns some \( B_j \). At this point we find the row \( y_j \) containing the minimum of \( \mathcal{M}(R, B_j) \) using \( \mathcal{M}'(\text{CURRENT-MIN-ROW}(B_j)) \). The data structure \( Y \) and the arrays \texttt{first} and \texttt{last} are updated accordingly.

As the block \( B_j \) is moved out of \( \overline{B} \), we need to compute the initial values \( c\text{min}(c) \) for \( c \in B_j \). Let \( y_j^- \) be the row returned by \( \mathcal{M}'(\text{CURRENT-MIN}(B_{j-1})) \) if \( j > 0 \) and \( r_1 \) otherwise. Similarly, set \( y_j^+ \) to be the row returned by \( \mathcal{M}'(\text{CURRENT-MIN}(B_{j+1})) \) if \( j < b \) and \( r_k \) otherwise. Clearly, \( y_j^- \geq y_j \geq y_j^+ \). First we prove that for each column \( c \in B_j \), we have
\[
\min \{ \mathcal{M}(\overline{R}, \{c\}) \} = \min \{ \mathcal{M}(\overline{R} \cap \{y_j^+, \ldots, y_j^-, \}, \{c\}) \},
\]
that is, the search for the minimum in column \( c \) can be limited to rows \( y_j^+ \) through \( y_j^- \). By the definition of \( \mathcal{M}' \), for some column \( c_j \in B_j \), the minimum \( \mathcal{M}(\overline{R}, \{c_j\}) \) is located in row \( y_j \). Now assume that \( c \in B_j \) is to the left of \( c_j \). By Fact 3, one minimum of \( \mathcal{M}(\overline{R}, \{c\}) \) is located in the rows of \( \overline{R} \) (weakly) below \( y_j \). If \( j > 0 \), then for some column \( c_j^- \in B_{j-1} \) one minimum of \( \mathcal{M}(\overline{R}, \{c_j^-\}) \) is located in row \( y_j^- \). By Fact 3 the minimum of \( \mathcal{M}(\overline{R}, \{c\}) \) is located in rows (weakly) above \( y_j^+ \). Analogously we prove that for \( c \in B_j \) to the right of \( c_j \), the minimum is located in rows \( y_j^+ \) through \( y_j \).
We first add the rows $y_j^−, y_j^+$ to $D_{j \mod 2}$. From the definition of set $D_{j \mod 2}$, for each column $c \in B_j$, it suffices to only consider the elements $\mathcal{M}_{r,c}$, where $r \in D_{j \mod 2} \cap \{y_j^−, \ldots, y_j^+\}$ as potential minima in column $c$. All such rows $r$ can be found with $O(\log \log m)$ overhead per row using predecessor search on $D_{j \mod 2}$. Now we prove that after this step all such rows $r$ except of $y_j^−$ and $y_j^+$ can be safely removed from $D_{j \mod 2}$. Indeed, let $c_k$ be a column in some block $B_k \in \mathcal{B}$ such that $k \equiv j \mod 2$ and $k < j$. In fact, we have $k < j - 1$. By the Monge property, we have $\mathcal{M}_{y_j^−,c_k} + \mathcal{M}_{r,c_j^−} \leq \mathcal{M}_{r,c_k} + \mathcal{M}_{y_j^+,c_j^−}$. Also, from the definition of $y_j^−$, $\mathcal{M}_{y_j^−,c_k} \leq \mathcal{M}_{r,c_k}$. If we had $\mathcal{M}_{y_j^−,c_k} > \mathcal{M}_{r,c_k}$, that would lead to a contradiction. Thus, $\mathcal{M}_{y_j^−,c_k} \leq \mathcal{M}_{r,c_k}$, and removing $r$ from $D_{j \mod 2}$ does not break the invariant posed on $D_{j \mod 2}$, as $y_j^− \in D_{j \mod 2}$. The proof of the case $k > j$ is analogous.

Let us now bound the total time spent on updating values $\text{cmin}(c)$ during the calls \text{BLOCK-ENSURE-BOUND}. For each column $c \in B_j$, all entries $\mathcal{M}_{r,c}$, where $r \in D_{j \mod 2} \cap \{y_j^−, \ldots, y_j^+\}$ are tried as potential column minima. Alternatively, we can say that for each such row, we try to use it as a candidate for minima of $O(\Delta)$ columns. However, only two of these rows are not deleted from $D_{j \mod 2}$ afterwards. If we assign a credit of $\Delta$ to each row inserted into $D_{j \mod 2}$, this credits can be used to pay for considering all the rows except of $y_j^−$ and $y_j^+$. Thus, the total time spent on testing candidates for the minima over all calls to \text{BLOCK-ENSURE-BOUND} can be bounded by $O \left( \left( \frac{1}{\Delta} \Delta + I \Delta \right) \right)$, where $I$ is the number of insertions to either $D_0$ or $D_1$. However, $I$ can be easily seen to be $O \left( \left( k + \frac{1}{\Delta} \right) \right)$ and thus the total number of candidates tried by \text{BLOCK-ENSURE-BOUND} is $O(k\Delta + l)$. The total cost spent on maintaining and traversing sets $D_q$ is $O \left( \left( \frac{1}{\Delta} \frac{1}{\Delta} \right) \log \log m \right) = O \left( \left( \frac{1}{\Delta} \frac{1}{\Delta} \right) \log \log m \right).

**Activate-Row** Suppose we activate the row $r \in R \setminus \bar{R}$. The first step is to call \text{M'.ACTIVATE-Row}(r) and add $r$ to sets $D_0$ and $D_1$. The introduction of the row $r$ may change the minima of some columns $c \in \bigcup(B \setminus \bar{B})$. We now prove that there can be at most $O(\Delta)$ changes. Recall that for each $B_j \in \mathcal{B} \setminus \bar{B}$, for some column $c_i \in B_i$ the minimum of $\mathcal{M}(R, \{c_i\})$ is located in row $y_i$. Note that $r \neq y_i$, as $r$ has just been activated. Let $u$ be such that $y_u > r$. Then, for each block $B_j \in \mathcal{B} \setminus \bar{B}$, where $j < u$, Fact 3 implies that all the columns of $B_j$ have their minima in rows below $y_u$ (or exactly at $y_u$) and thus the introduction of row $r$ does not affect their minima. Analogously, if $y_u < r$, then the introduction of row $r$ does not affect columns in blocks to the right of $B_u$. Hence, $r$ can only affect the exact minima in at most two blocks: $B_u, B_v$, where $u = \text{last}(Y.\text{Succ}(r))$ and $v = \text{first}(Y.\text{Pred}(r))$. The blocks can be found in $O(\log \log m)$ time, whereas updating the values $\text{cmin}(c)$ (along with pushing them to the queue $\text{UPDATES}$) takes $O(\Delta)$ time.

Let us bound the total running time of any sequence of operations \text{ACTIVATE-Row} and \text{BLOCK-ENSURE-Bound}. By Lemma 4 the time spent on executing the data structure $\mathcal{M'}$ operations is $O \left( k \log m \log \log m + \frac{1}{\Delta} \log \log m \right)$ whereas the time spent on maintaining the predecessor structures and updating the column minima is $O \left( k \Delta + k \log \log m + l + \frac{1}{\Delta} \log \log m \right)$. The following lemma follows.

**Lemma 5.** Let $\mathcal{M} = \text{off}(\mathcal{M}_0, d)$ be a $k \times l$ rectangular offset Monge matrix. Let $\Delta$ be the block size. Assume we can perform subrow minima queries spanning at most $\Delta$ columns of $\mathcal{M}_0$ in $O(1)$ time. There exists a data structure supporting $\text{INIT}$ in $O(k + l + \frac{1}{\Delta} \log m)$ time and both \text{BLOCK-LOWER-Bound} and \text{CURRENT-MIN} in $O(1)$ time. Any sequence of \text{ACTIVATE-Row} and \text{BLOCK-ENSURE-Bound} operations is performed in $O \left( k \left( \frac{\log m}{\log \log m} + \Delta \right) + l + \frac{1}{\Delta} \log m \right)$ time, where $m = \max(k, l)$. 

15
5 Online Column Minima of a Staircase Offset Monge Matrix

In this section we show a data structure supporting a similar set of operations as in Section 3, but in the case when the matrices $M_0$ and $M = \text{off}(M_0, d)$ are staircase Monge matrices with $m$ rows $R = \{r_1, \ldots, r_m\}$ and $m$ columns $C = \{c_1, \ldots, c_m\}$. We still aim at reporting the column minima of $M$, while the set $\bar{R}$ of revealed rows is extended and new bounds on $\min\{M(R \setminus \bar{R}, C)\}$ are given.

In comparison to the data structure of Section 3, we loosen the conditions posed on the operations LOWER-BOUND and ENSURE-BOUND-AND-GET. Now, LOWER-BOUND might return a value smaller than $\min\{M(\bar{R}, C)\}$ and a single call to ENSURE-BOUND-AND-GET might not report any new column minimum at all. However, ENSURE-BOUND-AND-GET can still only be called if $\min\{M(R \setminus \bar{R}, C)\} \geq \text{LOWER-BOUND}()$ and the data structure we develop in this section guarantees that a bounded number of calls to ENSURE-BOUND-AND-GET suffices to report all the column minima of $M$.

The exact set of operations we support is the following:

- **INIT($R, C$)** – initialize the data structure and set $\bar{R} = \emptyset$ and $\bar{C} = C$.
- **ACTIVATE-ROW($r$)**, where $r \in R \setminus \bar{R}$ – add $r$ to the set $\bar{R}$.
- **LOWER-BOUND()** – return a number $v$ such that $\min\{M(\bar{R}, \bar{C})\} \geq v$. If $\bar{R} = \emptyset$ or $\bar{C} = \emptyset$, return $\infty$.
- **ENSURE-BOUND-AND-GET()** – tell the data structure that we have $\min\{M(R \setminus \bar{R}, C)\} \geq \text{LOWER-BOUND}()$.

As for previous data structures, it is the responsibility of the user to guarantee that this condition is in fact satisfied.

With this knowledge, the data structure may report some column $c \in \bar{C}$ such that $\min\{M(R, \{c\})\}$ is known. However, it’s also valid to not report any new column minimum (in such case nil is returned) and only change the known value of LOWER-BOUND().

- **CURRENT-MIN($c$)**, where $c \in \bar{C}$ – if $c \in C \setminus \bar{C}$, return the known minimum in column $c$. Otherwise, return $\infty$.

5.1 Partitioning a Staircase Matrix into Rectangular Matrices

Before we describe the data structure, we prove the following lemma on partitioning staircase matrices into rectangular matrices.

**Lemma 6.** For any $\epsilon \in (0, 1)$, a staircase matrix $M$ with $m$ rows and $m$ columns can be partitioned in $O(m)$ time into $O(m)$ non-overlapping rectangular matrices so that each row appears in $O\left(\frac{\log m}{\log \log m}\right)$ matrices of the partition, whereas each column appears in $O\left(\frac{\log^{1+\epsilon} m}{\log \log m}\right)$ matrices of the partition.

**Proof.** Let $\epsilon \in (0, 1)$ and set $b = \lceil \log^\epsilon m \rceil$. For $m > 1$, we have $b \geq 1$.

We first describe the partition for matrices $M'$ with $m' = b^2$ rows $\{r'_1, \ldots, r'_{m'}\}$ and $m'$ columns $\{c'_1, \ldots, c'_{m'}\}$, where $z \geq 0$. Our partition will be recursive. If $z = 0$, then $M'$ is a $1 \times 1$ matrix and our partition consists of a single element $M'$.

Assume $z > 0$. We partition $M'$ into $b$ staircase matrices $M'^{r}_{1}, \ldots, M'^{r}_{b}$ and $b - 1$ rectangular matrices $M'^{\ell}_{1}, \ldots, M'^{\ell}_{b-1}$. For $i = 1, \ldots, b$, we set the $i$-th staircase matrix to be

$$M'^{r}_{i} = M'(\{r'_{(i-1)b^{z-1}+1}, \ldots, r'_{ib^{z-1}}\}, \{c'_1, \ldots, c'_z\})$$
whereas for \(j = 1, \ldots, b - 1\), the \(j\)-th rectangular matrix is defined as
\[
M'_r = M'(\{r'_{(i-1)b+1}, \ldots, r'_{ib-1}\}, \{c'_{ib+1}, \ldots, c'_{m'}\}).
\]

See Figure 3 for a schematic depiction of such partition.

Each of matrices \(M'_r\) is of size \(b^z - 1 \times b^z - 1\) and is then partitioned recursively.

Let us now compute the value \(\text{rowcnt}(z) = (\text{colcnt}(z))\) defined as the maximum number of matrices in partition that some given row (column resp.) of a staircase matrix \(M'\) of size \(b^z \times b^z\) appears in. Clearly, on the topmost level of recursion, each row appears in exactly one staircase matrix \(M'_0\) and at most one rectangular matrix \(M'_r\). Thus, we have \(\text{rowcnt}(0) = 1\) and \(\text{rowcnt}(z + 1) \leq \text{rowcnt}(z) + 1\), which easily implies \(\text{rowcnt}(z) \leq z + 1\).

Each column appears in exactly one matrix \(M'_0\) and no more than \(b - 1\) matrices \(M'_r\). Hence, we have \(\text{colcnt}(0) = 1\) and \(\text{colcnt}(z + 1) \leq \text{colcnt}(z) + b - 1\). We thus conclude \(\text{colcnt}(z) \leq zb - z + 1\).

Analogously we can compute the value \(\text{rectcnt}(z)\) denoting the total number of rectangular matrices in such recursive partition. We have \(\text{rectcnt}(0) = 1\) and \(\text{rectcnt}(z + 1) \leq b \cdot \text{rectcnt}(z) + b - 1\). An easy induction argument shows that \(\text{rectcnt}(z) \leq 2b^z - 1\).

The partition for an arbitrary matrix \(\mathcal{M}\) of \(m\) is obtained as follows. We find the smallest \(y\) such that \(b^y \geq m\). We next find the recursive partition of matrix \(\mathcal{M}^y\) which is defined as \(\mathcal{M}\) padded so that it has \(b^y\) rows and \(b^y\) columns. The last step is to remove some number of dummy rightmost columns and bottommost rows from each rectangular matrix of the partition.

Now, each row of \(\mathcal{M}\) appears in at most
\[
y + 1 = O(\log_b m) = O \left( \frac{\log m}{\log b} \right) = O \left( \frac{\log m}{\epsilon \log \log m} \right) = O \left( \frac{\log m}{\log \log m} \right)
\]
rectangular matrices of a partition. Each column of \(\mathcal{M}\) appears in at most
\[
yb - y + 1 \leq yb + 1 = O(b \log_b m) = O \left( \frac{b \log m}{\log b} \right) = O \left( \frac{\log^{1+\epsilon} m}{\epsilon \log \log m} \right) = O \left( \frac{\log^{1+\epsilon} m}{\log \log m} \right)
\]
matrices of the partition. The partition consists of at most \(2b^y - 1 = O(m)\) rectangles. The time needed to compute the row and column intervals constituting the rows and columns of the individual matrices of the partition is \(O(\text{rectcnt}(y)) = O(m)\).
5.2 The Data Structure Components

The Short Subrow Minimum Queries Infrastructure  Let $\Delta = \lfloor \log^{1-\epsilon/2} m \rfloor$. In order to be able to use the data structure of Lemma 5 with block size $\Delta$, we need the following lemma.

Lemma 7. The staircase Monge matrix $\mathcal{M}_0$ can be preprocessed in $O(m \Delta \log m)$ time to allow performing subrow minimum queries on $\mathcal{M}_0$ spanning at most $\Delta$ columns in $O(1)$ time.

Proof. We use the following result of $\mathcal{M}$. (Lemma 3. of $\mathcal{M}$)

Lemma 8. Given a $y \times x$ rectangular Monge matrix $\mathcal{M}'$, one can construct in $O(x \log y)$ time an $O(x)$-space data structure supporting subrow minimum queries spanning all columns of $\mathcal{M}'$ in $O(1)$ time, if $x = O(\log y)$.

Let $q$ be the maximum integer such that $2^q < \Delta$. For $j \in [0, q]$ and $i \in [1, m - 2^j + 1]$, let $\mathcal{M}^j_i = \mathcal{M}(\{r_1, \ldots, r_i\}, \{c_i, \ldots, c_i+2^j-1\})$, i.e., $\mathcal{M}^j_i$ is a rectangular submatrix of $\mathcal{M}$ with columns $\{c_i, \ldots, c_i+2^j-1\}$ and all rows that have values defined for these columns. By Fact 1 $\mathcal{M}^j_i$ is a Monge matrix. For each $\mathcal{M}^j_i$, we build a data structure of Lemma 8. This takes $O \left( \sum_{j=0}^{q} \sum_{i=1}^{m-2^j+1} 2^j \log m \right) = O \left( \sum_{j=0}^{q} 2^j m \log m \right) = O(2^q m \log m) = O(m \Delta \log m)$ time. Now we show how to handle a subrow minimum query $S(r, a, b)$ on $\mathcal{M}_0$, where $b-a+1 \leq \Delta$. Let $u$ be the greatest integer such that $2^u \leq b-a+1$. Then we can cover our subrow minimum query with two possibly overlapping queries of length $2^u$. Hence, to answer $S(r, a, b)$ it is enough to find the minimum in row $r$ in $\mathcal{M}^j_i$ and the minimum in row $r$ in $\mathcal{M}^j_{b-2^j+1}$ and return the smaller one. By Lemma 8 this takes $O(1)$ time.

The Partition $\mathcal{M}_1, \ldots, \mathcal{M}_q$. We partition the staircase Monge matrix $\mathcal{M}$ into $O(m)$ rectangular Monge matrices $\mathcal{M}_1, \ldots, \mathcal{M}_q$ such that each $\mathcal{M}_i$ is a subrectangle of $\mathcal{M}$. By Lemma 6 we can ensure that each row appears in $O \left( \frac{\log m}{\log \log m} \right)$ subrectangles and each column appears in $O \left( \frac{\log^{1+\epsilon/2} m}{\log \log m} \right)$ subrectangles. Every element of $\mathcal{M}$ is covered by exactly one matrix $\mathcal{M}_i$. For each row $r$ (column $c$) we compute the set $W_r$ ($W_c$ respectively) of matrices of the partition in which $r$ ($c$ resp.) appears.

We build the block data structure of Section 4 for each $\mathcal{M}_i$. For each $\mathcal{M}_i$ we use the same block size $\Delta$. As each $\mathcal{M}_i$ is a subrectangle of $\mathcal{M}$, Lemma 4 guarantees that we can perform subrow minimum queries on $\mathcal{M}_i$ spanning at most $\Delta$ columns in $O(1)$ time. For brevity, we identify the matrix $\mathcal{M}_i$ and its associated data structure. We use the dot notation to denote operations acting on specific matrices, e.g. $\mathcal{M}_i$.INIT.

For each matrix $\mathcal{M}_i$ we use notation analogous as in previous sections: $\mathcal{R}_i$ and $\mathcal{C}_i$ are the sets of rows and columns of $\mathcal{M}_i$, respectively. Let $k_i = |\mathcal{R}_i|$ and $l_i = |\mathcal{C}_i|$. Denote by $\bar{\mathcal{R}}_i$ the set of active rows of $\mathcal{M}_i$. Recall that the blocks of the matrix $\mathcal{M}_i$ are partitioned into two sets $\bar{\mathcal{B}}_i$ and $\mathcal{B}_i \setminus \bar{\mathcal{B}}_i$. Denote by block($\mathcal{M}_i$) the submatrix $\mathcal{M}_i(\bar{\mathcal{R}}_i, \cup \mathcal{B}_i)$ and by exact($\mathcal{M}_i$) the submatrix $\mathcal{M}_i(\bar{\mathcal{R}}_i, \cup (\mathcal{B}_i \setminus \bar{\mathcal{B}}_i))$.

The Priority Queue $H$. The core of our data structure is a priority queue $H$. At any time, $H$ contains an element $c$ for each column $c \in \bar{\mathcal{C}}$ and at most one element $\mathcal{M}_i$ for each matrix $\mathcal{M}_i$. Thus the size of $H$ never exceeds $O(m)$.

We maintain the following invariants after INIT and each call ACTIVATE-ROW or ENSURE-BOUND-AND-GET resulting in $\bar{\mathcal{C}} \neq \emptyset$:
H.1 For each $c \in \bar{C}$, the key of $c$ in $H$ is equal to
\[ \min\{M_i.CURRENT-MIN(c) : M_i \in W_c\}. \]

H.2 For each $M_i$ such that $block(M_i)$ is not empty, the key of $M_i$ in $H$ is equal to
\[ \min\{block(M_i)\} = M_i.BLOCK-LOWER-BOUND(). \]

Lemma 9. Assume invariants $H.1$ and $H.2$ are satisfied. Then $H.MIN-KEY() \leq M(\bar{R}, \bar{C})$.

Proof. Let $v = H.MIN-KEY()$. Assume the contrary, that there exists an element $M_{r,c} < v$, where $r \in \bar{R}$ and $c \in \bar{C}$. Let $M_i$ be the rectangular Monge matrix containing element $M_{r,c}$. If $c \in \bigcup B_i$, then $v > M_{r,c} \geq M_i.BLOCK-LOWER-BOUND()$. But then the key of $M_i$ in $H$ is $M_i.BLOCK-LOWER-BOUND()$, a contradiction. Similarly, if $c \in \bigcup(B_i \setminus \bar{B})$, then $M_i.CURRENT-MIN(c) \leq M_{r,c} < v$, a contradiction. \qed

5.3 Implementing the Operations

Initialization The procedure $Init$ first builds the short subrow minimum query data structure of Lemma [7]. Then, the data structure of Lemma [5] is initialized for each $M_i$. The total time needed to initialize these structures is thus
\[ O\left(m\Delta \log m + m\frac{\log^{1+\epsilon/2} m}{\log m} + m \frac{\log^{2+\epsilon/2} m}{\Delta \log \log m}\right) = O\left(m \log^{2-\epsilon/2} m\right). \]

Next, $Init$ inserts into the priority queue $H$ an element $c$ with key $\infty$ for each $c \in C$ and an element $M_i$ with key $\infty$ for each matrix $M_i$. This takes additional $O(m)$ time. Clearly, the invariants $H.1$ and $H.2$ are satisfied immediately after the initialization.

Lower-Bound By Lemma [9] the value $v = H.MIN-KEY()$ is a lower bound on the value $\min\{M(\bar{R}, \bar{C})\}$. The function $LOWER-BOUND$ returns $v$ and thus works in $O(1)$ time.

Activate-Row The call $ACTIVATE-ROW(r)$ may require changes to some keys of the entries of $H$ in order to satisfy invariants $H.1$ and $H.2$. However, the activation of $r$ does not alter what the functions $M_i.CURRENT-MIN(c)$ or $M_i.BLOCK-LOWER-BOUND()$ return for matrices $M_i \notin W_r$. For all $M_i \in W_r$ we call $M_i.ACTIVATE-ROW(r)$. By Lemma [5], the columns $c_j$ of exact($M_i$) with changed minima can be read in linear time from $M_i.UPDATE$. If $c_j \in \bar{C}$ and the current key of $c_j$ in $H$ is greater than $M_i.CURRENT-MIN(c_j)$, we decrease key of $c_j$ in $H$. Analogously, the call $ACTIVATE-ROW(r)$ can incur the change of $M_i.BLOCK-LOWER-BOUND()$ and thus we may need to decrease the key of $M_i$ in $H$. In both cases, as the operation $H.DECREASE-KEY$ runs in $O(1)$ time, the time spent on decreasing keys in $H$ is asymptotically no more than the running time of $M_i.ACTIVATE-ROW(r)$.

Ensure-Bound-And-Get Let $v = LOWER-BOUND() = H.MIN-KEY()$. Recall that the precondition of $ENSURE-BOUND-AND-GET$ requires $\min\{M(R \setminus \bar{R}, \bar{C})\} \geq \min\{M(R \setminus \bar{R}, \bar{C})\} \geq v$. Also, $\min\{M(\bar{R}, \bar{C})\} \geq v$, so we can conclude $\min\{M(R, \bar{C})\} \geq v$. We have two cases. 1. If the top element of $H$ is a column $c$, then from invariant $H.1$, we know that $c \in \bar{C}$ and for some $M_j \in W_c$, we have:
\[ \min\{M(R, \bar{C})\} \geq v = M_j.CURRENT-MIN(c) \geq \min\{M(R, \{c\})\}. \]
However, clearly \( \min\{\mathcal{M}(R, \{c\})\} \geq \min\{\mathcal{M}(R, \tilde{C})\} \), so we conclude that the inequalities are in fact equalities and \( v \) is indeed the minimum in column \( c \). In that case \( c \) is returned by Ensure-Bound-And-Get and \( c \) is removed from \( \tilde{C} \). It can be easily verified that after calling \( H.\text{Extract-Min}() \) invariants \( H.1 \) and \( H.2 \) still hold. This case arises at most once for each column of \( C \) so the total cost of \( H.\text{Extract-Min} \) calls for all columns is \( O(m \log m) \).

2. Now consider the case when the top element of \( H \) is a matrix \( \mathcal{M}_i \). In this case we return \texttt{nil} and do not alter the set \( \tilde{C} \). As \( \mathcal{M}_i \) is a subrectangle of \( \mathcal{M} \), from the precondition we have

\[
\min\{\mathcal{M}_i(R_i \setminus \tilde{R}, C_i)\} \geq \min\{\mathcal{M}(R \setminus \tilde{R}, C)\} \geq v = \mathcal{M}_i.\text{Block-Lower-Bound}().
\]

Hence, we can call \( \mathcal{M}_i.\text{Block-Ensure-Bound}() \). Recall that this operation shrinks the set \( \tilde{B}_i \) and thus we need to update \( H \) so that the invariants \( H.1 \) and \( H.2 \) are satisfied. First we pop the entry \( \mathcal{M}_i \) from \( H \) with \( H.\text{Extract-Min}() \) in \( O(\log m) \) time. Now, if \( \tilde{B}_i \neq \emptyset \), we once again need to insert into \( H \) an element \( \mathcal{M}_i \) with key \( \mathcal{M}_i.\text{Block-Lower-Bound}() \) in order to satisfy invariant \( H.2 \). To satisfy invariant \( H.1 \), we decrease key of each \( c_j \in \mathcal{M}_i.\text{Updates} \) to \( \mathcal{M}_i.\text{Current-Min}(c_j) \), if appropriate. Again, as decreasing a key in \( H \) takes constant time, the time spent on decreasing column keys is asymptotically the same as the cost of the recent call to \( \mathcal{M}_i.\text{Block-Ensure-Bound}() \).

A call to \( \mathcal{M}_i.\text{Block-Ensure-Bound} \) can happen at most \( O(l_i/\Delta) \) times, so the additional time spent on \( H \) operations incurred by the calls to \( \mathcal{M}_i.\text{Block-Ensure-Bound} \) is \( O((l_i/\Delta) \cdot \log m) \). For the same reason, the call \( \text{Ensure-Bound-And-Get}() \) returns \texttt{nil} at most \( O(\sum_i l_i/\Delta) \) times. The total number of calls to \( \text{Ensure-Bound-And-Get} \) to compute all the column minima of \( \mathcal{M} \) is thus \( O(m + \sum_i l_i/\Delta) = O(m \log^\epsilon m) \). The total cost of operations on \( H \) that were not charged to \( \mathcal{M}_i.\text{Block-Ensure-Bound} \) calls is \( O(m \log^{1+\epsilon} m) \).

Let us now compute the total time spent in the calls \( \mathcal{M}_i.\text{Activate-Row} \) and \( \mathcal{M}_i.\text{Block-Ensure-Bound} \).

\[
\sum_i O\left(k_i \left(\Delta + \frac{\log m}{\log \log m}\right) + \frac{l_i}{\Delta \log m}\right) = O\left(\frac{\log m}{\log \log m} \sum_i k_i + \frac{\log^\epsilon}{2} m \sum_i l_i\right) = O\left(m \left(\frac{\log m}{\log \log m}\right)^2 + m \log^{1+\epsilon} m\right) = O\left(m \left(\frac{\log m}{\log \log m}\right)^2\right).
\]

**Lemma 10.** Let \( \mathcal{M} = \text{off}(\mathcal{M}_0, d) \) be a \( m \times m \) offset staircase Monge matrix and let \( \epsilon \in (0, 1) \). There exists a data structure supporting \( \text{Init} \) in \( O(m \log^{2-\epsilon} m) \) time and both \( \text{Lower-Bound} \) and \( \text{Current-Min} \) in \( O(1) \) time. Any sequence of \( \text{Activate-Row} \) and \( \text{Ensure-Bound-And-Get} \) operations can be performed in \( O\left(m \left(\frac{\log m}{\log \log m}\right)^2\right) \) time. All the column minima are computed after \( O(m \log^\epsilon m) \) calls to \( \text{Ensure-Bound-And-Get} \).

**Remark 3.** Lemma 10 also holds for flipped staircase matrices.

**Proof.** A flipped staircase matrix \( \mathcal{M}' \) can be seen as a staircase matrix \( \mathcal{M} \) with both the rows and columns reversed. Each subrow minimum query on \( \mathcal{M}' \) translates easily into a single subrow minimum query on \( \mathcal{M} \). \( \square \)

6 Single-Source Shortest Paths in Dense Distance Graphs

In this section we study the possibly most general instance of the problem of computing single-source shortest paths in dense distance graphs, that fits all the most important applications.
The overall structure of our algorithm resembles Dijkstra’s algorithm and is also similar to both [6] and [15]. Nevertheless, we give a complete implementation and analysis.

Let \( G = (V, E) \) be a weighted planar digraph and let \( G_1, \ldots, G_g \) be some partition of \( G \) into connected regions with few holes. Denote by \( X_{i,j} \) the vertices of \( \partial G_i \) lying on the \( j \)-th hole of \( G_i \), in clockwise order. Also assume that for each \( u, v \in \partial G_i \) there exists a path in \( G_i \) – each region could be easily extended with bidirectional copies of edges of \( G_i \) with some very large length so that we can tell if the path actually exists by only looking at the weight of the shortest path.

The graph \( G \), the partition \( G_1, \ldots, G_g \) and the dense distance graphs \( \text{DDG}(G_i) \) constitute the „fixed input” of our problem. We are allowed to preprocess each \( \text{DDG}(G_i) \) once in time asymptotically no more than the time used for construction of \( \text{DDG}(G_i) \). To the best of our knowledge, in all known applications this time is no less than \( O(|V(G_i)| + |\partial G_i|^2 \log |V(G_i)|) \), which is the running time of the method described in Section 2.1. Denote by \( \text{DDG}(G_i)[x, y] \) the length of the shortest path \( x \rightarrow y \) in \( G_i \).

Now, let \( P \) be some set of “outer” directed edges with both endpoints in \( \partial G \), not necessarily contained in \( E \) and not necessarily preserving the planarity of \( G \). Denote by \( \ell(e) \in \mathbb{R} \) the length of edge \( e \in P \). Also, let \( \phi \) be a function \( \partial G \rightarrow \mathbb{R} \), called a price function. We define reduced lengths with respect to \( \phi \) for both edges of \( P \) and distances in dense distance graphs.

- for \( (x, y) \in P \) let \( \ell^\phi((x, y)) = \ell((x, y)) - \phi(x) - \phi(y) \),
- for \( (x, y) \in \partial G_i \times \partial G_i \), let \( \text{DDG}(G_i)^\phi[x, y] = \text{DDG}(G_i)[x, y] + \phi(x) - \phi(y) \).

A price function is called feasible, if all the reduced lengths are non-negative. In all the relevant applications we also assume that for each \( G_i \) we are given (as part of the „fixed” input) a feasible price function \( \phi_i^0 \).

**Remark 4.** In the flow-related applications ([4], [14]), graphs \( \text{DDG}(G_i) \) typically contain non-negative lengths, and hence \( \phi_i^0 \equiv 0 \). The distance oracles ([14], [15]) typically handle negative edges during their initialization. Actually, any algorithm following the original recursive approach of Fakcharoenphol and Rao [6] to construct dense distance graphs (and simultaneously compute single-source shortest paths in the case of real edge lengths) can be extended to find the feasible \( \phi_i^0 \) for each \( G_i \).

Given the set \( P \), the function \( \ell \), a feasible \( \phi \) and a vertex \( s \in \partial G \), our goal is to design an efficient subroutine computing the lengths of the shortest paths from \( s \) to all vertices of \( \partial G \) in graph \( (\partial G, P) \cup \text{DDG}(G) \), assuming edge-lengths reduced by \( \phi \). As the reduction of lengths does not change the shortest paths, we can follow the general approach of Dijkstra’s algorithm, which assumes non-negative edge lengths. However, our subroutine has to be robust enough to not preprocess the entire graph \( \text{DDG}(G) \) each time the subroutine is called with different parameters \( \phi \) and \( P \). We call this problem the *single-source shortest paths in a dense distance graph* problem.

Such a subroutine has been used e.g. in an \( O(n \log^3 n) \) time algorithm of Borradaile et al. [4], computing the multiple-source multiple-sink maximum flow in a directed planar graphs. Their subroutine extends FR-Dijkstra [6] to work with reduced lengths for the case of a single-region graph \( G \) with distinguished boundary vertices \( \partial G \) lying on a single face of \( G \) and a set of “outer” edges \( P \). The computation of the lengths of shortest paths from \( s \in \partial G \) to all vertices of \( \partial G \) takes \( O(|\partial G| \log^2 |\partial G| + |P| \log |\partial G|) \) time and is a bottleneck of their algorithm. In this section we propose a more efficient implementation.
6.1 The Algorithm

Lemma 11. Suppose a feasible price function $\phi_i^0$ for $DDG(G_i)$ is given. The graph $DDG(G_i)$ can be decomposed into a set of $O(1)$ (flipped) staircase Monge matrices $D_i$ of at most $|\partial G_i|$ rows and columns. For each $u,v \in \partial G_i$ we have:

- for each $M \in D_i$ such that $M_{u,v}$ is defined, $M_{u,v} \geq DDG(G_i)[u,v]$.
- there exists $M \in D_i$ such that $M_{u,v}$ is defined and $M_{u,v} = DDG(G_i)[u,v]$.

The decomposition can be computed in $O(|V(G_i)| + |\partial G_i|^2 \log |V(G_i)|)$ time.

Proof. Let $h$ be the number of holes of $G_i$. We describe the set of (flipped) staircase Monge matrices $D_i$.

First, for the $j$-th hole we add to $D_i$ a staircase matrix $M_i^+$ and a flipped staircase matrix $M_i^-$ with rows $X_{i,j}$ and columns $X_{i,j}$. The order imposed on the rows and columns is the clockwise order on the $j$-th hole. For $u, v \in X_{i,j}$, we set $M_{u,v} = DDG(G_i)^0[u,v]$. For $u \geq v$, we set $M_{u,v} = DDG(G_i)^0[u,v]$. The matrices $M_i^+$ and $M_i^-$ represent the distances between the nodes of a single hole. We now prove that both $M_i^+$ and $M_i^-$ are Monge. Let $v, x, y, z$ be some nodes of $X_{i,j}$ in clockwise order.

Assume $M_{v,y}^+ + M_{v,z}^+ < M_{v,y}^+ + M_{v,z}^+$, or, equivalently, $DDG(G_i)[v, y] + DDG(G_i)[x, z] < DDG(G_i)[v, z] + DDG(G_i)[x, y]$. Recall that the matrix $DDG(G_i)$ represents distances between all pairs of vertices of $\partial G_i$ in $G_i$. As the vertices of $X_{i,j}$ lie on a single face of a planar graph $G_i$, any path $v \rightarrow y$ in $G_i$ has to cross each path $x \rightarrow z$ in $G_i$. Specifically, the shortest path $v \xrightarrow{p_1} y$ and the shortest path $x \xrightarrow{p_2} z$ have some common vertex $u$ in $G_i$. Thus, the total length of paths $v \xrightarrow{p_1} u \xrightarrow{p_1} y$ and $x \xrightarrow{p_2} u \xrightarrow{p_2} z$ is $DDG(G_i)[v, y] + DDG(G_i)[x, z]$. But the paths $v \xrightarrow{p_1} u \xrightarrow{p_2} z$ and $x \xrightarrow{p_2} u \xrightarrow{p_1} y$ also have the same total length and that length cannot be less than $DDG(G_i)[v, z] + DDG(G_i)[x, y]$. This contradicts $DDG(G_i)[v, y] + DDG(G_i)[x, z] < DDG(G_i)[v, z] + DDG(G_i)[x, y]$ and thus proves that $M_i^+$ is a staircase Monge matrix. The proof that $M_i^-$ is a flipped staircase Monge matrix is analogous. Both $M_i^+$ and $M_i^-$ are computed in $O(|\partial G_i|^2)$ time.

Now we describe the matrices of $D_i$ representing the distances between nodes lying on the $j$-th hole and nodes on the $k$-th hole (for $j \neq k$). Mozes and Wulff-Nilsen [17], Section 4.4) showed that given the initial feasible price function $\phi_i^0$, in $O(|V(G_i)| + |\partial G_i|^2 \log |V(G_i)|)$ time one can compute two rectangular Monge matrices $M_{i,k,L}^+$ and $M_{i,k,R}^+$, with rows $X_{i,j}$ and columns $X_{i,k}$, such that for each $u \in X_{i,j}$ and $v \in X_{i,k}$ we have $DDG(G_i)[u, v] = \min(M_{i,k,L}^+, M_{i,k,R}^+)$ (for more details about this construction, see also [11], Section 5.3). Each square Monge matrix can be easily decomposed into a staircase Monge matrix and a flipped staircase Monge matrix. A rectangular Monge matrix can be padded with either some number of copies of the last row or some number of copies of the last column in order to make it square. Thus, for each pair $(k, l), k \neq l$, we add to $D_i$ four (flipped) staircase Monge matrices. In total, the set $D_i$ has $2h + 4h(h - 1) = O(1)$ staircase Monge matrices, each of size no more than $|\partial G_i| \times |\partial G_i|$.

We use Lemma 11 to decompose $DDG(G_i)$ into staircase Monge matrices. Now, given a price function $\phi$, for each region $G_i$ we define the set of matrices $D_i^\phi$. For each $M \in D_i$, we include in $D_i^\phi$ a matrix $M^\phi$ with the same rows and columns as $M$, such that $M_{u,v}^\phi = M_{u,v} + \phi(u) - \phi(v)$. It is easy to notice that the terms $\phi(*)$ do not influence the Monge property. We stress that the set $D_i^\phi$ is not computed explicitly and the preprocessing of $DDG(G_i)$ happens only once, immediately after $DDG(G_i)$ is created. Each entry of some matrix of $D_i^\phi$ can be obtained from the entry of the corresponding matrix in $D_i$ in constant time.
We now show how Dijkstra’s algorithm can be simulated on \((\partial G, P) \cup \bigcup \text{DDG}(G_i)\) with reduced lengths in order to compute lengths of shortest paths from the source vertex \(s \in \partial G\) to \(\partial G\), using the data structure developed in Section 5.

Recall that Dijkstra’s algorithm run from the source \(s\) in graph \(G = (V, E)\) grows a set \(S\) of visited vertices of \(V\) such that the lengths \(d(v)\) of the shortest paths \(s \rightarrow v\) for \(v \in S\) are already known. Initially \(S = \{s\}\) and we repeatedly choose a vertex \(y \in V \setminus S\) such that the value \(z(y) = \min_{x \in S} \{d(x) + \ell(x, y) : (x, y) \in E\}\) is the smallest. \(y\) is then added to \(S\) with \(d(y) = z(y)\). The vertices \(y \in V \setminus S\) are typically stored in a priority queue with keys \(z(y)\), which allows to choose the best \(y\) efficiently.

Our implementation (see Algorithm 1) also maintains a growing subset \(S \subseteq \partial G\) of visited vertices and the values \(d(x)\) for \(x \in S\). We build a data structure of Lemma 10 for each matrix in \(\bigcup_{i=1}^{q} D_i^\phi\). \(D_i^\phi\) is an „offset“ version of \(D_i^\phi\). For each matrix \(M \in D_i^\phi\), there is a corresponding offset matrix \(M' = \text{off}(M, d)\) in \(D_i^\phi\) with the same rows and columns. The row \(u\) of \(M \in D_i^\phi\) is activated (see Section 5) immediately once \(u\) is added to \(S\). By Fact 3, the matrices of \(D_i^\phi\) are Monge matrices. The matrices \(D_i^\phi\) are never stored explicitly. Each entry is computed from the corresponding entry in \(D_i\), the price function \(\phi\) and the array \(d\) in \(O(1)\) time every time it is accessed.

We have a priority queue \(H\) storing an element \(x\) for each \(x \in \partial G \setminus S\). Denote by \(key(e)\) the key of an element \(e \in H\). Let \(W_r\) (\(W_c\) respectively) be the set of all matrices of \(\bigcup D_i^\phi\) with row \(r\) (column \(c\)). For some data structure \(M\) of Lemma 10 denote by \(C^* (M)\) the set of columns of \(M\), for which the minima have been already reported.

In our algorithm, we cannot afford to set \(key(y)\) for each \(y \in \partial G \setminus S\) to

\[ z(y) = \min_{x \in S} \left\{ \min\{d(x) + \ell^\phi(x, y) : (x, y) \in P\}, \min\{M_{x,y} : M \in W_x \cap W^y\} \right\}, \]

as would Dijkstra’s algorithm do. Instead, for \(y \in \partial G \setminus S\), \(key(y)\) satisfies

\[ key(y) = \min_{x \in S} \left\{ \min\{d(x) + \ell^\phi(x, y) : (x, y) \in P\}, \min\{M_{x,y} : M \in W_x, y \in C^* (M)\} \right\}, \]

We also add \(O(g)\) special elements \(\{M : M \in \bigcup_{i=1}^{q} D_i^\phi\}\) to our priority queue \(H\). At all times we have \(key(M) = M.\text{LOWER-BOUND}()\). We also ensure that for each \(x \in S\), in every \(M \in W_x\), row \(x\) is activated.

The above invariants imply that for \(y \in \partial G \setminus S\) we have

\[ z(y) \geq \min\{key(y), \min\{M.\text{LOWER-BOUND}() : M \in W^y\}\}. \tag{1} \]

Indeed, for each \(x \in S\) and \(M \in W_x\) such that \(y \notin C^* (M)\), by the definition of \(M.\text{LOWER-BOUND}\), we have \(\min\{M_{x,y} : y \notin C^* (M)\} \geq M.\text{LOWER-BOUND}()\). Also the definition of \(key(y)\) implies that if \(key(y) \neq \infty\) then \(key(y)\) is the length of some \(s \rightarrow y\) path.

One can easily verify that the key invariants are satisfied before the first iteration of the while loop in line 20.

Assume the element that gets extracted from \(H\) in line 22 is some vertex \(x \in \partial G \setminus S\). We need to prove that \(x\) has the least value \(z(x)\) among all vertices of \(\partial G \setminus S\) and that \(z(x) = key(x)\). As the keys of \(H\) include all keys \(key(y)\) where \(y \in \partial G \setminus S\) and all keys \(key(M)\) for the \(O(y)\) data structures, for each \(y \in \partial G \setminus S\) we have \(z(y) \geq key(x)\). But there actually exists a path \(s \rightarrow x\) of length \(key(x)\), so \(z(y) \geq key(x) = z(x)\) and thus \(x\) has the minimal \(z(x)\) among all vertices in \(\partial G \setminus S\). Consequently, \(x\) can be safely added to \(S\). The procedure \(\text{Visit}()\) is used to update the set \(S\), the array \(d\) and all the keys of \(H\) affected by inserting \(x\) to \(S\).

Otherwise, the element extracted from \(H\) is some data structure \(Z\). We try to extract some previously unknown column minimum of \(Z\) with the call \(Z.\text{Ensure-Bound-And-Get}()\). In
Algorithm 1 Pseudocode of our single-source shortest paths algorithm. The function \textsc{Dijkstra} returns a vector \(d\) containing the lengths of the shortest paths from \(s\) to all other vertices of \(\partial G\). We assume that \(\text{DDG}(G)\) is preprocessed so that we can access the matrices of sets \(D_1, \ldots, D_g\).

1: \textbf{function} \textsc{Dijkstra}(\(P, \ell, \phi, s\))
2: \hspace{1em} Initialize the data structures of Lemma 10 for each \(M \in \bigcup_i D_i^{\phi}\).
3: \hspace{1em} \(H := \text{empty priority queue}\)
4: \hspace{1em} \(S := \emptyset\)
5: \hspace{1em} \textbf{procedure} \textsc{Visit}(\(x, \text{val}\))
6: \hspace{2em} \(S := S \cup \{x\}\)
7: \hspace{2em} \(d(x) := \text{val}\)
8: \hspace{2em} \textbf{for} \(M \in W_x\) \textbf{do}
9: \hspace{3em} \(M.\text{Activate-Row}(x)\)
10: \hspace{3em} \(H.\text{Decrease-Key}(M, M.\text{Lower-Bound})\)
11: \hspace{2em} \textbf{for} \((x, y) \in P\) \textbf{do}
12: \hspace{3em} \textbf{if} \(y \notin S\) \textbf{then}
13: \hspace{4em} \(H.\text{Decrease-Key}(y, d(x) + \ell^{\phi}(x, y))\)
14: \hspace{2em} \textbf{for} \(x \in \partial G \setminus \{s\}\) \textbf{do}
15: \hspace{3em} \(d(x) = \infty\)
16: \hspace{3em} \(H.\text{Insert}(x, \infty)\)
17: \hspace{2em} \textbf{for} \(M \in \bigcup_i D_i^{\phi}\) \textbf{do}
18: \hspace{3em} \(H.\text{Insert}(M, \infty)\)
19: \hspace{2em} \textsc{Visit}(\(s, 0\))
20: \hspace{2em} \textbf{while} \(S \neq \partial G\) \textbf{and} \(H.\text{Min-Key}() \neq \infty\) \textbf{do}
21: \hspace{3em} \(v := H.\text{Min-Key}()\)
22: \hspace{3em} \(Z := H.\text{Extract-Min}()\)
23: \hspace{3em} \textbf{if} \(Z\) \text{ is a vertex of } \partial G \text{ then}
24: \hspace{4em} \textsc{Visit}(\(Z, v\))
25: \hspace{3em} \textbf{else}
26: \hspace{4em} \(x = Z.\text{Ensure-Bound-And-Get}()\)
27: \hspace{4em} \textbf{if} \(x \neq \text{nil}\) \textbf{and} \(x \notin S\) \textbf{then}
28: \hspace{5em} \(H.\text{Decrease-Key}(x, Z.\text{Current-Min}(x))\)
29: \hspace{5em} \(H.\text{Insert}(Z, Z.\text{Lower-Bound})\)
30: \hspace{3em} \textbf{return} \(d\)

In order to do this, we need to guarantee that all the rows of \(Z\) that are not active at that point contain only values not less than \(Z.\text{Lower-Bound}()\). Notice that after each extraction of an element with key \(v\) from \(H\), we update some other keys in \(H\) to values not less than \(v\). Thus, each extracted element has key not less than the previously extracted elements. In particular, we know that for each \(y \in \partial G \setminus \{s\}\), \(d(y) \geq Z.\text{Lower-Bound}()\). For each \(M \in W_y\), the values in row \(y\) are not less than \(d(y)\) and indeed \(x = Z.\text{Ensure-Bound-And-Get}()\) can be called. If \(x \neq \text{nil}\), a column minimum of \(Z\) has been found and the key of \(x\) is updated. Finally, \(Z\) is reinserted into \(H\) with the key equal to the new value of \(Z.\text{Lower-Bound}()\).

Let us now bound the running time of the function \textsc{Dijkstra}. By Lemma 10, the initialization along with any sequence of operations \textsc{Activate-Row} and \textsc{Block-Ensure-Bound} can be performed on \(M \in D_i^{\phi}\) in \(O\left(|\partial G_i| \left(\frac{\log |\partial G_i|}{\log \log |\partial G_i|}\right)^2\right)\) time.
The time spent on extracting elements from $H$ is $O(I \log |\partial G|)$, where $I$ is the number of insertions into $H$. Clearly $H$ never contains more than $O(|\partial G| + g) = O(|\partial G|)$ elements. Each vertex of $\partial G$ is inserted into $H$ at most once and, by Lemma [10], each data structure $M \in \mathcal{D}^{\delta}$ is inserted into $H$ at most $O(|\partial G| \log^\epsilon |\partial G|)$ times before it reports all the column minima. Hence, the total time spend on $H$.\textsc{Extract-Min}$ is $O \left( \log |\partial G| \sum_i |\partial G_i| \log^\epsilon |\partial G| \right)$. The operation $H$.\textsc{Decrease-Key}$ takes constant time and thus we can neglect the calls to $H$.\textsc{Decrease-Key}$ in line [13] which cannot be neglected this way. Taking into account the preprocessing of Lemma [11] we conclude with the following theorem.

**Theorem 3.** Let $\epsilon \in (0, 1)$. After preprocessing $DDG(G)$ in $O \left( \sum_i (|V(G_i)| + |\partial G_i|^2) \log |V(G_i)| \right)$ time, an instance of the single-source shortest paths problem on $DDG(G)$ can be solved in $O \left( \sum_i |\partial G_i| \left( \frac{\log^2 |\partial G_i|}{\log^2 \log |\partial G_i|} + \log^\epsilon |\partial G_i| \log |\partial G_i| \right) + |P| \right)$ time.

**Remark 5.** Currently the most efficient known algorithm for computing $DDG(G_i)$ given a feasible price function $\phi_i^0$ runs in $O \left( \left( |V(G_i)| + |\partial G_i|^2 \right) \log |V(G_i)| \right)$ time, which is asymptotically the same as the time needed for preprocessing in Theorem 3. Consequently, we neglect the preprocessing time in Theorem 3 when discussing applications.

### 7 Implications

The implications of Theorem 3 are numerous. In this section we mention some planar graph problems for which the best known algorithms compute single-source shortest paths in dense distance graphs and such step constitutes the main bottleneck of their running times.

**Multiple-Source Multiple-Sink Maximum Flow in Directed Planar Graphs** In this problem we are given a directed planar graph $G = (V, E)$ with real edge capacities. Let $n = |V|$. We are also given two subsets $S, T \subseteq V$, $S \cap T = \emptyset$. The set $S$ contains source vertices, while $T$ contains sink vertices. Our goal is to send as much flow from the vertices $S$ to vertices of $T$ without violating edge capacity constraints and flow conservation on the vertices $V \setminus S \setminus T$. Although in general graphs this problem can be reduced to single-source single-sink maximum flow by adding a super-source and a super-sink (connected with all sources and all sinks, respectively), such a reduction does not work for planar graphs as it does not preserve planarity. Note that the problem of computing maximum matching in a bipartite planar graph can be reduced to a single-source single-sink maximum flow instance.

Borradaile et al. [4] found an $O(n \log^3 n)$ algorithm for this problem. Their algorithm recursively partitions $G$ in a balanced way with cycle separators of size $C = O(\sqrt{n})$. The results of recursive calls are combined using $O(C)$ computations of single-source shortest paths in a single-region dense distance graph with boundary size $O(C)$ and $O(C)$ additional edges. The implementation they use runs in $O(C \log^2 C)$ time. If we replace it with the implementation of Theorem 3 we obtain the following corollary.

**Corollary 1.** The multiple-source multiple-sink maximum flow and the maximum bipartite matching in a planar graph can be computed in $O \left( n \frac{\log^3 n}{\log^2 \log n} \right)$ time.

**Single-Source All-Sinks Maximum Flow in Directed Planar Graphs** In this problem we are also given a directed planar graph $G = (V, E)$ with real edge capacities and some $s \in V$. Our goal is to compute the values of the maximum flow between $s$ and all vertices $t \in V \setminus \{s\}$. 

Łącki et al. [14] gave an $O(n \log^3 n)$-time algorithm for this problem. The overall structure of their algorithm is similar to this of Borradaile et al. [4] and the bottleneck on each level of the recursive decomposition is to solve $O(X)$ instances of a single-source shortest path problem in a dense distance graph with a total boundary of $O(X)$, where $X = O(\sqrt{n})$.

**Corollary 2.** The single-source all-sinks maximum flow in planar graphs can be solved in $O\left(\frac{n \log^3 n}{\log \log n}\right)$ time.

**Exact Distance Oracles for Directed Planar Graphs** Moses and Sommer [16] considered the following problem. Given a planar digraph $G = (V, E)$ with real edge lengths and space allocation $S \in [n \log \log n, n^2]$, construct a data structure of size $O(S)$ answering exact distance queries in $G$ as efficiently as possible. They proposed a data structure that can be constructed in $O\left(S \frac{\log^2 n}{\log \log n}\right)$ time, and is capable of answering the distance queries in $O\left(\frac{n}{\sqrt{S}} \log^2 n \log^3/2 \log n\right)$ time. At the heart of their query algorithm lies the basic version of FR-Dijkstra (without reduced costs), and thus replacing it with our algorithm gives a faster query algorithm for $S = O(n^{2-\epsilon})$, for any $\epsilon > 0$.

**Corollary 3.** Given a planar graph $G$ and $S \in [n \log \log n, n^2 - \epsilon]$, one can construct a $O(S)$-space exact distance oracle for $G$ in $O\left(\frac{S \log^3 n}{\log \log n}\right)$ time. The oracle answers shortest path queries $O\left(\frac{n}{\sqrt{S}} \log^2 n \log \log n\right)$ time.

**Fully-Dynamic Distance Oracles for Directed Planar Graphs** In this problem we are given a directed planar graph $G$ with real edge lengths which undergoes edge insertions and deletions. It is also guaranteed that edge insertions do not break the planarity of $G$. Italiano et al. [10] showed a fully dynamic data structure limited to the case of non-negative edge lengths. On the other hand, Kaplan et al. [11] showed a data structure processing updates and answering queries in $O(n^{2/3} \log^{5/3} n)$ time in the case, when only edge-length updates are allowed. Both data structures can be easily combined in order to allow both edge set updates and negative lengths. Again, FR-Dijkstra on a dense distance graph induced by an $r$-division can be identified as one of the bottlenecks of both query and update algorithms. The second bottleneck is the computation of a dense distance graph of a piece using the data structure of Klein [12] in $O(r \log r)$ time. The terms $O\left(\frac{n}{\sqrt{r}} \log^2 \frac{n}{\log \log n}\right)$ and $O(r \log n)$ can be balanced for $r = n^{2/3} \frac{\log^{2/3} n}{\log^{2/3} \log \log n}$.

**Corollary 4.** For a directed planar graph $G$, in $O\left(\frac{n \log^2 n}{\log \log n}\right)$ we can construct a data structure supporting both edge updates (insertions and deletions) and distance queries in $O\left(\frac{n^{2/3} \log^{5/3} \frac{n}{\log \log n}}{\log^{2/3} \log \log n}\right)$ amortized time.
