Abstract

Porting applications to new hardware or programming models is a tedious and error prone process. Every help that eases these burdens is saving developer time that can then be invested into the advancement of the application itself instead of preserving the status-quo on a new platform.

The Alpaka library defines and implements an abstract hierarchical redundant parallelism model. The model exploits parallelism and memory hierarchies on a node at all levels available in current hardware. By doing so, it allows to achieve platform and performance portability across various types of accelerators by ignoring specific unsupported levels and utilizing only the ones supported on a specific accelerator. All hardware types (multi- and many-core CPUs, GPUs and other accelerators) are supported for and can be programmed in the same way. The Alpaka C++ template interface allows for straightforward extension of the library to support other accelerators and specialization of its internals for optimization.

Running Alpaka applications on a new (and supported) platform requires the change of only one source code line instead of a lot of #ifdefs.

Keywords. Heterogeneous computing, HPC, C++, CUDA, OpenMP, platform portability, performance portability

1 Introduction

1.1 Motivation

Performance gain by employing parallelism in software nowadays faces a variety of obstacles. Parallel performance currently relies on the efficient use of many-core architectures that are commonly found in a heterogeneous environment of multi-core CPU and many-core accelerator hardware.

Heterogeneous systems often expose a memory hierarchy that has to be used efficiently as high computational performance usually requires high memory throughput, demanding the development of efficient caching strategies by application developers.

The same developers face a variety of parallel computing models either specific to a certain hardware or with limited control over optimization. Many models aim for providing easy to learn interfaces that hide the complexities of memory management and parallel execution while promising performance portability, but ultimately fall short of at least one of their aims.

Due to the Herculean effort associated with main-
taining a multi-source application even large development teams thus usually have to choose a strategy of trading performance for portability or vice versa by choosing one single programming model.

Alpaka was designed to prevent this trade off by providing a single source abstract interface that exposes all levels of parallelism existent on today’s heterogeneous systems. Alpaka heavily relies on existing parallelism models, but encapsulates them via a redundant mapping of its abstract parallelization hierarchy [4] to a specific hardware, allowing for mixing various models in a single source C++ code at runtime. Thus, hardware-specific optimizations are possible without the necessity for code replication.

Alpaka therefore is open to future performance optimizations while providing portable code. This is only possible as Alpaka relies on the developers ability to write parallel code by explicitly exposing all information useful for defining parallel execution in a heterogeneous environment rather than hiding the complexities of parallel programming.

Moreover, Alpaka limits itself to a simple, pointer based memory model that requires explicit deep copies between memory levels. This puts the developer in the position to develop portable parallel caching strategies without imposing restrictions on the memory layout. Thus, developers achieve performance portability by skillful code design for which Alpaka provides a single source, explicit redundant parallelism model without any intrinsic optimization hidden from the user.

In the following, we define some categories in order to compare Alpaka to existing models for parallel programming.

Openness By Openness we refer to models licensed as open source or defined by an open standard.

Single source A model that provides for single source code allows for the application code to be written in a single programming language. It furthermore does not require extensive multiple compilation branches with varying implementations of an algorithm specific to a certain hardware. Single source models may provide annotations (e.g. compiler directives) or add defined words to the language that describe parallel execution.

Sustainability We define a sustainable parallel programming model as a model where the porting of an algorithm to another hardware requires minimum changes to the algorithmic description itself. Sustainable models furthermore should be adaptable to future hardware and be available for at least two varieties of current hardware architectures.

Heterogeneity Parallel programming models map to heterogeneous systems if they allow for developing a single source code in such a way that execution on various hardware architectures requires minimum specific changes (e.g. offloading, memory scope), execution of a single algorithmic implementation on various architectures can happen in the same program and at the same time during run time.

Maintainability We define a parallel programming model to serve code maintainability if it provides a single source code that is sustainable and allows for execution on heterogeneous hardware by changing or extending the programming model rather than the application source code.

Testability A model provides testability if an algorithmic implementation can be tested on a specific hardware and give, in a lose sense, the same results when migrating to another hardware. Testability requires sustainability, heterogeneity and maintainability but furthermore demands a separation of the algorithmic description from hardware specific features.

Optimizability We define an optimizable model by the fact that it provides the user with complete control over the parallelization of the algorithm as well as the memory hierarchy in a heterogeneous system. Furthermore, fine-tuning algorithmic performance to a specific hardware should not force developers to write multiple implementations of the same algorithm, but rather be provided for by the model.

Data structure agnostic A data structure agnostic model does not restrict the memory layout, it instead provides full control over the memory allocation and layout on all hierarchy levels, exposes deep copies between levels and does not assume a certain distribution of the memory over the various hierarchy levels. Specifically, it does not provide distributed data types that are intertwined with the parallelization scheme itself.

Performance Portability A model provides per-
formance portability if for a given single source sustainable and maintainable implementation of an algorithm the hardware utilization on various systems is the same within reasonable margins, taking into account the limitations of the specific hardware. Performance portability does not require optimum utilization of the hardware.

2 Related Work

In the following we briefly discuss other libraries targeting the portable parallel task execution within nodes. Some of them require language extensions, others advertise performance portability across a multitude of devices. However, none of these libraries can provide full control over the possibly diverse underlying hardware while being only minimally invasive. Furthermore, many of the libraries do not satisfy the requirement for full single-source (C++) support.

CUDA[3] is a parallel computing platform and programming model developed by NVIDIA. The user is bound to the usage of NVIDIA GPUs. CUDA is not open source and does not provide for Sustainability, heterogeneity, maintainability and testability. For CUDA enabled hardware it provides for optimizability.

PGI CUDA-X86[1] is a compiler technology that allows to generate x86-64 binary code from CUDA C/C++ applications using the CUDA runtime API but does not support the CUDA driver API. Compared to CUDA it allows for heterogeneity, maintainability and testability, but it currently falls behind in adapting to the latest CUDA features, thus has limited support for sustainability. As it does not provide for control of optimizations for X86 architectures, it lacks optimizability.

GPU Ocelot[2] is an open source dynamic JIT compilation framework based on llvm which allows to execute native CUDA binaries by dynamically translating the NVIDIA PTX virtual instruction set architecture to other instruction sets. It supports NVIDIA and AMD GPUs as well as multicore CPUs via a PTX to LLVM translator. The project is not in active development anymore and only supports PTX up to version 3.1 while the current version is 4.2. Thus, it is in many respects similar to PGI CUDA-X86.

OpenMP[2] is an open specification for vendor agnostic shared memory parallelization which allows to easily parallelize existing sequential C/C++/Fortran code in an incremental manner by adding annotations ( pragmas in C/C++) to loops or regions. Up to version 4.5 there is no way to allocate device memory that is persistent between kernel calls in different methods because it is not possible to create a device data region spanning both functions in the general case. Currently OpenMP does not allow for controlling the hierarchical memory as its main assumption is a shared memory pool for all threads. Therefore, the block shared memory on CUDA devices cannot be explicitly utilized and both heterogeneity and optimizability are not provided for.

OpenACC[3] is an open pragma based programming standard for heterogeneous computing which is very similar to OpenMP and provides annotations for parallel execution and data movement as well as run-time functions for accelerator and device management. It allows for limited access to CUDA block shared memory but does not support dynamic allocation of memory in kernel code. It thus does not provide for optimizability and in a practical sense, due to the very limited number of implementations, heterogeneity and sustainability.

OpenCL[4] is an open programming framework for heterogeneous platforms. It supports heterogeneity as it can utilize CPUs and GPUs of nearly all vendors. Versions prior to 2.1 (released in March 2015) did only support a C-like kernel language. Version 2.1 introduced a subset of C++14, but there are still no compilers available. OpenCL thus does not support single source programming. Furthermore, it does not allow for dynamic allocation of memory in kernel code and thus does not fully support optimizability.

SYCL[5] is an open cross-platform abstraction layer based on OpenCL and thus shares most deficiencies

2 http://openmp.org/
3 http://www.openacc-standard.org/
4 https://www.khronos.org/opencl/
5 https://www.khronos.org/sycl/
with OpenCL, however it in principle would allow for optimizability. In contrast to OpenCL it allows for single source heterogeneous programs, but as of now there is no usable free compiler implementation available that has good support for multiple accelerator devices, thus it currently lacks sustainability.

C++ AMP\textsuperscript{6} is an open specification from Microsoft which is implemented on top of DirectX 11 and thus currently limited in terms of heterogeneity, sustainability and testability. It is a language extension requiring compiler support that allows to annotate C++ code that then can be run on multiple accelerators. It lacks full control of parallel execution and memory hierarchy and thus falls short of supporting optimizability. Due to restrictions on data types that provide for portability (see e.g. concurrency::array) it is not data structure agnostic.

KOKKOS\textsuperscript{7} is an open source abstract interface for portable, high-performance shared memory-programming and in many ways similar to Alpaka. However, kernel arguments have to be stored in members of the function object coupling algorithm and data together. It thus is not data structure agnostic and in this sense limited in its optimizability.

Thrust\textsuperscript{[1]} is an open source parallel algorithms library resembling the C++ Standard Template Library (STL) which is available for CUDA, Thread Building Blocks\textsuperscript{8} and OpenMP back-ends at make-time. Its container objects are tightly coupled with the parallelization strategy, therefore Thrust is not data structure agnostic. Thrust aims at hiding the memory hierarchy and is limited in expressing parallel execution, thus it cannot achieve full optimizability.

Table 1 provides a summary of all related work and a comparison to Alpaka.

stored in simple buffers with support for copies between devices and access to memory is completely data structure agnostic. Thus, the user needs to take care of distribution of data between devices.

Alpaka does neither automatically decompose the algorithmic execution domain and data domain, nor does it assume any default or implicit states such as default device, current device, default stream, implicit built-in variables and functions.

3.2 Model of Parallel Abstraction

Alpaka abstracts data parallelism following the redundant hierarchical parallelism model [4], thereby enabling the developer to explicitly take the hierarchy of processing units, their data parallel features and corresponding memory regions into account. The Alpaka abstraction of parallelization is influenced by and based on the groundbreaking CUDA and OpenCL abstractions9 of a multidimensional grid of threads with additional hierarchy levels in between. Furthermore, it is amended with additional vectorization capabilities.

The four main hierarchies introduced by Alpaka are called grid, block, thread and element level, shown in Figure 1 together with their respective parallelization and synchronization features as discussed below.

Each parallelization level corresponds to a particular memory level (Figure 2): global memory (grid), shared memory (block) and register memory (thread).

The Alpaka model enables to separate the parallelization strategy from the algorithm. The algorithm is described by kernel functions that are executed by threads. A kernel is the common set of instructions executed by all threads on a grid.

The parallelization strategy is described by the accelerator and the work division (See Section 3.3 and 3.4). An accelerator defines the acceleration strategy by a mapping of the parallelization levels

---

9Both, CUDA and OpenCL are industry standards for accelerator programming.
Figure 2: The memory hierarchy of the Alpaka abstraction model. Threads have exclusive access to fast register memory. All threads in a block can access the same shared memory. All blocks in a grid can access the same global memory.

to the hardware. The device is the actual hardware onto which these levels are mapped.

### 3.2.1 Grid

A grid is an n-dimensional set of blocks with a usually large global memory accessible by all threads in all blocks. Grids are independent of each other and can thus be executed either sequentially or in parallel. Grids can be synchronized to each other via explicit synchronization evoked in the code.

### 3.2.2 Block

A block is an n-dimensional set of threads with a high bandwidth, low latency but small amount of shared memory. All blocks on a grid are independent of each other and can thus be executed either sequentially or in parallel. Blocks cannot be synchronized to each other. The shared memory can only be accessed explicitly by threads within the same block and gets discarded after the complete block has finished its calculation.

### 3.2.3 Thread

A thread represents the execution of a sequence of instructions. All threads in a block are independent of each other and can thus be executed either sequentially or in parallel. Threads can be synchronized to each other via explicit synchronization evoked in the code. Threads can by default always access their private registers, the shared memory of the block and the global memory. All variables within the default scope of a kernel are stored within register memory and are not shared between threads. Shared and global memory can be allocated statically or at runtime before the kernel start.

### 3.2.4 Element

The element level represents an n-dimensional set of elements and unifies the data parallel capabilities of modern hardware architectures e.g. vectorization on thread level. This is necessary as current compilers do not support automatic vectorization of basic, non-trivial loops containing control flow statements (e.g. if, else, for) or non-trivial memory operations. Furthermore, vectorization intrinsics as they are available in intrin.h, arm_neo.h, altivec.h are not portable across varying back-ends. Alpaka therefore currently relies on compiler recognition of vectorizable code parts. Code is refactored in such a way that it includes primitive inner loops over a fixed number of elements.

The user is free to sequentially loop over the elements or to utilize vectorization where a single instruction is applied to multiple data elements in parallel e.g. by utilizing SIMD vector registers. Processing multiple elements per thread on some architectures may enhance caching.

### 3.3 Mapping of Abstraction to Hardware

Alpaka clearly separates its parallelization abstraction from the specific hardware capabilities by an explicit mapping of the parallelization levels to the hardware. A major point of the hierarchical parallelism abstraction is to ignore specific unsupported levels of the model and utilize only the ones sup-

---

10 However, Alpaka allows for atomic operations that serialize thread access to global memory.
ported on a particular device. Mapping is left to the implementation of the accelerator.

This allows for variable mappings as shown in the examples below and, therefore, an optimum usage of the underlying compute and memory capabilities—albeit with two minor limitations: The grid level is always mapped to the whole device being in consideration and the kernel scheduler can always execute multiple kernel grids from multiple streams in parallel by statically or dynamically subdividing the available resources.

Figure 3 shows a mapping of the Alpaka abstraction model onto a CPU, a many integrated cores device (MIC) and a GPU architecture. For the MIC architecture a second mapping is shown, which spans a block over all cores to increase the shared memory. CPU and MIC process multiple elements per thread and benefit from their vectorization units, while a GPU thread processes only a small amount of elements.

The code within the kernel is written in C++11 (re-called on the particular accelerator device.

Finally, the user needs to decide which back-end to use for which device. It can be selected from the set of predefined accelerators or the user can write its own accelerator implementation. The set of predefined accelerator mappings are listed in Table 2.

3.4 Alpaka Programming Interface

In the following each part of the Alpaka interface is described briefly. The provided listings assume that the Alpaka namespace is used. Source code examples are provided to give a more detailed insight into Alpaka.

3.4.1 Kernel

The kernel is the central unit in Alpaka that acts as the bridge between host and accelerator code through a C++ class or a C++ lambda (C++14 required). The algorithm is described from the block down to the element level which removes the need for a nested loop structure like it is used in OpenMP and SYCL. The kernel function object needs to implement the template operator() member function as it is shown in Listing 1. This member function is the first function called on the particular accelerator device.

The code within the kernel is written in C++11 (restricted by the utilized back-end compilers) with additional calls to the Alpaka run-time API. There exist no implicit built-in variables and functions like it is usual in CUDA or OpenCL. All information can be retrieved from the accelerator object (Listing 1 : 4).
3.4.2 Accelerator Executable Functions

Alpaka defines the macros ALPAKA_FN_HOST, ALPAKA_FN_ACC and ALPAKA_FN_HOST_ACC to define that functions are callable from host, from accelerator or from both host and accelerator device. All functions called from accelerator code need to be prefixed by these macros.

3.4.3 Work Division and Index Retrieval

The work division defines the extent and dimensionality of each level of the Alpaka abstraction model. Listing 2 shows the declaration of a two-dimensional work division on the host where the grid level has an extent of 128 blocks and the other levels have an extent of one.

3.4.4 Memory

Alpaka provides simple memory buffers that store the plain pointer to memory of the particular device and additional information like residing device, extent, pitch and dimension. These buffers are uniform for all devices which allows for copying memory between different devices with respect to pitch and extents, see Listing 4.

3.4.5 Streams

A stream is the work queue of a particular device. Operations in streams are always executed in-order: No operation in a stream will begin before all previously issued operations in the stream have completed. Streams can be synchronous or asynchronous with respect to operations on the host. If an operation is
Listing 4: Allocation of a two dimensional host and a device buffer with one hundred elements each. Moreover, the host buffer is copied to the device buffer.

Listing 5: Full example of a kernel execution. The kernel is executed with a work division of 256 blocks and 16 threads per block on a single accelerator (in this case the sequential CPU back-end is selected).

4 Evaluation

This section provides an evaluation of Alpaka on a variety of hardware platforms using various back-ends, see Table 3. All CUDA evaluations are compiled with CUDA 7.0 and all CPU evaluations with gcc 4.9.2. Source codes denoted as native are not wrapped by Alpaka, but contain pure CUDA or OpenMP code.

The evaluation was performed in five stages: First, the PTX and assembler code generated during compilation of an Alpaka DAXPY program is compared to the respective native versions. Then, the overhead of two naïve Alpaka DGEMM kernels with respect to their native versions is measured. As a next step, it is investigated what happens to performance portability when the naïve Alpaka DGEMM kernels
are mapped to an inappropriate back-end followed by the description of a single source DGEMM kernel and how it can obtain performance portability with the help of Alpaka. Finally, the applicability of Alpaka to real world applications was evaluated using HASEonGPU [5].

4.1 Conceptual Comparison

This section compares the Alpaka implementation of the generalized vector addition algorithm in double precision (DAXPY) to a sequential C++ and CUDA implementation on the source code and assembler level.

DAXPY computes \( \mathbf{Y} \leftarrow \alpha \mathbf{X} + \mathbf{Y} \) where \( \mathbf{X} \) and \( \mathbf{Y} \) are vectors while \( \alpha \) is a scalar. DAXPY was selected as a trivial example on the one hand to showcase the non obfuscation abstraction and on the other hand the zero overhead abstraction of Alpaka. The source code of the various DAXPY implementations are available in our GitHub repository

From a developers point of view, the source codes are very similar to each other. However, Alpaka related changes are necessary: Alpaka adds the additional accelerator template argument together with the according function argument to the kernel function call. Each function that should be called from a accelerator needs to be annotated with the Alpaka specific macro \texttt{ALPAKA_FN_ACC}. Furthermore, Alpaka replaces the for loop index calculations by an Alpaka equivalent that calculates the correct index for each thread.

Figure 4 shows snippets of the PTX codes of the compiled Alpaka and CUDA implementations.

Comparing the generated PTX code leads to the result that these codes are identical up to two additional but unused function parameters in the Alpaka variant as well as different internal variable names and the use of non coherent texture cache once. It can be seen that modern compilers are able to remove all the meta-programming abstraction introduced by Alpaka. This perfectly demonstrates the zero overhead abstraction of the Alpaka interface regarding the CUDA interface.

4.2 Performance

As a next step, the performance characteristics of the CUDA and OpenMP Alpaka back-ends are evaluated. First, an algorithm is implemented for both Alpaka and the particular native API to show the pure Alpaka overhead in numbers. Then, the native Alpaka kernel is mapped to the non-native back-end to show that Alpaka is not na"ively performance portable. Afterwards, an enhanced single source Alpaka kernel is introduced and mapped to various architectures and it is shown that it can match the performance of the native implementations when using the appropriate Alpaka back-ends.

For comparison the double generalized matrix-matrix-multiplication (DGEMM) has been selected as a compute bound problem. DGEMM computes

\[ C \leftarrow \alpha AB + \beta C \] where \( C, A \) and \( B \) are matrices \( A = (a_{i,j}), B = (b_{i,j}) \) while \( \alpha \) and \( \beta \) are scalars.

DGEMM implementations can utilize all levels of parallelism on GPUs and CPUs ranging from blocking over shared memory to vectorization, providing a perfect showcase of these techniques within the Alpaka library. All DGEMM implementations are available in our GitHub repository \(^2\). All input matrices are dense and always have square extents to minimize bias towards implementations preferring column- or row-major layout. Initially, the matrices are filled with random values in the range \([0.0, 10.0]\). The matrices are mapped to 1D memory buffers with Alpaka aligning rows to optimum memory boundaries. Measurements do not include times for allocating the matrices on the host, filling them, a possible data transfer between the processor and a co-processor as well as device and stream initialization.

### 4.2.1 Zero Overhead Abstraction

Alpaka does not add additional overhead to the algorithm execution time. In order to show this zero overhead, native CUDA and OpenMP 2 kernels were translated one-to-one to Alpaka kernels.

The CUDA kernels use a block parallelized tiling algorithm based on the CUDA programming guide (\([3]\), Sec. 3.2.3) and were executed on a compute node with a NVIDIA K20 GK210. The OpenMP kernels use a standard DGEMM algorithm with nested for loops and were executed on a compute node with two Intel E5-2630v3 CPUs. The kernels were executed with an increasing matrix size and their execution time was measured. Figure 5 shows the speed of the Alpaka kernels mapped to the corresponding back-end relative to their native implementations.

The native CUDA Alpaka kernel provides more than 94% relative performance for almost all matrix sizes, which is an overhead of 6% or less. After a deep inspection of the compiled PTX code it turned out that this overhead results from move and forward operators translated to copies. These operators are used for grid index calculations within an Alpaka kernel. Furthermore, a small number of additional CUDA runtime calls by the alpaka CUDA back-end are necessary. The native OpenMP Alpaka kernel provides an average relative performance of 100%.

\(^2\)https://github.com/BenjaminW3/mats/mats
The native Alpaka kernels with swapped back-ends leads to poor performance. Alpaka does not guarantee performance portability when data access, work division and cache hierarchies are not considered.

One-to-one translation of a particular algorithm to an Alpaka kernel demonstrates a minimal amount of overhead compared to the native implementation on the same architecture. However, Alpaka does not guarantee that such a kernel will also show the same run-time characteristics when it is mapped onto another back-end, as it neither provides optimized nor architecture dependent data access and work division automatically. Figure 6 shows the performance of the previously used kernels when their back-ends are swapped relative to the native implementation.

The Alpaka kernels originally translated from the opposite back-end do not perform well. There are at least two reasons why these mappings are not performance portable. First, the back-ends require completely different data access patterns to achieve optimum data access performance e.g. strided data access in CUDA. Second, the amount of data a single thread can process effectively is different because of different cache sizes and hierarchies and varying optimal work divisions.

Nevertheless, it is possible to write competitive code for each back-end. Both, the NVIDIA CUDA (nvcc) and the gcc compiler remove all the abstraction layers introduced by Alpaka.

A naïve port of a kernel to an architecture it was not meant to be executed on will almost always lead to poor performance. Thus, providing a single, performance portable kernel is not trivial. The following section shows that Alpaka is able to provide performance for various back-ends with a single source kernel.

4.2.2 Single Source Kernel / Performance

It is possible to write a single source kernel that performs well on all tested Alpaka back-ends without a drop in performance compared to the native implementations. In order to reach this performance, the developer needs to abstract the access to data, optimize the work division, and consider cache hierarchies. The single source Alpaka DGEMM kernel implements a tiling matrix-matrix multiplication algorithm and considers the architecture cache sizes by adapting the number of elements processed per thread or block and the size of the shared memory to provide minimal access latency. A lot of processor architectures benefit from the Alpaka element level parallelism when calculating multiple elements in parallel in the vector processing unit.

Figure 7 provides a brief description of the hierarchical tiling algorithm. A block calculates the result of a tile in matrix C. Each thread in this block loads a set of elements of matrices A and B into shared memory to increase memory reuse. It then calculates the partial results of its set of elements before the block continues with the next tiles of A and B.

Figure 8 shows the performance of the tiling kernel mapped to the CUDA and OpenMP back-ends relative to the original native implementations. No performance loss compared to native implementations is observed but instead performance gain in the majority of cases is seen. This is due to the more descriptive nature of the Alpaka kernel which enables even further optimizations by the back-end compilers.

It is clear that there exist even more optimized versions of the algorithm, e.g. in mathematical libraries such as cuBlas, which is fine tuned for differ-

---

In this case the triple nested loop is compiled using the CUDA back-end, while the tiled shared-memory version is mapped to OpenMP.

---
ent compute-capabilities of NVIDIA GPUs, or MKL, which is an optimized OpenMP kernel library. These provide higher peak performance than Alpaka, but may require additional setup (cuBlas data transfers) or include implicit—and maybe unwanted—data migration between the host and the device. Nevertheless, if it should be necessary to use one of these optimized algorithms it is possible to use them with Alpaka as well by utilizing template specialization within Alpaka kernels.

### 4.2.3 Performance Portability

Figure 9 shows the performance of the Alpaka tiling kernel executed on varying architectures relative to the theoretical peak performance of the corresponding architecture. The kernel work division was selected in a way that provides good performance for the particular architecture. CPU devices were accelerated by the OpenMP 2 back-end, while NVIDIA devices were accelerated by the CUDA back-end. The performance of all architectures lies around 20% of the theoretical peak performance. This shows that a single Alpaka kernel using all levels of the abstraction model together with optimized data access patterns is able to provide performance portability over various architectures.

### 4.3 Real World Example

HASEonGPU is an open-source adaptive massively parallel multi-GPU Monte Carlo integration algorithm for computing the amplified spontaneous emission (ASE) flux in laser gain media pumped by pulsed lasers\textsuperscript{14}.

The source code consists of about ten thousand lines of code and has been ported in three weeks by one person to Alpaka (HASEonAlpaka). After the porting has been finished, HASEonAlpaka has successfully been executed on GPU and CPU clusters.

Figure 10 shows the relative speed of a HASEonAlpaka computation executed with identical parameters on different systems. The original native CUDA version is used as the basis for comparison. The Alpaka version using the CUDA back-end running on the same NVIDIA K20 GK110 cluster as the native version does not show any overhead at all leading to identical execution times.

\textsuperscript{14}https://github.com/ComputationalRadiationPhysics/haseongpu
Figure 9: Performance of the Alpaka kernel executed on various architectures relative to the theoretical peak performance of the corresponding architecture. The Alpaka kernel provides about 20% relative peak performance on all measured architectures.

On the Intel Xeon E5-2630v3 and AMD Opteron 6276 clusters the OpenMP 2 back-end without support for the not required thread level parallelism is used, i.e each block contains exactly one thread computing multiple elements. This perfectly maps to the CPUs capabilities for independent vectorized parallelism and leads to very good results. The nearly doubled time to solution on both, the Intel and AMD clusters, is on par with the halved double precision peak performance of those systems relative to the NVIDIA cluster used as reference.

Figure 10: HASEonGPU was ported to Alpaka within three weeks by one person. The application shows almost perfect performance portability on all evaluated platforms.

5 Conclusion

We have presented the abstract C++ interface Alpaka and its implementations for parallel kernel execution across multiple hierarchy levels on a single compute node. We have demonstrated platform and performance portability for all studied use cases. A single source Alpaka DGEMM implementation provides consistently 20% of the theoretical peak performance on AMD, Intel and NVIDIA hardware, being on par with the respective native implementations. Moreover, performance measurements of a real world application translated to Alpaka unanimously demonstrated that Alpaka can be used to write performance portable code.

Performance portability, maintainability, sustainability and testability were reached through the usage of C++ metaprogramming techniques abstracting the variations in the underlying architectures. Alpaka code is sustainable, optimizable and easily extendable to support even more architectures through the use of C++ template specialization. It is data structure agnostic and provides a simple pointer based memory model that requires explicit deep copies between memory levels.

Future work will focus on including more Alpaka back-ends, e.g. for OpenACC and OpenMP 4.x target offloading and studying performance portability for additional architectures (e.g Intel Xeon Phi and OpenPower) and applications.

Alpaka is an open-source project and available in our GitHub repository15.
