Abstract—To recover simultaneous multiple failures in erasure coded storage systems, Patrick Lee *et al* introduce concurrent repair based minimal storage regenerating codes to reduce repair traffic. The architecture of this approach is simpler and more practical than that of the cooperative mechanism in non-fully distributed environment, hence this paper unifies such class of regenerating codes as concurrent regenerating codes and further studies its characteristics by analyzing cut-based information flow graph in the multiple-node recovery model. We present a general storage-bandwidth tradeoff and give closed-form expressions for the points on the curve, including concurrent repair mechanism based on minimal bandwidth regenerating codes. We show that the general concurrent regenerating codes can be constructed by reforming the existing single-node regenerating codes or multiple-node cooperative regenerating codes. Moreover, a connection to strong-MDS is also analyzed.

On the other respect, the application of RGC is hardly limited to "repairing". It is of great significance for "scaling", a scenario where we need to increase(decrease) nodes to upgrade(degrade) redundancy and reliability. Thus, by clarifying the similarities and differences, we integrate them into a unified model to adjust to the dynamic storage network.

Index Terms—distributed storage system, regenerating codes, cooperative, concurrent, cut-set flow graph, multiple failures

I. INTRODUCTION

With the scale of distributed storage system (DSS) growing, component (e.g., disk, server or rack) failures due to various reasons become normal events, driving redundant strategy to provide fault-tolerance reliability. Replication is a simple way used in most systems, such as GFS [1], HDFS [2] and S3 [3], where triple copies are dispersed across different nodes. In general, $m + 1$ copies are needed to tolerant m failures, which is a high cost of storage. Due to the lower storage cost but higher reliability than simple replication, erasure codes become popular in new generation DSS, such as Cleversafe [4], GFS2 [5] and HDFS-RAID [6]. However, it is a disadvantage of erasure codes to repair failure nodes in a precious bandwidth environment. For instance, we divide an original file, with a size of B , into k pieces, encode them into n pieces and distribute the coded pieces to n storage nodes, each of which stores $\frac{B}{k}$ data. Although the (n, k) maximum distance separable (MDS) property guarantees that any k out of n nodes can reconstruct the original file, we must download the whole file to recover mere one piece in a replacement node (newcomer) to maintain the system in the same state when there is one node failed.

To reduce the repair traffic, network coding [7] is applied to erasure codes in the premise of keeping MDS property. Reconsider the above example, the $\frac{B}{k}$ data in each piece are further divided into $d - k + 1$ strips, a linear combination of these strips is downloaded from d active nodes (helpers) to recover the lost piece. To some extent, the total repair bandwidth can be reduced to $\frac{Bd}{k(d-k+1)}$ for $d > k$. Using network coding, Dimakis *et al* [8] [9] cast the storage problem as a network multicast problem and clarified the tradeoff between storage and bandwidth. They proposed regenerating codes (RGC) based on the points of the tradeoff curve. The famous codes are the minimal storage regenerating (MSR) codes and minimal bandwidth regenerating (MBR) codes that based on the two extreme points on the curve. Subsequently, varieties of construction of the codes are proposed [10] [11] [12] [13]. A survey launched by Dimakis [14] summarizes the rapid development of RGC. Nevertheless, the researches mainly center on single failure.

In some situation, there might be multiple failures, say $t > 1$ failures. To repair multiple failures, the repair traffic is still rather heavy in the way of conventional process. Thus, it is quite natural to turn to RGC for help. The simplest method is to repair them one by one by using RGC, which can be independently optimal in each recovery. Yet the cumulative traffic is not minimal. Wang *et al.* [15] improved this method by allowing a newcomer to connect to both of the helpers and repaired nodes to complete the whole recovery. It is a multi-loss flexible recovery (MFR) mechanism focusing on minimal storage point. Nevertheless, it is suboptimal in contrast with cooperative RGC [16] [17], which can minimize this traffic by further mutually exchanging information among t repaired nodes after each node downloads data from original helpers. Both the original traffic from helpers to newcomers and the coordinate traffic among repaired nodes are taken into consideration. Kermarrec *et al.* [18] went beyond these work and proposed adaptive regenerating codes. Shum and Hu [19] exhaustively presented the storage-bandwidth tradeoff, on the curve of which are the two extreme points that respectively correspond to minimal-storage cooperative regenerating (MSCR) codes and minimal bandwidth cooperative regenerating (MBCR) codes. Explicit constructions of MBCR are proposed in [20] and that of MSCR with different parameters in [21] [22].

However, the disadvantages of cooperative RGC mainly are:

- 1 In each regeneration period, every newcomer needs to communicate with d helpers in the first phase and $t - 1$ other newcomers in the second phase. We treat the information channel between two nodes as link. Logically, the system need to maintain totally about $td + t(t - 1)/2$ links.
- 2 The data sent out to other newcomers at the second phase cannot be generated until the newcomer receives all the data from d helpers. Meanwhile, the final recovered data cannot be generated until the newcomer receives all the data from other $t - 1$ newcomers. These processes need high synchronization and consistency.
- 3 For this mechanism is highly coupled, one minor error in a phase would lead to the failure of the whole repair.

The application of cooperative RGC requires a fully decentralized network. The way of "teamwork" for repair highly depends on the cooperation of other members, then the codes have limitations (e.g., robustness, consistency and management problems) in some environments, such as the centralized-management datacenters. Therefore, we need a more appropriate method for repairing multiple failures in non-fully distributed network.

In fact, Li *et al.* [23] [24] developed a distributed storage system, the CORE, based on MSR codes. It introduces a concurrent repair framework for both single and multiple failures. The repair process in CORE is that the engine collects data from d helpers, regenerates all the lost data and then disperse them into newcomers. Similar to conventional erasure coded system, CORE only considers the traffic that help to recover the whole lost data and ignore the retransmitted traffic of recovered data to distributed nodes. The framework reserves the advantages of erasure codes so that it can be easily accepted and deployed in the mainstream systems, such as HDFS-RAID [25].

Nevertheless, the authors only focus on the minimal storage point and prefer the system design to theoretical analysis. In this paper, we further study this mechanism, analyze its cut-based information flow graph and give the closed-form expressions for the points on the storage-bandwidth tradeoff curve. Moreover, CORE used *virtual nodes* to prove the possibility of multiple repair and showed the bad failure pattern that can not be repaired. We disproves the existence of bad failure pattern. Meanwhile, we build a connection to strong-MDS properties proposed in [16] when $t = k$.

On the other respect, DSS provides both huge storage volume for magnanimity information and parallel services for billions of intensive accesses [26]. Apart from ensuring no information lost, the system needs to adjust the redundancy of data according to the change of workload. For example, when new software is released, software company might distribute as many copies as possible to cope with the outburst downloading, regardless of using cache or disk. When the hot degree of the information goes down, it merely keep few ones for the normal downloading. Thus, flexibility is of the same importance as reliability for content delivery network (CDN) and information centric network (ICN) [27]. Based

on the same perspective that replication means more resource and energy consuming, we study the role of erasure codes (EC) in scalability. For instance, we upgrade (n, k) codes into $(n + 3, k)$ codes to store more data pieces. Thus, similar problems crop up because of large upgrade bandwidth if the original file is invalid. Since the flexibility of multicast in turn implies the scalability of storage, we extract potential value of RGC and initially represent its fetching characteristics in scalability. The second result in this paper is that we extend the functional RGC for upgrade and clarify the difference between repair and upgrade.

The remainders of this paper are organized as follows: in section II we present preliminary background and related work about failure repair in erasure codes DSS. In section III we analyze cut-based information flow graph in a concurrent model and give closed-form expressions for the points on the tradeoff curve. We also present how to construct concurrent regenerating codes by using existing approaches and prove the pervasive strong-MDS property. The second contribution of this paper is presented in section IV. We give our conclusion in section V. We summer the notation in table I.

TABLE I: Summary of key notations

Notation	Meaning
B	The size of the source file.
n	The total number of storage nodes.
k	The minimal number of nodes for reconstruction.
d	The total number of helpers.
\mathbf{h}	The d -length capacity vector for upgrade.
k^*	The flexible k for strong-MDS property.
\mathbf{c}^*	The k^* -length capacity vector for reconstruction.
t	The number of nodes repair concurrently.
s	The number of extended nodes for upgrading (n, k) to $(n + s, k)$ MDS codes.
α	Storage per node.
β	Repair/upgrade bandwidth from each helper.
γ	The total repair/upgrade bandwidth.
λ	The number of links built in a repair/upgrade scenario.

II. PRELIMINARY BACKGROUND AND RELATED WORK

A. Regenerating Code for Single Failure

By casting the storage problem as a multicast communication problem, Dimakis *et al.* [8] [9] analyzed the cut-based information flow graph for single failure.

Lemma 1. (Mincuts of Information Flow Graphs in Single Repair Model [9]): Consider the information flow graph $\mathcal{G}(n, k, d, \alpha, \beta)$ formed by n initial nodes connecting to a virtual source (VS) and obtaining α units data. The additional nodes join the graph by connecting to d existing nodes, obtaining β units from each and storing α units data per node. A data collector (DC) can connect to arbitrary k -node subset of \mathcal{G} to reconstruct the original file, which must satisfy:

$$\text{mincut}(VS, DC) \geq \sum_{i=0}^{\min(d,k)-1} \min\{(d-i)\beta, \alpha\} \quad (1)$$

TABLE II: Cut-set bound of information flow graph in erasure coded system

type	closed-form expression	reference
single repair	$\sum_{i=0}^{\min(d,k)-1} \min\{(d-i)\beta, \alpha\}$	[9]
cooperative multiple repair	$\min_{\mathbf{u} \in P} (\sum_{i=0}^{g-1} u_i \min(\alpha, (d - \sum_{j=0}^{i-1} u_j)\beta_1 + (t - u_i)\beta_2))$	[17] [19]
concurrent multiple repair	$\min_{\mathbf{u} \in P} (\sum_{i=0}^{g-1} \min(u_i\alpha, (d - \sum_{j=0}^{i-1} u_j)\beta))$	this paper

We call the *capability* of graph \mathcal{G}^*

$$C(\mathcal{G}^*) \triangleq \sum_{i=0}^{\min(d,k)-1} \min\{(d-i)\beta, \alpha\}.$$

To guarantee that the collector can reconstruct the origin file, the necessary condition is $C(\mathcal{G}^*) \geq B$, which drives the tradeoff between storage α and repair bandwidth $\gamma = d\beta$. Thus, the codes that can achieve every point on this optimal tradeoff curve are called regenerating codes (RGC). Specially, the two extreme points of this bound are greatly practical in real systems, namely, minimum storage regenerating (MSR) codes:

$$(\alpha_{MSR}, \gamma_{MSR}) = \left(\frac{B}{k}, \frac{Bd}{k(d-k+1)} \right) \quad (2)$$

and minimum bandwidth regenerating (MBR) codes:

$$(\alpha_{MBR}, \gamma_{MBR}) = \left(\frac{2Bd}{k(2d-k+1)}, \frac{2Bd}{k(2d-k+1)} \right). \quad (3)$$

In repair situation, the range of d is subject to

$$k \leq d \leq n-1 \quad (4)$$

when $d = n-1$, repair bandwidth of both MSR and MBR gets minimal.

According to whether the repaired information is exactly the pre-lost data, there are mainly three repair models based on the two codes: *exact repair*, *functional repair* and *exact repair of systematic parts* [14]. Functional repair mainly uses random linear network coding technology under proper finite field [12]. In addition to matrix product (PM) [10] construction for both exact MSR ($n \geq 2k-1$) and exact MSR, there are mainly interference alignment (IA) [11] construction for MSR ($n \geq 2k-1$) and repair-by-transfer [28] mechanism for MBR.

Note that the interior points on the tradeoff are impossible for exact repair [28] and hardly significant for functional repair because of involving more variable parameters, only MSR and MBR are taken into account in practical system.

B. Cooperative Regenerating Codes for Multiple Failure

Due to the salient feature of minimizing repair traffic for single failure, it is natural to apply RGC step by step to repair multiple failure. However, although the traffic is optimal for each step, the cumulative traffic is not optimal. To improve this strategy, a MFR [15] mechanism is proposed on the minimal storage point. The t replacement nodes are denoted as sequence y_1, \dots, y_t and then y_i can download data from any available nodes, including active original nodes and other

repaired newcomers, e.g., $y_j, j < i$. Suppose there are d_i helpers for repairing y_i , the lower bound of the total repair traffic is

$$\sum_{i=1}^t \frac{Bd_i}{k(d_i - k + 1)} \quad (5)$$

In the practical code construction, we split the original file into mk packets, where m is the Least Common Multiple (LCM), namely $m = LCM(d-k+1, \dots, d-k+t)$. Whereas, MFR inefficiently uses the help of newcomers since the later repaired newcomers have no contribution to the former ones, e.g., y_j cannot download data from y_i for $j > i$. Hence, the optimal way is to sufficiently exchange information between these newcomers, which is just the achievement of the cooperative regenerating codes [16] [17] [18] [19]. In the first phase, each newcomer connects to d active helpers and downloads β_1 unit data from each helper. In the second phase, each newcomer exchanges β_2 unit with other $t-1$ newcomers.

The cut analysis of information flow graph for cooperative repair drives the following lemma:

Lemma 2. (Mincuts of Information Flow Graphs in Cooperative Multiple Repair Model [18]): Consider the information flow graph $\mathcal{G}(n, k, d, \alpha, \beta, t)$ formed by n initial nodes connecting to a virtual source (VS) and obtain α units data. The additional nodes join the graph in group of t nodes by connecting to d existing nodes, obtaining β_1 units from each existing node and β_2 units from other $t-1$ joining nodes and storing α units data per node. A data collector (DC) can connect to arbitrary k -node subset of \mathcal{G} to reconstruct the original file, which must satisfy:

$$\text{mincut}(VS, DC) \geq \min_{\mathbf{u} \in P} \left(\sum_{i=0}^{g-1} u_i \min(\alpha, (d - \sum_{j=0}^{i-1} u_j)\beta_1 + (t - u_i)\beta_2) \right) \quad (6)$$

where $\mathbf{u} = [u_i]_{1 \times g}$, $\sum_{i=0}^{g-1} u_i = k$, $1 \leq u_i \leq t$, $\lceil \frac{k}{t} \rceil \leq g \leq k$, and P is set of all possible \mathbf{u} . Set $\sum_{j=0}^{-1} u_j = 0$.

In [17] [19], the *capability* of the flow graph is simplified into

$$C(\mathcal{G}^*) \triangleq u_0\alpha + \sum_{i=0}^{g-1} u_i \left((d - \sum_{j=0}^{i-1} u_j)\beta_1 + (t - u_i)\beta_2 \right).$$

Then, for $i = 0, \dots, g-1$, the storage-bandwidth tradeoff is

$$\alpha = \frac{B(d-k+t(i+1))}{D_i} \quad (7)$$

$$\gamma = \frac{Bt(d+t-1)}{D_i} \quad (8)$$

where

$$D_i = k(d+t(i+1)-k) - \frac{i(i+1)t^2}{2} \quad (9)$$

The two extreme points on this tradeoff curve are respectively minimal storage cooperative regenerating (MSCR) point and minimal bandwidth cooperative regenerating (MBCR) point. For MSCR,

$$(\alpha_{MSCR}, \gamma_{MSCR}) = \left(\frac{B}{k}, \frac{Bt(d+t-1)}{k(d-k+t)} \right) \quad (10)$$

For MBCR,

$$(\alpha_{MBCR}, \gamma_{MBCR}) = \left(\frac{B(2d+t-1)}{k(2d+t-k)}, \frac{Bt(2d+t-1)}{k(2d+t-k)} \right) \quad (11)$$

In the same literature [19], Shum, K.W. *et al.* proposed the functional construction of the two codes based on linear network coding. The explicit product-matrix based constructions of exact MBCR and exact MSCR are proposed in [20] and in [22] respectively. Similarly, Chen *et al.* [21] introduce the interference alignment to MSCR.

Cooperative repair can be adopted in a regular distributed and robust network. However, due to the shortcomings would complicate the management, the benefits of this approach may be outweighed by its drawbacks in the real systems, like the huge computer cluster of GFS2.

C. Concurrent Repair Mechanism

Li *et al.* separately realize related application in NCFS [29], NCCloud [30] and CORE [23]. NCFS presented its bandwidth saving for single repair under same tolerant nodes as Reed-Solomon codes, NCCloud shifts NCFS in cloud storage and shows functional MSR can minimize both repair bandwidth and I/O in archive (cold) data storage. Based on the previous work of NCFS and NCCloud, CORE supports both single and multiple failure repair. In CORE, the authors proposed a concurrent repair mechanism. When t nodes fail, an engine starts to download γ data from d available nodes and then dispatch recovered data to newcomers, the lower bound of repair bandwidth is:

$$\gamma = \begin{cases} \frac{Btd}{k(d+t-k)} & t < k, \\ B & t \geq k. \end{cases} \quad (12)$$

where $\alpha = \frac{B}{k}$. For conventional erasure coded storage system, once the number of failure reaches a certain threshold, a daemon starts to collect B data, re-encode t pieces and then dispatch them into t replacement nodes. In this way, only the "collect" bandwidth is treated as the actual network cost. So the traffic from the engine to the newcomers has no contribution to γ in this framework. Namely, if the engine runs in one newcomer, the traffic among t newcomers (i.e., the bandwidth of the second phase in cooperative repair) is ignored.

Apart from the minimal storage point, a closer study of con-

current repair mechanism is necessary because of its practical applications. We present a similar storage-bandwidth tradeoff based on the cut analysis of information flow graph.

III. CONCURRENT REGENERATING CODES

A. A Cut-set Bound Analysis

We analyze the cut of the information flow graph and find a lower bound of bandwidth for generating multiple nodes in the concurrent repair as CORE. By referring the procedure of literature [18], we have the following theory.

Theorem 1. Denote the information flow graph as $\mathbf{G}(n, k, d, \alpha, \beta, t)$ formed by n initial nodes connecting to a virtual source (VS) and obtaining α units data. There are t newcomers connecting to a virtual daemon (VD) and storing α units data for each. The virtual daemon connect to d existing nodes and obtaining β units from each. Any data connector (DC) can connect to any k -subset of nodes of G must satisfy

$$\text{mincut}(VS, DC) \geq \min_{\mathbf{u} \in P} \left(\sum_{i=0}^{g-1} \min(u_i \alpha, (d - \sum_{j=0}^{i-1} u_j) \beta) \right) \quad (13)$$

with $P = \{\mathbf{u} = [u_i]_{1 \times g} \mid \sum_{i=0}^{g-1} u_i = k, 1 \leq u_i \leq t\}$.

Proof: In the graph illustrated in figure 1, there are initially n nodes labeled from 1 to n connecting to virtual source VS with each edge capacity of α . At time stage i , a virtual daemon labeled as VD_i is used to generate t newcomers labeled as x_1^i, \dots, x_t^i , each of which connects to VD_i with edge capacity of α . We call these nodes the children of VD_i .

To recover the whole file, a data collector labeled as DC collects data from any k -node subset of the whole active nodes, denoted as U . Suppose DC selects u_i children of VD_i (the corresponding set is U_i) and there are g group of children to construct U . Let $I = \{0, \dots, g-1\}$ denote the set of group labels. Then, a recovery scenario is defined as a sequence $\mathbf{u} = [u_i, i \in I, 1 \leq |U_i| = u_i \leq t$ and $\sum_{i=1}^g u_i = k, \lceil \frac{k}{t} \rceil \leq g \leq k, U = \bigcup_{i=1}^g U_i$. Also, let P be the set of all the recovery scenarios.

For each regenerating process, the daemon node VD_i connects to d helpers. One part of the helpers is composed of $\sum_{j=0}^{i-1} v_j$ newcomers, where v_j is the number of selected children of $VD_j, j = \{0, \dots, i-1\}$, and the other part is composed of $d - \sum_{j=0}^{i-1} v_j (> 0)$ initial nodes. Thus, sequence v_0, \dots, v_{g-1} constructs a regenerating scenario $\mathbf{v} = [v_i, i \in I, 1 \leq v_i \leq t$. Let V_i be the corresponding set of v_i helpers, then $V = \bigcup V_i$. Also, let Q be the set of such scenarios. Since the number of generating stage is unlimited while recovery scenario is constrained by g groups, only considering the same number of groups for regenerating scenarios can be enough analyzing the min-cut. In other words, we have

$$\forall \mathbf{u} \in P, \exists \mathbf{v} \in Q \rightarrow \mathbf{u} = \mathbf{v}. \quad (14)$$

Note that in both scenarios we have $j < i$, for nodes of the i -th stage cannot depend on nodes considered at j -th stage with $j > i$.

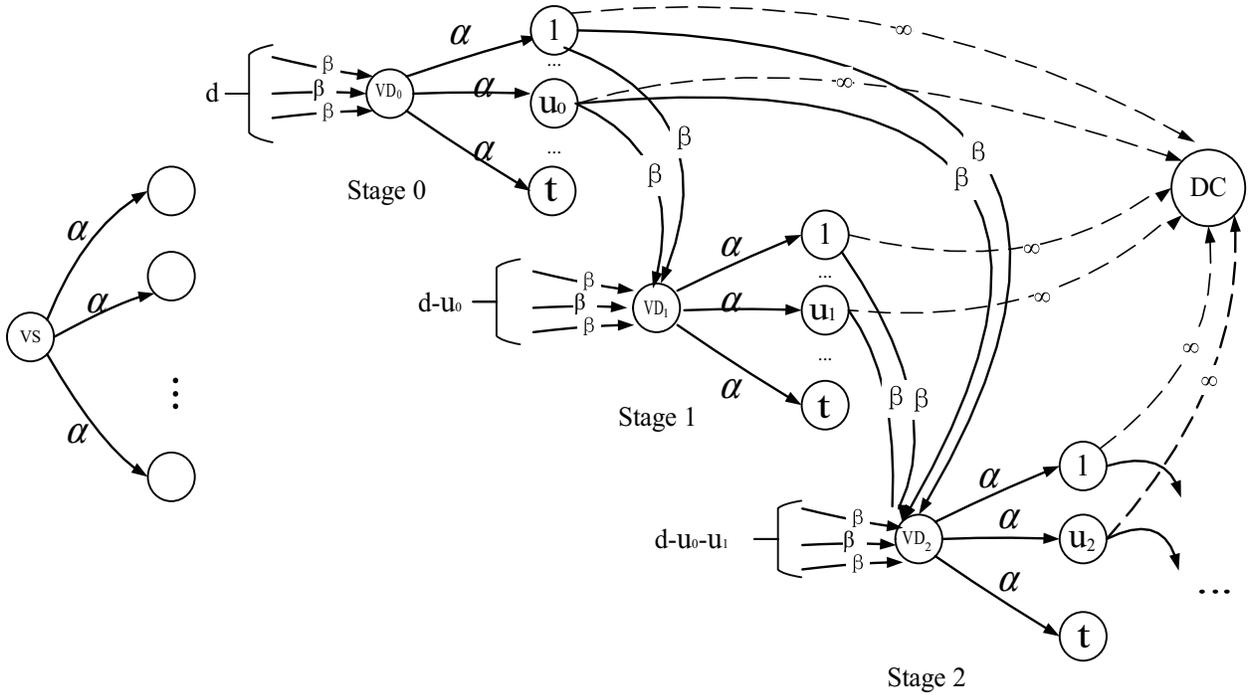

Fig. 1: The information graph $G(n, k, d, \alpha, \beta, t)$ of concurrent repair mechanism

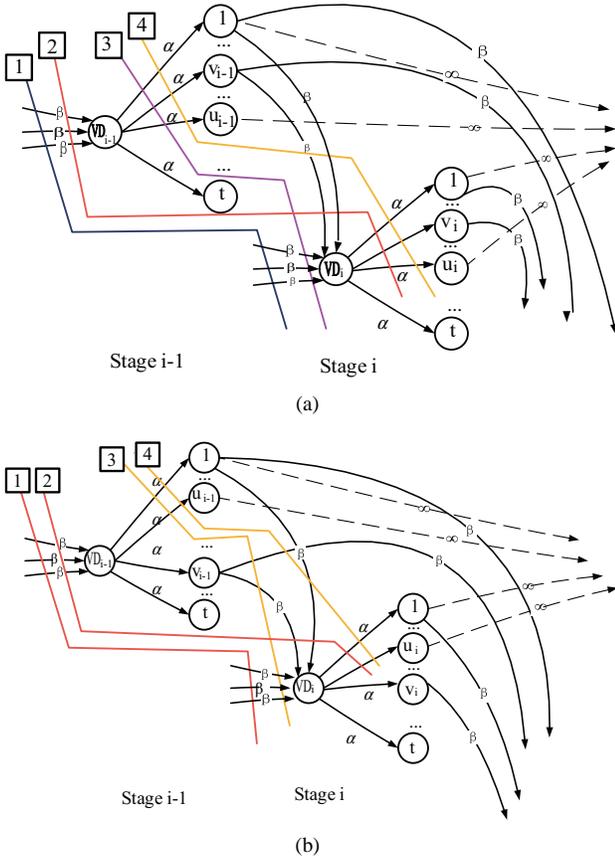

Fig. 2: The two cases of cut at stage i . (a) case (i) (b) case (ii).

Moreover, we denote the intersection of helper set and generating set on the i -th stage as $L_i = U_i \cap V_i$ with size of $\ell_i = |L_i|$.

For a regenerating scenario $\mathbf{v} \in Q$ and a recovery scenario $\mathbf{u} \in P$, we consider the min-cuts (A, \bar{A}) with $VS \in A$ and $U \subset \bar{A}$.

Let \mathcal{C} denote the edges in the cut. Firstly, consider the \mathcal{C} on the i -th stage, denoted as \mathcal{C}_i . If $VD_i \in A$, then the edges $VD_i \rightarrow x_j^i \in \mathcal{C}_i$, where $j \in U_i$, each with capacity of α .

If $VD_i \in \bar{A}$, there are two cases to be considered.

- (i) As illustrated in figure 2(a), if $\forall j < i, VD_j \in \bar{A}$, then the $d - \sum_{j=0}^{i-1} v_j$ edges from initial node are in \mathcal{C}_i , each with capacity of β .
- (ii) In figure 2(b), if $\exists S \subset \{0, \dots, i-1\}, VD_{j:j \in S} \in A$, both the $d - \sum_{j=0}^{i-1} v_j$ edges from initial node and $\sum_{j \in S} (v_j - \ell_j)$ edges from $\bigcup_{j \in S} (V_j/L_j)$ are in \mathcal{C} , each with capacity of β , since there are edges from children of $VD_s \in S$ to VD_i .

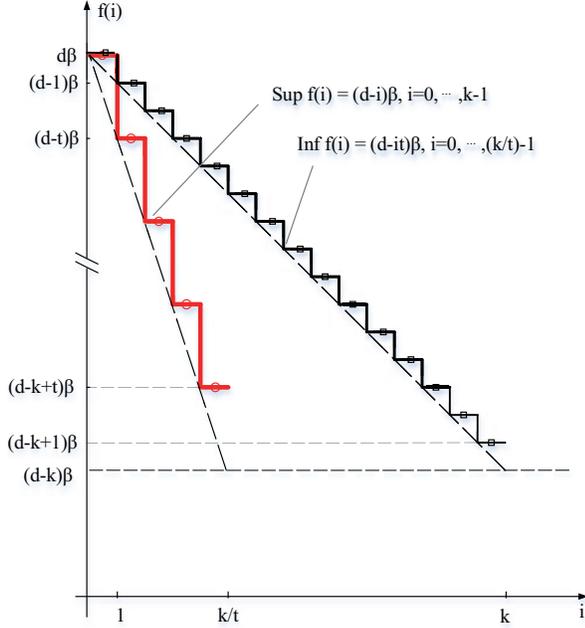

Therefore, the minimal value of \mathcal{C}_i is

$$\min \mathcal{C}_i = \min(u_i \alpha, c_i) \quad (15)$$

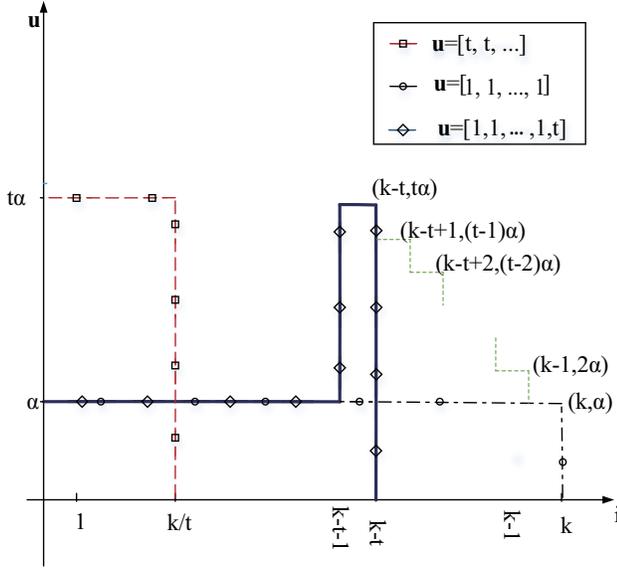

where

$$c_i = \begin{cases} (d - \sum_{j=0}^{i-1} v_j) \beta, & \text{case (i)} \quad (16) \\ (d - \sum_{j=0}^{i-1} v_j + \bigcup_{j \in S} (v_j - \ell_j)) \beta, & \text{case (ii)} \quad (17) \end{cases}$$

Since $\forall j \geq 0, \ell_j \leq v_j$ and when $V_j \subset U_j$ the cut of case (ii) reach the same minimal value as case (ii), then $v_i \leq u_i$ on the

(a)

(b)

Fig. 3: The stair function $f(i)$ and $g(i)$ under different \mathbf{u} . (a) The lower and upper bound of $f(i)$. (b) three examples of $g(i)$

TABLE III: partitions of integer $k=7$ when $t=3$

g	\mathbf{u}	number of cases
7	[1,1,1,1,1,1,1]	1
6	[2,1,1,1,1,1]	6
5	[3,1,1,1,1];[2,2,1,1,1]	15
4	[2,2,2,1];[3,2,1,1]	16
3	[2,2,3];[3,3,1]	6

i -th stage. Refer to (14), we need to maximize v_i to minimize

c_i for all the regenerating scenarios under a recovery scenario. Thus if $u_i = v_i$ or $U_j = V_j$, (15) can be rewritten as

$$\min C_i = \min(u_i \alpha, (d - \sum_{j=0}^{i-1} u_j) \beta). \quad (18)$$

Finally, we have min-cut of \mathcal{C} under certain recovery scenario

$$\min \mathcal{C} = \sum_{i=0}^{g-1} \min C_i = \sum_{i=0}^{g-1} \min(u_i \alpha, (d - \sum_{j=0}^{i-1} u_j) \beta) \quad (19)$$

If $\forall \mathbf{u} \in P$, the minimal value of (19) is just the min-cut of (VS, DC). Hence the claim follows. ■

B. The Storage-bandwidth Tradeoff

Next, we need to find the similar tradeoff between storage and bandwidth. With the same assumption as [9], an valid generation must satisfy

$$\hat{C} \triangleq \min_{\mathbf{u} \in P} \sum_{i=0}^{g-1} \min(u_i \alpha, (d - \sum_{j=0}^{i-1} u_j) \beta) \geq B. \quad (20)$$

where \hat{C} denotes the *capacity* of $\mathbf{G}(n, k, d, \alpha, \beta, t)$.

Note that single node repair is a special situation of (20) when $t = 1$, for there is only one recovery scenario, $\mathbf{u} = [1]_{1 \times k}$. Hereinafter, we assume $t > 1$ if there is no special specification. Firstly, it is easy to compute (19) under a certain \mathbf{u} while hard to find the minimal one under all the \mathbf{u} . Since the total number of recovery scenarios grows exponentially as t growing, which is, in fact, an integer composition problem that satisfies $\sum_{i=0}^{g-1} u_i = k$ and subjects to $1 \leq u_i \leq t$. As a example in table III, we enumerate all the possible compositions of \mathbf{u} when $k = 7$ and $t = 3$. To be simple, the second column of table only illustrates all the partitions (composition is an order matter of partition) of \mathbf{u} and the third column list the number of corresponding compositions. Therefore, it is unpractical to check every compositions. Then we have the following theorem:

Theorem 2. *the capacity of $\mathbf{G}(n, k, d, \alpha, \beta, t)$ is minimal if and only if the composition of k is*

$$\mathbf{u} = \begin{cases} [t, \dots, t]_{1 \times g} & t \mid k, \\ [k - \lfloor \frac{k}{t} \rfloor t, t, \dots, t]_{1 \times g} & t \nmid k. \end{cases} \quad (21)$$

Proof: Consider the function $f(i) = (d - \sum_{j=0}^{i-1} u_j) \beta$ and $g(i) = u_i \alpha$, $0 \leq i \leq g - 1$. Define set $Y = \{u_i | g(i) \geq f(i), i \in I\}$ and $\bar{Y} = \{u_i | g(i) < f(i), i \in I\}$. Suppose $t \mid k$, when \mathbf{u} take the value of (21), we can obtain the lower bound of $f(i)$

$$\inf f(i) = (d - it) \beta$$

when $\mathbf{u} = [1]_{1 \times k}$, the upper bound is

$$\sup f(i) = (d - i) \beta.$$

As illustrated in figure 3(a), for all the other kinds of \mathbf{u} , $f(i)$ locates between the two bound. Here we use a stair function to

describe $f(i)$ since the area closed by i -axis, vertical axis, $f(i)$ and $i = g-1$ equals to \widehat{C} when $Y = \emptyset$. Note that $\inf f(i)$ make the area minimal. On the other respect, function $g(i) = u_i\alpha$ with $\mathbf{u} = [t, t, \dots]$ and $\mathbf{u} = [1, 1, \dots]$ is depicted in figure 3(b). When $Y = \emptyset$, the similar closed area reflects the value of \widehat{C} . Note that the area closed purely by arbitrary $g(i)$ equals to $k\alpha$.

We assume that β is fixed and α is variable and merge the two function into the same coordinate system. Then \widehat{C} equals to the intersection area closed by i -axis, vertical axis, $\min(g(i), f(i))$ and $i = g-1$ for all the situations of Y . Because $\inf f(i)$ make the minimal area, thus we only scale $g(i)$ with the same \mathbf{u} as $\inf f(i)$ to find minimal \widehat{C} among all $\mathbf{u} \in P$.

Suppose $t \nmid k$ and $k - \lfloor \frac{k}{t} \rfloor t = r$. From the analysis of first part, we know the minimal area is achieved if g is maximal. Thus, we only consider the permutation of $\mathbf{u} = [r, t, \dots, t]_{1 \times g}$. For $d\beta \geq t\alpha$ and $r\alpha$ is the smallest area that contribute to $\min(g(i), f(i))$, there is only one possibility for minimizing bandwidth if there exist $Y = \{u_i | t\alpha \geq g(i)\}$. Thus, let $\min \mathcal{C}_0 = \min(r\alpha, d\beta) = r\alpha$, \widehat{C} can be minimized as the change of α . In this way, $\inf f(i) = (d' - it)\beta = (d - r - it)\beta, i = 1, \dots, g-1$. ■

The following examples present the minimal capacity:

Example 1. Consider

$$n = 14, k = 6, d = 10, t = 3,$$

$$C^* = \min(3\alpha, d\beta) + \min(3\alpha, (d-t)\beta)$$

$$C^* = \begin{cases} 6\alpha, & \alpha \in (0, \frac{7}{3}\beta] \\ 3\alpha + 7\beta, & \alpha \in (\frac{7}{3}\beta, \frac{10}{3}\beta] \\ 17\beta & \alpha \in (\frac{10}{3}\beta, +\infty) \end{cases}$$

Example 2. Consider

$$n = 14, k = 7, d = 10, t = 3,$$

$$C^* = \min(\alpha, d\beta) + \min(3\alpha, (d-1)\beta) + \min(3\alpha, (d-t-1)\beta)$$

$$C^* = \begin{cases} 7\alpha, & \alpha \in (0, \frac{6}{3}\beta] \\ 4\alpha + 6\beta, & \alpha \in (\frac{6}{3}\beta, \frac{9}{3}\beta] \\ \alpha + 15\beta, & \alpha \in (\frac{9}{3}\beta, 10\beta] \\ 21\beta, & \alpha \in (10\beta, +\infty) \end{cases}$$

To simplify notation, introduce $b_i = \inf f(i)$, we have the general form:

$$C_* = \begin{cases} k\alpha & \alpha \in [0, \frac{b_{g-1}}{t}] \\ (k-t)\alpha + b_{g-1} & \alpha \in (\frac{b_{g-1}}{t}, \frac{b_{g-2}}{t}] \\ \vdots & \vdots \\ (k-(g-1)t)\alpha + \sum_{j=1}^{g-1} b_j & \alpha \in (\frac{b_1}{t}, \frac{b_0}{k-(g-1)t}] \\ b_0 + b_1 + \dots + b_{g-1} & \alpha \in (\frac{b_0}{k-(g-1)t}, +\infty) \end{cases} \quad (22)$$

Suppose the minimal α^* such that $C_* = B$ and $B \leq b_0 + b_1 +$

$\dots + b_{g-1}$, then

$$\alpha_* = \begin{cases} \frac{B}{k} & B \in [0, \frac{kb_{g-1}}{t}] \\ \frac{B-b_{g-1}}{k-t} & B \in (\frac{kb_{g-1}}{t}, \frac{(k-t)b_{g-2}}{t} + b_{g-1}] \\ \vdots & \vdots \\ \frac{B-\sum_{j=1}^{g-1} b_j}{k-(g-1)t} & B \in (\frac{(k-(g-1)t)b_1}{t} + \sum_{j=1}^{g-1} b_j, \sum_{j=0}^{g-1} b_j] \end{cases} \quad (23)$$

Let $\beta = \frac{\gamma}{d}$, for $i = 1, \dots, g-1$,

$$\begin{aligned} \sum_{j=g-i}^{g-1} b_j &= \sum_{j=g-i}^{g-1} (d-jt)\beta \\ &= [i - \frac{(2g-i-1)it}{2}] \frac{\gamma}{d} \\ &= \frac{[2d - (2g-i-1)t]i}{2d} \gamma \\ &= p(i)\gamma \end{aligned} \quad (24)$$

and

$$\begin{aligned} \frac{(k-it)b_{g-i}}{t} + \sum_{j=g-i}^{g-1} b_j &= \frac{(k-it)(d-(g-i)t)}{t} \beta + p(i)\gamma \\ &= \frac{2k[d - (g-i)t] - i(i-1)t^2}{2td} \gamma \\ &= q(i)\gamma \end{aligned} \quad (25)$$

Thus we have the following storage-bandwidth tradeoff:

$$\alpha_* = \begin{cases} \frac{B}{k} & \gamma \in [\frac{B}{q(i)}, +\infty), \\ \frac{B-p(i)\gamma}{k-it} & \gamma \in [\frac{B}{q(i+1)}, \frac{B}{q(i)}]. \end{cases} \quad (26)$$

where

$$p(i) = \frac{[2d - (2g-i-1)t]i}{2d}, \quad (27)$$

$$q(i) = \frac{2k[d - (g-i)t] - i(i-1)t^2}{2td}. \quad (28)$$

C. The Two Extreme Points

If $t \mid k$, then $k = gt$ while if $t \nmid k$, let $k = (g-1)t + r$ where $0 < r < t$. Then,

$$q(i) \begin{cases} \frac{k(d-k+t)}{td} & t \mid k, i = 1 \\ \frac{k(d'-k+r+t)}{td} & t \nmid k, i = 2 \end{cases} \quad (29)$$

We can obtain the minimal storage point:

$$(\alpha_{MS}, \gamma_{MS}) = (\frac{B}{k}, \frac{Btd}{k(d-k+t)}) \quad (30)$$

when $i=g-1$,

$$q(i+1) = q(g) = \begin{cases} \frac{k(2d-k+t)}{2td} & t \mid k, \\ \frac{k(2d'-k+2r-t)}{2td} & t \nmid k \end{cases} \quad (31)$$

We can obtain the minimal bandwidth point:

$$(\alpha_{MB}, \gamma_{MB}) = (\frac{2Bd}{k(2d-k+t)}, \frac{2Btd}{k(2d-k+t)}) \quad (32)$$

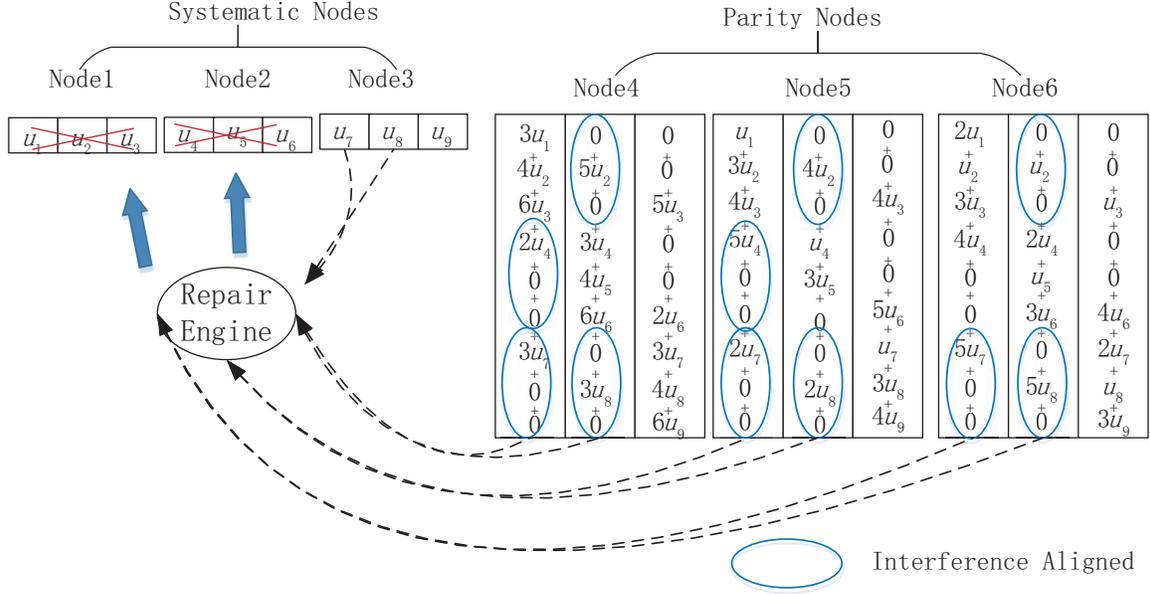

Fig. 4: Example of concurrent repair of $[B=9, n=6, k=3, d=4, t=2]$ code over \mathbb{F}_7 , the single repair example appears in literature [31].

D. Discussion and Simple Code Construction

As can be seen from above expression (9) and (28), if $k = gt$ we have

$$q(i) = \frac{D_{i-1}}{td}, \quad (33)$$

implying that the bandwidth of concurrent repair mechanism have the same bound as that of the first phase of cooperative regenerating code, namely, $t\beta_1 = \beta$.

Although the total bandwidth of cooperative repair is minimized by both β_1 and β_2 , it is impossible to maintain the tradeoff of cooperative RGC by further reducing β_1 and increasing β_2 . Exactly, concurrent repair provides a shared scheme that can be used in non-fully distributed system.

The above mentioned constructions of MSR and MBR can be easily extended for this kind of multiple repair.

As an example of concurrent MSR depicted in figure (4), we can extend interference alignment into multiple failure scenario, especially for exactly repair where $n, k, d+t \geq 2k-1$. Take $[B=9, n=6, k=3, d=4, t=2]$ as an example, we can see the repair engine downloads $\frac{Bt}{k(d-k+t)} = 2$ packets from $d = 4$ nodes and recover the systematic node 1 and 2. That is, by eliminating u_7 and u_8 under the help of node 3, we can obtain the nonsingular coefficient matrix of the 6 variates,

$$A = \begin{bmatrix} 3 & 4 & 6 & 2 & 0 & 0 \\ 0 & 5 & 0 & 3 & 4 & 6 \\ 1 & 3 & 4 & 5 & 0 & 0 \\ 0 & 4 & 0 & 1 & 3 & 4 \\ 2 & 1 & 3 & 4 & 0 & 0 \\ 0 & 1 & 0 & 2 & 1 & 3 \end{bmatrix}.$$

Then we can recover the 6 variates by using its inverse matrix. For more detail, please refer to [31]. The example verifies the

result of literature [21] where $n = d + t = 2k, k \geq 3, t = 2$. The deterministic codes can be found in [22]. By setting $d+t$ as a constant n , [18] propose an adaptive regenerating codes. As t changing, the number of helper $n - t$ is dynamically adjusted to adapt to the current state of the system.

For minimal bandwidth point, [18] figures out that fixed t and d are meaningful for constructing the related codes. Literature [20] shows such explicit codes for $n \geq d + t, d \geq k, t \geq 1$. Comparing with single repair model, the multiple mechanism requires smaller α result in lower storage cost at the minimal bandwidth point [20]. For example, if $n = 19, k = 10, t = 6, d = 13$, then $\alpha = \frac{2dB}{k(2d-k+t)} = 0.118B$, while if $n = 19, k = 10, t = 1, d = 18$ then $\alpha = \frac{2dB}{k(2d-k+1)} = 0.133B$. It can save 12.7% storage space. Similarly, the lazy repair mechanism of Total Recall [32] can be introduced into minimal bandwidth repair as long as we set the threshold equal to proper t [18]. The repetitious details need not be elaborated here.

E. Scalable-MDS Property

Yuchong Hu *et al.* [16] have proposed the concept of (n, k) strong-MDS codes. In detail, a file is divided into $k(n - k)$ packets and encoded into $n(n - k)$ packets. Any $k(n - k)$ packets out of the $n(n - k)$ packets can reconstruct the original file. Namely, let h_i denote the number of packets download from node $i \in \{1, \dots, n\}$. For $0 \leq h_i \leq n - k$, we can reconstruct the original file if $\sum_{i=1}^n h_i = k(n - k)$.

Reconsider our generating model we can find that the whole bandwidth to generate $t = k$ nodes is just B and the data are downloaded from $d (\geq k)$ nodes with each of $\beta = \frac{B}{d}$. Since these $t = k$ generated nodes keep the MDS properties, implying that we can reconstruct the original file by getting

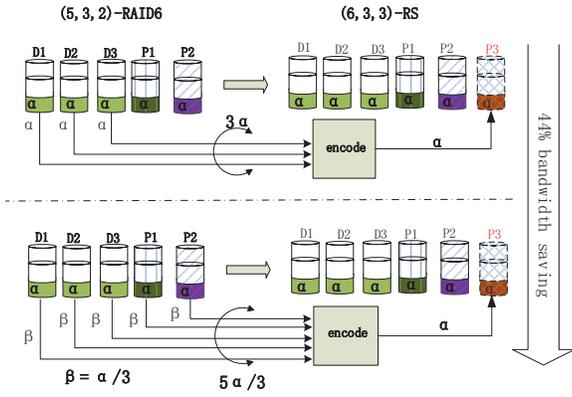

Fig. 5: Upgrade (5,3,2)-RAID6 to (6,3,3)-RS codes by using the idea of regenerating codes

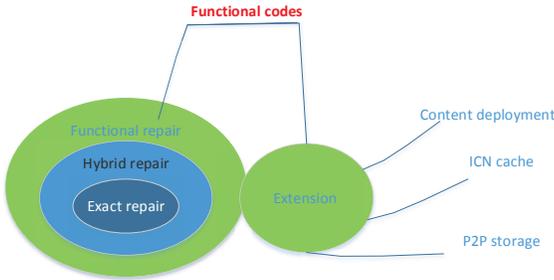

Fig. 6: Expansion of function regenerating codes for scalable application

data not only from k nodes but a flexible d nodes. In this way, we call it the scalable MDS properties, which verifies strong-MDS properties [16].

IV. EXPANSION OF REGENERATING MECHANISM

In this section, a new application of regenerating codes is exploited. Since the (n, k) -MDS property of erasure codes can provide $\binom{n}{k}$ choices for obtaining intact information in a distributed environment and dynamic n can adjust the number of choices according to the popularity of certain information, a flexible system is taken into consideration in next generation networks which pay more attention to information itself, such as content delivery network (CDN) and information centric network (ICN). Hence, regenerating codes can play another role in practical usage besides for archive or cold data storage. For instance depicted in figure 5, we add one parity node to transform RAID6 to RS by using the idea of regenerating codes, which can perform the same bandwidth saving feature as repair. This kind of upgrade adopts functional codes to guarantee the MDS property. In figure 6, we display the expansion. Based on the former analysis that the amount of data stored of minimal bandwidth point relates to n , we only consider the minimal storage point for practice.

A. Upgrade (n, k) to $(n+1, k)$

To add a new storage node to (n, k) is to functionally repair for $(n+1, k)$ erasure codes, where the new node is treated as a virtual node of $(n+1, k)$ codes.

As illustrated in figure 7, we represent the detail for the both repair and extension for $(n=5, k=3)$ -MDS codes by using IA. Because the helper number d is variable, $d_t = 4$ for repair and $d_s = 5$ for extension, we further divide each piece into L segments by referring (2), where $L = LCM(k(d_t - k + 1), k(d_s - k + 1)) = LCM(6, 9) = 18$. Let $B = 18$, then $\alpha = 6$, $\beta_t = 3$, $\beta_s = 2$. Denote $\mathbf{a} = [a_1, \dots, a_6]^t$, $\mathbf{b} = [b_1, \dots, b_6]^t$, $\mathbf{c} = [c_1, \dots, c_6]^t$, where $[\ast]^t$ indicates a transpose. \mathbf{A}_i , \mathbf{B}_i and \mathbf{C}_i are the corresponding $\alpha \times \alpha$ generator submatrices ($i=1,2,3$). In the repair side, each helper provides $\beta_t = 3$ linear combinations of the $\alpha = 6$ segments by multiplying $\alpha \times \beta_t$ repair project vectors \mathbf{p}_j , $j = 1, 2, 3, 4$, i.e., $\mathbf{a}^t \mathbf{p}_1$. In the extension side, each helper provides $\beta_s = 2$ linear combinations of the $\alpha = 6$ segments by multiplying $\alpha \times \beta_d$ extension project vectors \mathbf{q}_j , $j = 1, 2, 3, 4$, i.e., $\mathbf{a}^t \mathbf{q}_1$.

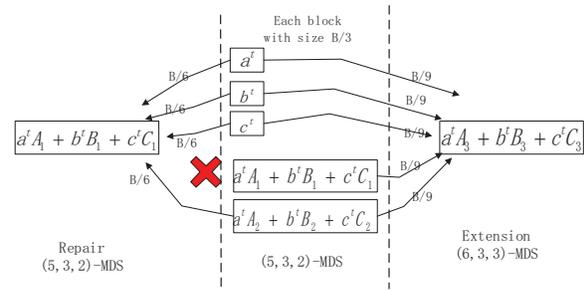

Fig. 7: The example for both repair and extension using regenerating code

B. (n, k) to $(n+s, k)$

So far we have demonstrated that we can download minimal data to construct one new node. Now we focus on whether is available to download more data from d helpers to construct more nodes that have the same MDS property. We unify both repair and scalability in one model. Firstly, we prove the capability achievement of multiple node scenario.

1) *the capability achievement of multiple node repair or upgrade*: Suppose the original file \mathbf{M} can be denoted as a $B \times L$ matrix with each entry defined in finite field \mathbb{F} . That is, file \mathbf{M} consists of B strips, each with size L . For the seek of distributed storage, we divide B into k pieces, each with α strips, and then encode k pieces into n pieces, each with the same number of strips. In practice, we adapt L to make strip as the minimal operation unit. Additionally, we denote $\mathcal{G} = \{G_1, \dots, G_n\}$ as the set of coding matrix in the same finite field, one element G_i of which is a $B \times \alpha$ matrix and specified by α column vectors $\{\mathbf{g}_j^i, j = 1, \dots, \alpha\}$ with dimension B . It is used to obtain one coded piece by $\mathbf{M}^T G_i$. To keep MDS property, namely, to reconstruct the original file \mathbf{M} from any k out of n nodes, say x_1, \dots, x_k , the span of the $k\alpha$ vectors in $\Phi = \{G_{x_1}, \dots, G_{x_k}\}$ should be full rank, which is

$$\text{rank}([G_{x_1}, \dots, G_{x_k}]) = k * \alpha. \quad (34)$$

Suppose a daemon connects to $d \geq k$ helpers, downloads β linear combinations of α strips in each one and re-encode

α strips for each of r newcomers from the whole downloaded $d\beta$ strips. Let $\mathcal{G}^{new} = \{G_1^{new}, \dots, G_r^{new}\}$ as the set of new coding matrices, the whole process can be denoted as the following linear transformation,

$$\begin{bmatrix} G_1^{new} \\ \vdots \\ G_r^{new} \end{bmatrix} = [G_{x_1}P_{x_1}, \dots, G_{x_d}P_{x_d}] \begin{bmatrix} Z^{(1)} \\ \vdots \\ Z^{(r)} \end{bmatrix} \quad (35)$$

where P_{x_w} is the project matrix of size $\alpha \times \beta$ on the w -th node out of d nodes and $Z^{(\ell)}$ is the linear transform matrix of size $d\beta \times \alpha$ for the ℓ -th newcomer. To guarantee MDS property is equivalent to make k out of n (if repair) or $n+s$ (if upgrade) encoding matrix satisfy (34). Thus, a new span Φ^{new} containing $k\alpha$ linear independent vectors arbitrarily selected from \mathcal{G}^{new} and $\mathcal{G}^{old} = \{G_1, \dots, G_T\}$ is constructed, where $T = n - t$ for repair or $T = n$ for upgrade. Then we have the following theorem:

Theorem 3. *Given a scalable MDS code (n, k, d) , the minimal data downloaded from d helpers to generating r newcomers is $\beta \geq \frac{rB}{d-k+r}$, whatever r newcomers are replacement nodes for repair or added nodes for upgrade.*

Proof: The problem exactly is to find the minimal $d\beta$ that makes the matrix $[\Phi^{new}] = [G_{1,k-q}^{old}, G_{1,q}^{new}] = [G_{y_1}, \dots, G_{y_{k-q}}, G_{x_1}^{new}, \dots, G_{x_q}^{new}]$ be full rank, where $0 \leq q \leq r$.

In the beginning, we only take repair scenario into consideration. Without loss of generalization, we let $y_1 = x_1, \dots, y_{k-q} = x_{k-q}$, then the vector format of $[\Phi^{new}]$ is $[\mathbf{g}_1^{x_1}, \dots, \mathbf{g}_\alpha^{x_1}; \dots; \mathbf{g}_1^{x_{k-q}}, \dots, \mathbf{g}_\alpha^{x_{k-q}}; \mathbf{g}_1^{x_1^{new}}, \dots, \mathbf{g}_\alpha^{x_1^{new}}; \dots; \mathbf{g}_1^{x_q^{new}}, \dots, \mathbf{g}_\alpha^{x_q^{new}}]$. We denote $p_{i,j}^{x_w}$ as the i -th row and j -th column element of P_{x_w} and $z_{i,j}^\ell$ as the i -th row and j -th column element of $Z^{(\ell)}$, then,

$$G_{x_w}P_{x_w} = [\sum_{i=1}^\alpha p_{i1}^{x_w} \mathbf{g}_i^{x_w} \quad \dots \quad \sum_{i=1}^\alpha p_{i\beta}^{x_w} \mathbf{g}_i^{x_w}]. \quad (36)$$

and the h -th vector of G_ℓ^{new} is

$$\begin{aligned} \mathbf{g}_h^{x_\ell^{new}} &= \sum_{w=1}^d \sum_{j=1}^\beta \sum_{i=1}^\alpha z_{j+(w-1)\beta, h}^\ell p_{i,j}^{x_w} \mathbf{g}_i^{x_w} \\ &= \sum_{w=1}^d \sum_{i=1}^\alpha f_{i,w,h}^\ell \mathbf{g}_i^{x_w} \end{aligned} \quad (37)$$

where $f_{i,w,h}^\ell = \sum_{j=1}^\beta z_{j+(w-1)\beta, h}^\ell p_{i,j}^{x_w}$, $1 \leq w \leq d$, $1 \leq \ell \leq m$ and $h \in \{1, \dots, \alpha\}$. By using elementary column operations on the matrix $[G_{1,k-q}^{old}, G_{1,q}^{new}]$, we initially update $\mathbf{g}_h^{x_\ell^{new}}$ by

$$\bar{\mathbf{g}}_h^{x_\ell^{new}} = \sum_{w=k-q+1}^k \sum_{i=1}^\alpha f_{i,w,h}^{\prime\ell} \mathbf{g}_i^{x_w}. \quad (38)$$

Due to the symmetrical effect of MDS property, we treat the vectors in Φ as the base vectors and other vectors of $G \notin \Phi$ are the linear combinations of the base vectors. Then

each $\mathbf{g}_i^{x_w}$ in $[G_{x_{k+1}}, \dots, G_{x_d}]$ can be denoted as the linear combination of $k\alpha$ base vectors, $\bar{\mathbf{g}}_h^{x_\ell}$ can also be treated as the new linear combination of the $r\alpha$ different base vector from $[G_{x_{k-q+1}}, \dots, G_{x_k}]$. If we guarantee each element in $[\mathbf{g}_1^{x_1^{new}}, \dots, \mathbf{g}_\alpha^{x_1^{new}}; \dots; \mathbf{g}_1^{x_q^{new}}, \dots, \mathbf{g}_\alpha^{x_q^{new}}]$ contains one non-eliminated base vector by using elementary column operations, the matrix would be full rank. In such way, each of the left $\beta(d-k+q)$ strips derived from $[G_{x_{k-q+1}}, \dots, G_{x_d}]$, if it is useful, at least contributes one mutually different base vector, which implies $q\alpha \leq \beta(d-k+q)$.

For $\alpha = B/k$, we have $\beta \geq \frac{qB}{k(d-k+q)}$. To make it suitable to all the $1 \leq q \leq r$, we have

$$\beta \geq \frac{rB}{k(d-k+r)}. \quad (39)$$

Then, we prove it for upgrade scenario. We need to prove that the coding matrix of the non-helpers keep the same MDS property with the coding matrix of the newcomers. Based on the same assumption that the code vector of each matrix of the non-helpers is the linear combination of the base vectors, it obviously satisfies the full rank requirement if we adopt the checking step. Hence the claim follows. ■

It is consistent with the result of the concurrent minimal storage point. Moreover, we have to determine the value of coefficients of each base vector result from different P_{x_w} and $Z^{(\ell)}$ to ensure such linear independence. Because the above description is based on the assumption that β and α is positive integer, we should select proper β for application. In cooperative minimal storage regenerating process each newcomer at least need one strip from each helper, which implies the minimal value of β is r ($\beta = r\beta_1$). Then we have $\alpha = d - k + r$ and $B = k(d - k + r)$ to construct such codes. In fact, it is the same way as the scalar codes proposed in [33]. For vector codes (e.g., $\beta = 2r$), the strip may not be the minimal operational unit and the size of the matrix P_{x_w} and $Z^{(\ell)}$ will be expanded.

Secondly, we show the scalable repair and upgrade for multiple nodes.

2) *scalable repair and upgrade for multiple nodes:* Review the adaptive codes for repairing when $d+t = n$. Then a file is divided into $M = k(n-k)$ packets and encoded into $n(n-k)$ packets $x_{1,1}, \dots, x_{1,n-k}, \dots, x_{n,1}, \dots, x_{n,n-k}$ by multiplying $k(n-k) \times n(n-k)$ matrix. Each one of the n nodes stores $\alpha = n-k$ packets. When there are t node failures, we download t linear combinations of $n-k$ packets from each of d helpers.

Similarly, we can apply the codes to extension by set $d+s = n$, treat s newcomers as s failures waiting for repair. In this way, there would be $n-s$ healthy nodes not to the helpers, while we need to guarantee them and the newcomers maintain the MDS properties.

Theorem 4. *Given a distributed storage system with (n, k) -MDS codes based on MSR scheme, where $B = k(d-k+1)$, $\alpha = B/k = d-k+1$. If d is fixed and there exist d*

available helpers, we at least need to download

$$\gamma^{(r)} = \frac{Br(d-r+1)}{k(d-k+1)} = r(d-r+1) \quad (40)$$

data from all the d helpers to generate r nodes simultaneous. We use a d -dimension vector \mathbf{h} to indicate the downloaded capacities from the helpers and h_i denotes the downloaded capacities from i -th helper, which subjects to $\sum_{i=1}^d h_i = r(d-r+1)$, $1 \leq h_i \leq r$.

Proof: It is easy to prove the special case when $h_1 = h_2 = \dots = r$, in which we let $d-k+1 = d' - k + r$, where d' is the number of helpers depicted in equation (30) and r is treated as the number of newcomers, then we have

$$\frac{Brd'}{k(d'-k+r)} = \frac{Br(d-r+1)}{k(d-k+1)} = r(d-r+1) \quad (41)$$

For general case, we only prove that the combinations are identical to that of the special case. As can be seen from the proof of theorem 3, all the combinations are based on the same base vectors and the matrix can be full as long as there are enough linear independent combinations. Then we can replace a combination of one helper with that of the other helper. It means that we can transfer any general case to special case, then the claim follows. ■

Example 3. Suppose $n=7, k=4, d=5, r=2, s=1$, the file size is $B = (d-k+r)k = 12$ packets. To repair two node, we need to download $\frac{Br}{k(d-k+r)} = 2$ from each of the 5 helpers, totally 10 packets. To upgrade from (7,4) to (8,4), we can set $d_s = 6$ and then need $\frac{d_s B}{k(d_s-k+1)} = 6$ packets from 6 helpers. To upgrade to (9,4), we can need $\frac{2(d_s-2+1)B}{k(d_s-k+1)} = 10$ packets from 6 helpers, where $\mathbf{h} = [2, 2, 2, 2, 1, 1]$. If we set $d_s = 7$, $\mathbf{h} = [2, 2, 2, 1, 1, 1, 1]$

Thus, we give the basic steps of the whole procedure for scalable storage. We set $d = d_r = n - t$

(1) File distribution

1) For proper (n, k, d, t) , the original file is divided into $k(d-k+t)$ packets and then encoded into $n(d-k+t)$ packets $\langle x_{1,1}, \dots, x_{1,d-k+t}; \dots; x_{n,1}, \dots, x_{n,d-k+t} \rangle$ with $x_{i,j} = \mathbf{M}^T \mathbf{g}_i^j$, $1 \leq i \leq n, 1 \leq j \leq d+t-k$. Each node X_i stores $d-k+t$ packets $\langle x_{i,1}, \dots, x_{i,d-k+t} \rangle$.

(2) Date repairing

- 1) Choose a set of t nodes Y_1, \dots, Y_t from idle nodes as replacement nodes and a set of d nodes X'_1, \dots, X'_d from the surviving nodes as helpers.
- 2) Each helper X'_i transmits t encoded packets $\langle \chi_{i,1} \dots \chi_{i,t} \rangle = [x_{i,1}, \dots, x_{i,d-k+t}] * P_i$ to the daemon, where P_i is a $(d-k+t) \times t$ coefficient matrix.
- 3) The daemon encode the accepted packet $\langle \chi_{1,1} \dots \chi_{1,t}; \dots; \chi_{d,1} \dots \chi_{d,t} \rangle$ into linear independent packets $\langle y_{1,1}, \dots, y_{1,d-k+t}; \dots; y_{t,1}, \dots, y_{t,d-k+t} \rangle$ by separately multiplying different linear transform matrices Z_1, \dots, Z_t of size $dt \times (d-k+t)$.
- 4) The daemon distributes the encoded packet

$\langle y_{i,1}, \dots, y_{i,d-k+t} \rangle$ to node Y_i for $1 \leq i \leq t$.

(3) Storage upgrade from (n,k) to $(n+s,k)$

- 1) Choose a set of s nodes S_1, \dots, S_s from idle nodes as upgrade nodes and a set of d_s nodes X'_1, \dots, X'_{d_s} from the surviving nodes as helpers.
- 2) Each helper X'_i transmits h_i encoded packets $\langle \varsigma_{i,1} \dots \varsigma_{i,h_i} \rangle = [x_{i,1}, \dots, x_{i,d-k+t}] * R_i$ to the daemon, where R_i is a $(d-k+t) \times h_i$ coefficient matrix and h_i is subject to $\sum_{i=1}^{d_s} h_i = s(d-s+1)$ and $\lfloor \frac{s(d-s+1)}{d_s} \rfloor \leq h_i \leq s$.
- 3) The daemon encodes the accepted packets $\langle \varsigma_{1,1} \dots \varsigma_{1,h_1}; \dots; \varsigma_{d_s,1} \dots \varsigma_{d_s,h_{d_s}} \rangle$ into linear independent packets $\langle s_{1,1}, \dots, s_{1,d-k+t}; \dots; s_{t,1}, \dots, s_{t,d-k+t} \rangle$ by separately multiplying different linear transform matrix Z_1, \dots, Z_s of size $s(d-s+1) \times (d-k+t)$.
- 4) The daemon distributes $\langle s_{i,1}, \dots, s_{i,d-k+t} \rangle$ to S_i for $1 \leq i \leq s$.

We have the following properties:

- 1 **Strong-MDS:** The data collector can reconstruct the original data by downloading minimal $\sum_{i=1}^{k^*} v_i = B$ data from any k^* out of n nodes, where $k \leq k^* \leq n$ and $1 \leq v_i \leq k$.
- 2 **Multiple repair:** It can concurrently repair t failures by downloading minimal $\frac{Btd_r}{k(d_r-k+t)}$ from d_r helpers with $\frac{Bt}{k(d_r-k+t)}$ for each, where $k \leq d_r \leq n-t$ and $1 \leq t \leq k$.
- 3 **Scalable upgrade:** It can upgrade (n,k) codes to $(n+s,k)$ codes by treating added nodes as failure ones so that implement the multiple repair procedure or downloading minimal $\sum_{i=1}^{d_s} h_i = \frac{Bs(d_s-s+1)}{k(d_s-k+1)}$ from d_s helpers, where h_i denotes the contribution of i -th helper, $0 < h_i \leq s, k \leq d_s \leq n$ and $1 \leq s \leq k$.

Observe the later two properties, we can fix the number of strips in each piece, namely $d_r + t = d_s + 1$ are preferred in practice. Thus, the DSS can be more flexible to adjust the amount of storage result from the popularity of data.

V. CONCLUSION

In this paper, we review the concurrent regenerating codes for multiple-node repair and give close-form expressions for the storage-bandwidth bound by using cut-set bound analysis. Referring the cooperative regenerating codes, the codes can simplify the design process of storage systems, which is practical in non-purely distributed storage environment. We show that the existing constructions of single-repair MSR with IA can be easily reformed to concurrent MSR. When the number of multiple nodes needed to concurrently repair is k , we build a connection between strong-MDS property with the codes. Besides repair, we expand the application of functional codes for extension to provide scalability for erasure coded distributed storage systems. Apart from simply reforming repairable codes to scalable codes, we propose both coupled and decoupled design for the extension, which can be flexibly used in the distributed network.
