#### Abstract

People construct quantum bound states either non-numerically (in not too many exceptional cases) or, in general, numerically (mainly using majorization or discretization techniques). We argue that there exists a class of interactions "in between" being, in conventional terminology, neither exactly solvable nor purely numerical. The idea is illustrated by the elementary exponential-well toy-model potential $V(x)=-g^{2} \exp (-|x|)$.

## 1 Introduction

For many smooth and confining phenomenological potentials $V(x)$ which vanish in infinity a quick and, often, fairly reliable upper estimate of their low-lying bound-state energies $E_{0}, E_{1}, \ldots$ is provided by the elementary approximation or majorization of Hamiltonian using a suitable harmonic-oscillator well

$$
\begin{equation*}
V_{+}^{(H O)}(x)=-M+\omega^{2} x^{2} . \tag{1}
\end{equation*}
$$

In practice and, in particular, for the spiked shapes of potentials $V(x)$ the approximation or majorization of such an oversimplified type need not work too well of course. For illustration let us consider bound-state Schrödinger equation

$$
\begin{equation*}
-\frac{\mathrm{d}^{2}}{\mathrm{~d} x^{2}} \psi_{n}(x)+V(x) \psi_{n}(x)=E_{n} \psi_{n}(x), \quad \psi_{n}(x) \in L^{2}(\mathbb{R}), \quad n=0,1, \ldots \tag{2}
\end{equation*}
$$

with one of the most elementary potential wells (cf. [1])

$$
\begin{equation*}
V(x)=-g^{2} \exp (-|x|), \quad x \in(-\infty, \infty) \tag{3}
\end{equation*}
$$

This potential is spiked in the origin and decreases, exponentially, at the large $x$. Once we decide to perform the above-mentioned majorization we find out that this approach does not lead to satisfactory results (cf. section 2 below for more details).

Alternatively we may make use of the standard numerical discretization techniques [2, 3] and we may successfully guarantee, at any trial energy $E$, the validity of the above-mentioned normalizability condition $\psi(x) \in L^{2}(\mathbb{R})$ by the (in general, numerical, discretization) construction of the asymptotically correct (often called "Jost solutions" 4]) $\psi(x)=\psi_{J o s t}(x, E)$. In this setting the role of the secular equation becomes played by the condition of the matching of the logarithmic derivatives of the left and right Jost solution in the origin.

In what follows we intend to reveal and emphasize that for the non-smooth and polynomially unsolvable but still sufficiently elementary potentials as sampled by Eq. (3) neither of the above two approaches looks optimal. Firstly, in the context of majorization we point out that the presence of the downward-oriented spike in the origin makes the approximation/majorization of function $V(x)$ by the exactly solvable model (1) fairly bad and insufficient.

In the second context and in the light of the Bessel-function solvability of differential equation (2) + (3) on both half axes one feels tempted to take the advantage and to use, in a way described in Ref. [1], the necessary Jost solutions in their available, closed analytic form. In practical computations, unfortunately, it is often difficult to guarantee the sufficient precision of the boundstate energies as obtained from the Jost-solution matching-generated secular equation (let us add
here that this discouragement is not universally valid - see, e.g., the recent remarkable amendment of the Jost-matching construction for the Coulomb-resembling $V(x)=1 / \sqrt{x}$ in paper [5]).

Our present paper is basically motivated by the latter, in general discouraging numerical experience. In particular, in section 3 we recommend the use of an alternative algorithm called, often, a "shooting algorithm" [2, 6]. In its framework the matching of the Jost solutions in the origin is replaced by the fine-tuning of the (in general, unphysical) asymptotics of the so called regular solutions, i.e., of the alternative Bessel-function solutions which are constructed as regular in the origin.

Our results and conclusions are shortly discussed in the last section 4. We emphasize there that the proposed semi-analytic version of the shooting algorithm appears remarkably user-friendly.

## 2 The majorization technique and the limitations of its efficiency

Figure 1: Sample of majorization of potential (3) with $g=\sqrt{2}$ (thick line) by harmonic oscillator (1) using $\omega=1$ with maximal shift $M=M(\omega)=1.455938091$ yielding the upper estimate of the ground-state energy $E_{0}<E_{+}^{(H O)}=-0.455938091$.

As long as our benchmark bound-state problem (2) + (3) does not belong to the traditional exactly solvable models, it does not look suitable, in spite of its extreme formal simplicity, to play the role
of an illustrative toy model in introductory textbooks. Moreover, in spite of its interesting shortrange nature resembling. e.g., the popular Yukawa (i.e., a "short-range Coulomb") interaction $V^{(\text {Yukawa })}(x) \sim e^{-x} / x$, we never found the model used in any phenomenologically oriented tests of approximation techniques. On this background we felt tempted to apply a few elementary variational approaches to the upper-bound estimate of ground-state energy $E_{0}=-k^{2}$, and we found the results a bit unexpected.

### 2.1 Misbehaved estimates of the ground-state energy eigenvalues

Let us now return to our toy model (21) + (3) and let us consider its most elementary majorization by harmonic oscillator (1). The results are sampled in Fig. (1). Initially, the inspection of the picture made an impression that the harmonic-oscillator-based upper estimate of the exact ground state energy $E_{0}$ cannot be too bad. Unfortunately, such an expectation appeared not well founded because the precision of the estimate was found unexpectedly strongly sensitive to our choice of the freely variable parameters in Eq. (1). In particular, as long as a routine, brute-force numerical solution of the problem yields $E_{0} \approx-0.817$, we immediately see that the correct ground-state energy value lies far below the HO-based upper-bound estimates, especially when obtained at a non-optimal value of $\omega$.

Figure 2: Upper-bound $F=E_{+}^{(H O)}$ of the ground state energy $E_{0}$ as function of coupling $g$ and of the osculation-coordinate optional parameter $\xi$.

The necessity of the careful optimization of the HO estimates is illustrated in Fig. 2. The picture offers not only a strong warning against a naive use of the harmonic-oscillator majorization but it also illustrates why one should replace the variationally motivated variability of the spring constant $\omega$ by the variability of the coordinate $x_{0}$ of the osculation of the two curves.

A few details of the underlying interesting mathematics are added in the separate forthcoming subsection - it is slightly more technical and could be skipped during the first reading.

### 2.2 The closed-form construction of the optimal majorizing $V_{+}^{(H O)}(x)$

The inspection of Fig. 1 indicates that once we select the strength of our one-parametric model [i.e., coupling $g$ in (3)] and once we choose an optimal majorizing harmonic oscillator (i.e., a tentative spring constant $\omega$ ) we have to determine the maximal, optimal value of shift $M=M(\omega)$ after which the two curves [viz., $V(x)$ of Eq. (3) and $V_{+}^{(H O)}(x)$ of Eq. (1)] touch at a symmetric pair of coordinates $x= \pm \xi$. This means that we have to satisfy the pair of osculation constraints

$$
\begin{equation*}
-g^{2} e^{-\xi}=\omega^{2} \xi^{2}-M, \quad g^{2} e^{-\xi}=2 \omega^{2} \xi \tag{4}
\end{equation*}
$$

Treating $\xi$ as a new free parameter we have, from the latter relation,

$$
\begin{equation*}
\omega=\omega(\xi)=\frac{g}{\sqrt{2 \xi e^{\xi}}} \tag{5}
\end{equation*}
$$

i.e., a one-to-one correspondence between small $\xi$ and large $\omega$ and vice versa. Next, the sum of relations (4) yields the second necessary definition

$$
\begin{equation*}
M=M_{(\xi)}(\omega)=\omega^{2}(\xi)\left(\xi^{2}+2 \xi\right)=g^{2} e^{-\xi}(1+\xi / 2) \tag{6}
\end{equation*}
$$

which is a smoothly decreasing function of $\xi$ as well. Thus, there emerges a conflict between the decrease and increase of the respective components of the resulting $\xi$-dependent upper bound

$$
\begin{equation*}
E_{n}^{(H O)}=E_{n}^{(H O)}(g, \xi)=(2 n+1) \omega(\xi)-M=\frac{g e^{-\xi / 2}}{\sqrt{2 \xi}}(2 n+1)-g^{2} e^{-\xi}(1+\xi / 2) . \tag{7}
\end{equation*}
$$

At $n=0$ the shape of this function is sampled in Fig. 2 showing that at every given coupling $g$ there exists a sharp minimum of the bound $E_{n}^{(H O)}(g, \xi)$ at a unique optimal value of $\xi=\xi_{0}(g)$.

Formula (7) for function $E_{n}^{(H O)}(g, \xi)$ of the two variables looks complicated but we may still try to determine the curve $\xi_{0}(g)$ of the minima at a fixed coupling. The problem looks complicated because the corresponding necessary condition $\partial_{\xi} E_{n}^{(H O)}\left(g, \xi_{0}\right)=0$ leads to a complicated equation
for $\xi_{0}(g)$. Fortunately, a pleasant surprise emerges after one employs a computer-assisted symbolic manipulation solver and obtains the inverse function $g\left(\xi_{0}\right)$ in an unexpectedly elementary form

$$
\begin{equation*}
g\left(\xi_{0}\right)=\sqrt{\frac{e^{\xi_{0}}}{2 \xi_{0}{ }^{3}}} . \tag{8}
\end{equation*}
$$

In a graphical representation this is a smooth U-shaped curve with a unique minimum at $\xi_{0}=3$. Its shape is determined by the decrease $\sim \xi_{0}^{-3 / 2}$ at small $\xi_{0}$ and by the increase $\sim \exp \left(\xi_{0} / 2\right)$ at large $\xi_{0}$.

We would like to add that the value of $\xi_{\text {critical }}=3$ separates the "curve of extremes" (8) into its left, $\xi_{0}=\xi_{0}^{(u s e f u l)} \in(0,3)$ branch (carrying the minima alias the optimal estimate values of $\left.E_{n}^{(H O)}\left(g\left(\xi_{0}\right), \xi_{0}\right)\right)$ and the spurious branch of the variationally useless (and, moreover, even positive, physically useless) maxima of the HO-based upper bound at $\xi_{0}=\xi_{0}^{(\text {useless })} \in(3, \infty)$.

## 3 Semi-analytic implementation of the shooting method

As we already mentioned, people often construct, numerically, the two asymptotically correct branches of wave functions and match their logarithmic derivatives near the minimum of $V(x)$ (cf. subsection 3.11). Using a toy model $V(x)=-g^{2} \exp (-|x|)$ we shall now discuss the situation in which such an approach leads to the less satisfactory results. An optimal strategy of the determination of the spectra will be then recommended as provided by the shooting algorithm which is initiated in the origin.

### 3.1 The Jost-solution technique and the limitations of its efficiency

Let us first return to the search for an effective alternative to the above-criticized majorization approximation approach. Let us also recollect that for potentials sampled by Eq. (3) it is really possible to search for the bound-state solutions via a proper matching of the left and right branches of the well known and asymptotically correctly vanishing Bessel-function solutions $\sim Z_{\nu}(y)$ with suitable index $\nu=\nu\left(E_{n}\right)$ and argument $y=y(x)$. Finally, let us remind the readers that the practical implementation and realization of such a form of matching in the origin may encounter numerous, mostly purely numerical obstacles.

One of them is connected with the common strategy of the trial-and-error choice and systematic amendment of the variable candidate-for-the-energy parameter $E=E_{(t r i a l)}$ in Eq. (2). Whenever one knows the general solution of the ordinary differential Schrödinger equation in the form of superposition $\psi(x)=c_{1} \psi_{1}(x)+c_{2} \psi_{2}(x)$ of the two known components $\psi_{1,2}(x)$, and whenever one
has to match them in the origin (which is also one of the promising options for our toy model (3) where the available wave function components are Bessel functions), one usually starts from imposing the correct asymptotic behavior analytically. Then one completes the construction via the "smoothness-in-the-origin" strategy, i.e., via the matching of the logarithmic derivatives of the candidate wave functions at $x=0$.

In the algorithm, the main theoretical difficulty may be seen in the lack of a friendly representation of the asymptotically correct Bessel wave functions $\sim Z_{\nu}(y)$ at small $y$ and near the origin [7]. Another, more practical difficulty reflects the smallness of changes of the resulting left and right $x \rightarrow 0^{ \pm}$limits of $\psi(x)$ after a small change of the value of $E_{(t r i a l)}$. In this sense, irrespectively of the representation of wave functions, the localization of the correct bound-state energy may prove slow and marred by numerical errors. This observation inspired also our present alternative methodical proposal of an opposite strategy.

### 3.2 The merits of the analytic shooting method

We shall now change the strategy and start from a guarantee of the correct behavior of the superpositions of Bessel-function solutions $\psi(x)=c_{1} \psi_{1}(x)+c_{2} \psi_{2}(x)$ in the origin. We will be able to take advantage not only of having the general solution represented by Bessel functions $Z_{\nu(E)}[y(x)]$ but also of the more easily satisfied duty of the localization of the correct bound-state energy $E_{n}(g)$ via the localization of the largest zero of $\psi(x)$.

Naturally, due to the left-right symmetry of potential (3) one has to distinguish between the even-parity states (with property $\psi(x)=\psi(-x)$, i.e., $\psi(0)=1$ and $\psi^{\prime}(0)=0$ ) and the odd-oparity states (with property $\psi(x)=-\psi(-x)$, i.e., $\psi(0)=0$ and $\psi^{\prime}(0)=1$ ). Without any significant loss of insight in the problem let us consider, for the sake of brevity, just the former case involving the ground state with $n=0$ and all of the excited states with even quantum numbers $n=2 m$.

We may stay, without loss of generality, on the positive half-axis of $x>0$. Via an elementary change of variables in Eqs. (2) + (3) the exact solvability of the model proves equivalent to the existence of all of the general even-parity wave functions in the non-numerical form

$$
\begin{equation*}
\psi(x)=D_{1}(k, g) J_{-2 k}\left(2 g e^{-1 / 2 x}\right)+D_{2}(k, g) Y_{-2 k}\left(2 g e^{-1 / 2 x}\right) . \tag{9}
\end{equation*}
$$

Here we may evaluate, after slightly tedious calculations,

$$
D_{1}(k, g)=-\frac{Y_{-2 k+1}(2 g)+k Y_{-2 k}(2 g) / g}{J_{-2 k+1}(2 g) Y_{-2 k}(2 g)-Y_{-2 k+1}(2 g) J_{-2 k}(2 g)}
$$

and

$$
D_{2}(k, g)=\frac{J_{-2 k+1}(2 g)+k J_{-2 k}(2 g) / g}{J_{-2 k+1}(2 g) Y_{-2 k}(2 g)-Y_{-2 k+1}(2 g) J_{-2 k}(2 g)} .
$$

In the subsequent step we simply choose a tentative value of $k$, plot the function (9) of variable $x \in(0, \infty)$ and count the number $\mathcal{Z}$ of its zeros.

In the search for the exact bound-state energy $E_{2 m}(g)$ we have two possibilities. In the first case marked by (a) with $\mathcal{Z}<m$ we declare the preselected value of $k$ "too large". Having recalled the standard oscillation theorems [8] we choose a slightly smaller next tentative value of $k$ in order to make our next, amended candidate (9) for wave function "more oscillatory". In the second case marked by (b) with $\mathcal{Z} \geq m$ we do the opposite. On the basis of the same oscillation theorems we choose a slightly larger (but not "too large") next tentative value of $k$ in order to make our amended candidate (9) for wave function "less oscillatory".

In practice, the graphical determination of the actual nodal count $\mathcal{Z}$ proves easily implemented because if the maximal node disappears in infinity, the asymptotic, exponentially quickly growing part of the tentative regular solution $\psi(x)$ must change its sign. This makes the resulting "analytic shooting method" fully analogous to its universal, quickly convergent numerical predecessors [4].

Figure 3: The sample of the changes of the asymptotics of the regular and real $x>0$ part of the ground-state wave function with the variation of the error term $z$ in $k=k(z)$ at the even-parity normalization $\psi_{(k)}(0)=1, \psi_{(k)}^{\prime}(0)=0$ and at the fixed coupling $g=\sqrt{2}$.

Typically, the implementation of the analytic shooting algorithm is easy as it may proceed simply by halving the interval of eligible $k$ s. Another, serendipitous advantage of the algorithm is its connection with oscillation theorems so that it generates, in practice, the sequence of parallel upper and lower bounds of the energies. For example, the above-mentioned approximate ground-
state result $E_{0}=-k_{0}^{2} \approx-0.817$ becomes replaced, in this manner, by the two-sided estimate $-0.81721<E_{0}<-0.81720$ and, subsequently, by the series of its higher-precision amendments whenever needed. For an illustration of the mechanism of this construction let us choose again $g=\sqrt{2}$ and make an ansatz $E_{0}=-k_{0}^{2}=-0.817200-z 10^{-6}$ containing a not yet specified error term $z$. Naturally, the "shooting" choice of the trial-and-error value of $z$ controls the behavior of the maximal nodal zero of the related regular solution $\psi(x)=\psi_{(k)}(x)$. For the four alternative choices of $z$ this behavior is displayed in Fig. 3,

## 4 Discussion

We may conclude that the model $V(x)=-g^{2} \exp (-|x|)$ exemplifies, nicely, the situation in which several standard approaches do not lead to a satisfactory result and in which an optimal strategy of the determination of the spectra is found in the shooting method initiated in the origin.

The unlimited-precision nature of the resulting bound-state energies is in one-to-one correspondence with the unlimited-precision availability of the Bessel-function wave-function candidates. In this sense one encounters a big difference between the models sampled by Eq. (3) (for which we would endorse the "exact solvability" status, cf. also [1]) and the more general interaction potentials for which the Jost or regular solutions must be generated by an approximate variational or discretization method.

This seems to imply that the status of exactly solvable (ES) one-dimensional quantum potentials $V(x)$ should be attributed not only to the conventional ES family (yielding wave functions proportional to classical orthogonal polynomials) and not only to the non-analytic square wells and point interactions (solvable by the matching techniques) but also to some interactions "in between".

The most characteristic feature of the $k$-dependent candidates for the wave functions is that these functions remain proportional to special functions. Near each physical bound-state value of parameter $k$ they remain normalizable and have to be matched in the origin of vice versa. Of course, this is a generic idea which might be applied to a fairly wide class of confining potentials. Needless to add that in our present model its implementation was perceivably facilitated by the parity-symmetry of the model.

Naturally, the theoretical roots of the whole idea are already very well known. Their origin dates back to the studies of the singular Sturm-Liouville problems as pioneered by H. Weyl in 1909 and as explained, e.g., in Chapter 9 of the classical monograph [9]. In the language of mathematicians one could change the conventions and speak also, equivalently, about the study of
the Titchmarsh-Weyl m-functions with the property that their poles correspond to the bound-state eigenvalues, etc.

In the opposite, fully practical context of quantum mechanics of simple atomic and molecular systems, traditionally, people make distinction between the general, numerical, and special, exactly solvable (ES) bound-state Schrödinger equation. In this context Eq. (2n) is usually assigned the SE status just for the square-well real and confining $V(x)[10]$ (or, in extremis, to the non-analytic point-interaction models) or, alternatively, for the strictly analytic potentials $V(x)$ for which some [11] or all [12] of the bound-state wave functions $\psi_{n}(x)$ happen to be proportional to polynomials.

Summarizing, by far the most important condition of the efficiency of the present semi-analytic version of the well known shooting algorithm lies in the explicit special-function form of the Jost or regular solutions. Without this condition one would return either just to the universal and wellknown, purely numerical techniques or to some other, less universal and less known techniques involving, pars pro toto, the so called Hill-determinant methods [13], the so called quasi-exact solvability [14] etc. In our present paper we simply promoted, on this basis, the possibility of having a new, "third" class of certain semi-numerical ES (SNES) potentials $V^{(S N E S)}(x)$.

This class was exemplified by the toy-model interaction (3). We demonstrated that our nonanalytic illustrative SNES model was tractable by the constructive use of the general regular solutions of the differential Schrödinger equation which appeared to be tractable, user-friendly and available in the form of specific, next to elementary special functions, i.e., in our case, of Bessel functions.
