INTRODUCTION

Spin generation and spin currents in semiconductor structures lie at the heart of the emerging field of spintronics and are a major and still growing direction of solid-state research. Among the plethora of concepts and ideas, current-induced spin polarization has attracted particular interest from both experimental and theoretical point of view, for reviews see Refs. [1–14]. In non-magnetic semiconductors or metals belonging to the gyrotropic point groups [15], see Refs. [7, 16–21], de electric current is generically accompanied by a non-zero average nonequilibrium spatially homogeneous spin polarization and vice-versa. The latter phenomenon is referred to the spin-galvanic effect observed in GaAs QWs [21], and other two-dimensional systems, see e.g. reviews [3, 7, 11, 13, 14, 22–27]. In low-dimensional semiconductor structures these effects are caused by asymmetric spin relaxation in systems with lifted spin degeneracy due to k-linear terms in the Hamiltonian, where k is the electron wave vector. In spite of the terminological resemblance, spin polarization by electric current fundamentally differs from the spin Hall effect [4, 5, 11–13, 26, 28–32], which refers to the generation of a pure spin current transverse to the charge current and causes spin accumulation at the sample edges. The distinctive features of the current-induced spin polarization are, that this effect can be present in gyrotropic media only, it results in nonzero average spin polarization, and does not depend on the real-space coordinates. Thus, it can be measured in the whole sample under appropriate conditions. The spin Hall effect, in contrast, does not yield average spin polarization and does not require gyrotropy, at least for the extrinsic spin Hall effect.

The ability of charge current to polarize spins in gyrotropic media has been predicted more than thirty years by Ivchenko and Pikus [33]. The effect has been considered theoretically for bulk tellurium crystals, where, almost to the same time, it has been demonstrated experimentally by Vorob’ev et al. [34]. In bulk tellurium current-induced spin polarization is a consequence of the unique valence band structure of tellurium with hybridized spin-up and spin-down bands (“camel back” structure) and, in contrast to the spin polarization in quantum well structures, is not related to spin relaxation. In zinc-blende structure based QWs this microscopic mechanism of the current-induced spin polarization is absent [33, 36]. Vas’ko and Prima [36], Aronov & Lyanda-Geller [37], and Edelstein [38] demonstrated that spin orientation by electric current is also possible in two-dimensional electron systems and is caused by asymmetric spin relaxation. Two microscopic mechanisms, namely scattering mechanism and precessional mechanism, based on Elliott-Yafet and D’yakonov-Perel’ spin relaxation, respectively, were developed. The first direct experimental proofs of this effect were obtained in semiconductor QWs by Ganichev et al. in (113)-grown p-GaAs/AlGaAs QWs [33, 40], Silov et al. in (001)-grown p-GaAs/AlGaAs heterojunctions [41, 42], Sih et al. in (110)-grown n-GaAs/AlGaAs QWs [43] and Yang et al. in (001)-grown InGaAs/InAlAs QWs [44], as well as in strained bulk (001)-oriented InGaAs and ZnSe epilayers by Kato et al. [45, 46] and Stern et al. [47], respectively. The experiments include the range of optical methods such as Faraday rotation and linear-circular dichroism in transmission of terahertz radiation, time resolved Kerr rotation and polarized luminescence in near-infrared up to visible spectral range. We emphasize that current-induced spin polarization was observed even at room temperature [48, 49, 50]. It has been demonstrated that depending on the point group symmetry electric current in 2D system may result in the in-plane spin orientation, like in the case of e.g. (001)-grown structures [41, 42, 43, 51], or may additionally align spins normal to the 2DEG’s plane. The latter take place in [111]-or [110]-oriented structures, e.g. [113]-, [110]- and [013]-grown QWs (see also [10, 30, 40, 42]). We also would like to note, that investigating spin injection from a ferromagnetic film into a two-dimensional electron gas, Hammar et al. [53, 54] used the concept of a spin orientation by current in a 2DEG (see also [55, 56]) to interpret their results. Though a larger degree of spin polarization was extracted the experiment’s interpretation is complicated by other effects [57, 58]. Later experiments on ferromagnet/(Ga,Mn)As bilayers [59], uniaxial (Ga,Mn)As epilayers [59], metallic interfaces and surfaces [60–63] and interfaces between ferromagnetic films and topological insulators [64, 67] clearly demonstrated the ability of spin polarization by electric current in ferromagnetics- and metal-based structures.

The experimental observation of current-induced spin polarization has given rise to extended theoretical studies of this phenomenon in various systems using various approaches and theoretical techniques. These include the semiclassical Boltzmann equation [52, 62, 72] derived from the quantum mechanical Liouville equation [74] and other diffusion-type equations describing the dynamics of spin expectation values [5, 75–83]. Other
authors have performed important and fruitful studies of the same issues using various Green’s function techniques of many-body physics \[2, 8, 91\]. The effect of external contacts to the system and boundaries was studied explicitly in Refs. \[56, 62, 92\], and in Refs. \[94, 95\] the spin response of an electron gas to a microwave radiation was calculated. The influence of four terminal geometry has been studied in Ref. \[96\] using a numerical Landauer-Keldysh approach, and weak localization corrections for current-induced spin polarization have been calculated in \[97\]. The current-induced spin polarization has also been investigated in hole systems \[89, 98, 99\]. A search for efficient spin generation and manipulation by all electrical means has given rise to theoretical analysis of current induced spin polarization in exotic regimes, like streaming caused by high electric fields \[73, 100\] or very weak electron-impurity interaction \[101\], in one-dimensional channels \[102, 103\] and combined structures with metal/insulator \[104\], ferromagnets/topological insulators \[105–108\] ferromagnets/graphene \[109, 110\] or metal/semiconductor \[62, 111\] interfaces.

Searching for publications on current-induced spin polarization one can be confused by the fact that several different names are used to describe it. Besides current-induced spin polarization (CISP) this phenomenon is often referred to as the inverse spin-galvanic effect (ISGE), current-induced spin accumulation (CISA), the magneto-electric effect (MEE) or kinetic magneto-electric effect (KMEEE) (this term was first used to describe the effect in non-magnetic conductors by Levitov et al. \[112\]), electric-field mediated in-plane spin accumulation. These variety of terms was extended further after the observation of the current-induced spin polarization at the interface between non-magnetic metals \[61\]. The authors introduce the new term - Edelstein effect (EE) - which, in followed up works, was modified to Rashba-Edelstein effect (REE) as well as to its inversion (IEE) corresponding to the spin-galvanic effect. Despite the enormous diversity of labels in all these cases we deal with one and the same microscopic effect: appearance of non-equilibrium spin polarization due to \textit{dc} electric current in the gyrotropic media with Rashba/Dresselhaus spin splitting of the bands. In our chapter we will use two of these terms: current-induced spin polarization and the inverse spin-galvanic effect.

**MODEL**

Phenomenologically, the electron’s averaged nonequilibrium spin $\mathbf{S}$ can be linked to the an electric current $\mathbf{j}$.

![FIG. 1. (a) Electric current-induced spin polarization in symmetric (110)-grown zinc-blende structure based QWs. (b) symmetry elements of symmetrical QW grown in the $z \parallel [110]$ direction. Arrows in the sketch (b) show reflection of the components of polar vector $j_x$ and axial vector $S_z$ by the mirror reflection plane $m_1$. An additional reflection by the mirror reflection plane $m_2$ does not modify the components of an in-plane polar vector $j_x$ as well as does not change the polarity of an out-plane axial vector $S_z$. Thus, the linear coupling of $j_x$ and $S_z$ is allowed for structures of this symmetry.](image-url)
plane average spin is allowed, demonstrating that a photocurrent $j_x$ can induce the average spin polarization $S_z$. In asymmetric (110)-grown QWs or (113)-grown QWs the symmetry is reduced to $C_\infty$ and additionally to the $z$-direction, spins can be oriented in the plane of QWs. Similar arguments demonstrate that in (001)-grown zinc-blende structure based QWs an electric current can result in an in-plane spin orientation only. In this case, the direction of spins depends on the relative strengths of the structure inversion asymmetry (SIA) and bulk inversion asymmetry (BIA) resulting in an anisotropy of the current-induced spin polarization.

A microscopic model of the current-induced spin polarization is sketched in Fig. 2(a). To be specific we consider an electron gas in symmetric (110)-grown zinc-blende QWs. The explanation of the effect measured in structures of other crystallographic orientation or in a hole gas can be given in a similar way. In the simplest case the electron’s (or hole’s) kinetic energy in a quantum well depends quadratically on the in-plane wavevector components $k_x$ and $k_y$. In equilibrium, the spin degenerated $k_x$ and $k_y$ states are symmetrically occupied up to the Fermi energy $E_F$. If an external electric field is applied, the charge carriers drift in the direction of the resulting force. The carriers are accelerated by the electric field and gain kinetic energy until they are scattered. A stationary state forms where the energy gain and the relaxation are balanced resulting in a non-symmetric distribution of carriers in $k$-space yielding an electric current. The electrons acquire the average quasi-momentum

$$\hbar \Delta k = eE \tau_{ps}$$

where $E$ is the electric field strength, $\tau_{ps}$ is the momentum relaxation time for a given spin split subband labeled by $s$, and $e$ is the elementary charge. As long as spin-up and spin-down states are degenerated in $k$-space the energy bands remain equally populated and a current is not accompanied by spin orientation. In QWs made of zinc-blende structure material like GaAs or strained bulk semiconductors, however, the spin degeneracy is lifted due to SIA and BIA and dispersion reads

$$E_{ks} = \frac{\hbar^2 k^2}{2m^*} + \beta_{lm} \sigma_j k_m$$

with the spin-orbit pseudotensor $\beta$, the Pauli spin matrices $\sigma_j$ and effective mass $m^*$ (note, the similarity to Eqs. (1) and (2)). The parabolic energy band splits into two subbands of opposite spin directions shifted in $k$-space symmetrically around $k = 0$ with minima at $\pm k_0$. For symmetric (110)-grown zinc-blende structure based QWs the spin-orbit interaction results in a Hamiltonian of the form $\beta_{zz} \sigma_j k_z$, the corresponding dispersion is sketched in Fig. 2(a). Here the energy band splits into two subbands of $s_z = 1/2$ and $s_z = -1/2$, with minima symmetrically shifted in the $k$-space along the $k_x$ axis from the point $k = 0$ into the points $\pm k_0$, where $k_0 = m^* \beta_{zz}/\hbar^2$. As long as the spin relaxation is switched off the spin branches are equally populated and equally contribute to the current. Due to the band splitting, spin-flip relaxation processes $ \pm 1/2 \rightarrow \mp 1/2$, however, become different because of the difference in quasi-momentum transfer from initial to final states. In Fig. 2(a) the $k$-dependent spin-flip scattering processes are indicated by arrows of different lengths and thicknesses. As a consequence different amounts of spin-up and spin-down carriers contribute to the spin-flip transitions causing a stationary spin orientation. In this picture we assume that the origin of the current-induced spin orientation is, as sketched in Fig. 2(a), exclusively due to scattering and hence dominated by the Elliott-Yafet spin relaxation (scattering mechanism). The other possible mechanism resulting in the current-induced spin orientation is based on the D’yakonov-Perel spin relaxation (precessional mechanism). In this case the relaxation rate depends on the average $\Delta k$-vector equal to $k_{1/2} = -k_0 + (\Delta k_x)$ for the spin-up and $k_{-1/2} = k_0 + (\Delta k_x)$ for the spin-down subband. Hence, also for the D’yakonov-Perel mechanism the spin relaxation becomes asymmetric in $k$-space and a current through the electron gas causes spin orientation.

Figure 2(b) shows that not only phenomenological equations but also microscopic models of the current-induced spin polarization and the spin-galvanic effect are similar. Spin orientation in the $x$-direction causes the unbalanced population in spin-down and spin-up subbands. As long as the carrier distribution in each subband is symmetric around the subband minimum at $k_{x\pm}$, no current flows. The current flow is caused by $k$-dependent spin-flip relaxation processes $ \mp 1/2 \rightarrow \mp 1/2$, spins oriented in the $z$-direction are scattered along $k_x$ from the higher...
filled, e.g., spin subband $| +1/2 \rangle_z$, to the less filled spin subband $| -1/2 \rangle_z$. The spin-flip scattering rate depends on the values of the wavevectors of the initial and the final states. Four quantitatively different spin-flip scattering events exist. They preserve the symmetric distribution of carriers in the subbands and, thus, do not yield a current. While two of them have the same rates, the other two, sketched in Fig. 2(b) by bent arrows, are inequivalent and generate an asymmetric carrier distribution around the subband minima in both subbands. This asymmetric population results in a current flow along the $x$-direction. Within this model of elastic scattering the current is not spin polarized since the same number of spin-up and spin-down electrons move in the same direction with the same velocity. Like current-induced spin polarization also spin-galvanic effect can result from the precessional mechanism based on the asymmetry of the Dyakonov-Perel spin relaxation.

In order to foster the above phenomenological arguments and models, let us discuss a microscopic description of such processes as introduced in Ref. [71]. This theory is based on an analytical solution to the semiclassical Boltzmann equation, which does not include the spin relaxation time explicitly. Instead one utilizes the so-called quasi-particle life time $\tau_0$, which is defined via the scattering probability alone. This is in contrast to the momentum relaxation time $\tau_{ps}$, which, in addition, depends on the distribution function itself and, therefore, should be self-consistently deduced from the Boltzmann equation written within the relaxation time approximation. In the framework of a simplest model dealing with the elastic delta-correlated scatterers the quasi-particle life time $\tau_0$ depends neither on carrier momentum nor spin index, and in that way it essentially simplifies our description.

Before we proceed let us first discuss the applicability of the quasiclassical Boltzmann kinetic equation to the description of the spin polarization in quantum wells observed in [41, 116]. There are two restrictions which are inherited by the Boltzmann equation due to its quasiclassical origin. The first one is obvious: The particle’s de Broglie length must be much smaller than the mean free path. At low temperatures (as compared to the Fermi energy) the characteristic de Broglie length $\lambda$ relates to the carrier concentration $n_e \sim \frac{m^*E_F}{\pi k_{B}^2}$ approximately as $\lambda \sim \sqrt{\frac{2\pi}{n_e}}$, whereas the mean free path $l$ can be estimated as $l \sim \frac{\hbar}{2\pi n_e \tau_0}$. Thus, the first restriction can be written as

$$n_e \gg \frac{\hbar^2}{8\pi \beta^2 \tau_0^2}, \quad (6)$$

where $\beta$ is the spin-orbit coupling parameter. This restriction can also be reformulated in terms of the mean free path $l$ and spin precession length $\lambda_\alpha \sim \pi/k_0$. Namely, $l$ must be much larger than $\lambda_\alpha$ so that an electron randomizes its spin orientation due to the spin-orbit precession between two subsequent scattering events. This restriction corresponds to the approximation which neglects the off-diagonal elements of the non-equilibrium distribution function in the spin space. Indeed, an electron spin can not only be in one of two possible spin eigenstates of the free Hamiltonian but in an arbitrary superposition of them, the case described by the off-diagonal elements of the density matrix. The latter is not possible in classical physics where a given particle always has a definite position in the phase space. Thus, we could not directly apply Boltzmann equation in its conventional form for the description of the electron spin in 2DEGs with spin-orbit interactions as long as the inequality (6) is not fulfilled. Note, on the other hand, that all the quantum effects stemming from the quantum nature of the electron spin can be smeared out by a sufficient temperature larger than the spin splitting energy $E_{s+k} - E_{s-k}$. Thus, the room temperature $T_{room} = 25$ meV being much larger than the spin-orbit splitting energy of the order of 3 meV (which is relevant for InAs quantum wells) makes the Boltzmann equation applicable for sure. In order to verify whether the conditions (5) and (6) are indeed satisfied, one can deduce the quasi-particle life time $\tau_0$ from the mobility $\mu = e\tau_0/m^*$. Then, using spin-orbit coupling parameters in the range usually found in experiments [117–119], the above inequalities turn out to be fulfilled. In the case when inequality (6) is not fulfilled, the theory based on spin-density matrix formalism yields the result for CISP degree depending on the ratio between energy and spin relaxation times [112, 120]. If energy relaxation is slower than Dyakonov-Perel spin relaxation, then the electrically induced spin is given by Eq. (11) derived for well-split spin subbands. This regime takes place at low temperatures. By contrast, spin density is twice larger in the opposite case of fast energy relaxation which is realized at moderate and high temperatures.

In general, the Boltzmann equation describes the time evolution of the particle distribution function $f(t,r,k)$, in the coordinate $r$ and momentum $k$ space. To describe the electron kinetics in presence of a small homogeneous electric field $E$ in a steady state one usually follows the standard procedure widely spread in the literature on solid state physics. The distribution function is then represented as a sum of an equilibrium $f_0(E_{sk})$ and non-equilibrium $f_1(s,k)$ contributions. The first one is just a Fermi-Dirac distribution, and the second one is
a time and coordinate independent non-equilibrium correction linear in \( E \). This latter contribution should be written down as a solution of the kinetic equation, however, it might be also deduced from qualitative arguments in what follows.

Let us assume that the scattering of carriers is elastic, which means, above all, that spin flip is forbidden. Then, the average momentum \( \Delta k \) which the carriers gain due to the electric field can be estimated relying on the momentum relaxation time approximation from Eq. \( \text{3} \).

If the electric field is small (linear response) then to get the non-equilibrium term \( f_1(s, k) \) one has to expand the Fermi-Dirac function \( f_0(E_{sk(\Delta k)}) \) into the power series for small \( \Delta k \) up to the term linear in \( E \). Recalling \( h \nu = -\partial_{\Delta k} E_{sk(\Delta k)} \mid_{\Delta k=0} \) the non-equilibrium contribution \( f_1(s, k) \) can be written as

\[
f_1(s, k) = -eE v \tau_{ps} \left[ -\frac{\partial f_0(E_{sk})}{\partial E_{sk}} \right]. \tag{7}
\]

Since \( f_1(s, k) \) is proportional to the derivative of the step-like Fermi-Dirac distribution function, the non-equilibrium term substantially contributes to the total distribution function close to the Fermi energy only, and the sign of its contribution depends on the sign of the group velocity \( v \). Note, that the group velocity \( v \) for a given energy and direction of motion is the same for both spin split subbands and, therefore, non-equilibrium addition to the distribution function would be the same for both branches as long as \( \tau_{ps} \) were independent of the spin index. The latter is, however, not true, and \( \tau_{ps} \) is different for two spin split subbands, as depicted in Fig. \( \text{2} \).

This is the microscopic reason why the non-equilibrium correction to the distribution function gives rise to the spin polarization.

The non-equilibrium correction can be also found as an analytical solution of the Boltzmann equation \( \text{[7]} \), and has the form

\[
g_1(s, k) = -eE k \tau_0 \left[ \frac{m^*}{\partial f_0(E_{sk})} \right]. \tag{8}
\]

In contrast to Eq. \( \text{7} \), Eq. \( \text{8} \) contains momentum \( k \) and quasiparticle life time as a prefactor \( \text{[12]} \). Since the quasiparticle life time does not depend on the spin index, and the quasiparticle momentum calculated for a given energy is obviously different for two spin split subbands Eq. \( \text{6} \), immediately allows us to read out the very fact that the non-equilibrium contribution depends on the spin index, see also Fig. \( \text{3} \). Thus, the spins are not compensated with each other as long as the system is out of equilibrium. Therewith one can see that the efficiency of the current-induced spin polarization is governed by the splitting between two subbands, i.e. it is directly proportional to the spin-orbit constant only. One can also prove the later statements just calculating the net spin density

\[
\langle S_{x,y,z} \rangle = \sum_s \int \frac{d^2k}{(2\pi)^2} S_{x,y,z}(k, s) g_1(s, k), \tag{9}
\]

with \( S_{x,y,z} \) being the spin expectation values.

To conclude this section we would like to emphasize that the two Eqs. \( \text{7} \) and \( \text{8} \) are just two ways to describe the same physical content. One can think about spin accumulation either in terms of the momentum relaxation time \( \tau_{ps} \) dependent on the spin split subband index, or one may rely on the exact solution Eq. \( \text{3} \) which relates the spin accumulation to the quasimomentum difference between electrons with the opposite spin orientations.
ANISOTROPY OF THE INVERSE SPIN-GALVANIC EFFECT

Similar to the spin-galvanic effect [7, 117, 118] the current-induced spin polarization can be strongly anisotropic due to the interplay of the Dresselhaus and Rashba terms. The relative strength of these terms is of general importance because it is directly linked to the manipulation of the spin of charge carriers in semiconductors, one of the key problems in the field of spintronics. Both Rashba and Dresselhaus couplings result in spin splitting of the band and give rise to a variety of spin-dependent phenomena which allow us to evaluate the magnitude of the total spin splitting of electron subbands [22, 23, 33, 116-119, 122, 132].

Dresselhaus and Rashba terms can interfere in such a way that macroscopic effects vanish though the individual terms are large [116, 125, 127]. For example, both terms can cancel each other resulting in a vanishing spin splitting in certain k-space directions [10, 14, 22, 127]. This cancellation leads to the disappearance of an anticalorization [123, 133], circular photogalvanic effect [118], magneto-gyrotropic effect [131, 132], spin-galvanic effect [117] and current-induced spin polarization [71], the absence of spin relaxation in specific crystallographic directions [116, 124], the lack of Shubnikov–de Haas beating [125, 126], and has also given rise to a proposal for spin field-effect transistor operating in the nonballistic regime [124].

While the interplay of Dresselhaus and Rashba spin splitting may play a role in QWs of different crystallographic orientations here we focus on anisotropy of the inverse spin-galvanic effect in (001)-grown zinc-blende structure based QWS. For (001)-oriented QWs linear in wave vector part of Hamiltonian for the first subband reduces to

\[ \mathcal{H}_k^{(1)} = \alpha (\sigma_{x_0} k_{y_0} - \sigma_{y_0} k_{x_0}) + \beta (\sigma_{x_0} k_{x_0} - \sigma_{y_0} k_{y_0}) \]  

where the parameters \( \alpha \) and \( \beta \) result from the structure-inversion and bulk-inversion asymmetries, respectively, and \( x_0, y_0 \) are the crystallographic axes [100] and [010].

To study the anisotropy of the spin accumulation one can just calculate the net spin density from Eq. (9), where the integral over \( k \) can be taken easily making the substitution \( \varepsilon = E(s, k) \) and assuming that \( -\partial f^0(\varepsilon)/\partial \varepsilon = \delta(E_F - \varepsilon) \). The rest integrals over the pole angle can be taken analytically, and after some algebra we have

\[ \langle S \rangle = \frac{e m^* \tau_0}{2 \pi \hbar^3} \begin{pmatrix} \beta & \alpha \\ -\alpha & -\beta \end{pmatrix} E. \]  

This relation between the spin accumulation and electrical current can also be deduced phenomenologically applying Eq. (2).

The magnitude of the spin accumulation \( \langle S \rangle = \sqrt{(S_x)^2 + (S_y)^2} \) depends on the relative strength of \( \beta \) and \( \alpha \) and varies after

\[ \langle S \rangle = \frac{e Em^* \tau_0}{2 \pi \hbar^3} \sqrt{\alpha^2 + \beta^2 + 2\alpha\beta \sin(2\pi E_e)}. \]  

It is interesting to note, that \( \langle S \rangle \) depends on the direction of the electric field (see Fig. 4), i.e. the spin accumulation is anisotropic. This anisotropy reflects the relation between Rashba and Dresselhaus spin–orbit constants. If either \( \alpha = 0 \) or \( \beta = 0 \) then the anisotropy vanishes. In the opposite case of \( \alpha \sim \beta \) the anisotropy reaches its maximum. Note, that the case of \( \alpha \) being exactly equal to \( \beta \) requires special consideration, and the nonequilibrium distribution function turns out to be different from [8]. Here, the effective magnetic field does not depend on the direction of motion and Dyakonov-Perel spin relaxation vanishes [10, 114, 124, 127]. A similar effect has also been found in rolled-up heterostructures [134], where Dyakonov-Perel spin relaxation also vanishes at a certain radius of curvature. In such situations spin orientation by electric current becomes only possible due to other mechanisms of spin relaxation. Nevertheless, the anisotropy of spin relaxation will reflect the anisotropy of the band structure and in our case of (001)-oriented QW will qualitatively correspond to the curve C in Fig. 4.

FIG. 4. Anisotropy of spin accumulation (in arbitrary units) vs. direction of the electric field in polar coordinates for different Rashba and Dresselhaus constants: A — \( \alpha = 3 \beta \), B — \( \alpha = 2.15 \beta \), C — \( \alpha \sim \beta \) (after [71]). The curve B corresponds to the n-type InAs-based QWs investigated in [117].

The simple Drude-like relation between electrical current and field allows us to write down a useful relation between the spin accumulation and charge current density

\[ \langle S \rangle = \frac{m^* e}{2 \pi \hbar^3 e n_c} \begin{pmatrix} \beta & \alpha \\ -\alpha & -\beta \end{pmatrix} j. \]  

Note that, in the coordinate system with the coordinate axes parallel to the mirror crystallographic planes \( x \parallel [110] \) and \( y \parallel [110] \), the Hamiltonian \( \mathcal{H}_k^{(1)} \) gets the form \( \beta_{xy} \sigma_x k_y + \beta_{yx} \sigma_y k_x \) with \( \beta_{xy} = \beta + \alpha, \beta_{yx} = \beta - \alpha \), and
the relation between $\langle S \rangle$ and $j$ simplifies to

$$\langle S \rangle = \frac{m^*}{2\pi \hbar^2 e n_e} \left( \begin{array}{cc} 0 & \beta + \alpha \\ \beta - \alpha & 0 \end{array} \right) j,$$  \hspace{1cm} (14)$$

Hence, for the spin accumulation $\langle S_{[110]} \rangle$ and $\langle S_{[1\bar{1}0]} \rangle$ provided by the electrical current along [110] and [1\bar{1}0] crystallographic directions, respectively we obtain

$$\frac{\langle S_{[110]} \rangle}{\langle S_{[1\bar{1}0]} \rangle} = \frac{\alpha + \beta}{\beta - \alpha}.$$  \hspace{1cm} (15)$$

From equations (15) or (14) one can see that the spin accumulation is strongly anisotropic if the constants $\alpha$ and $\beta$ are close to each other. As it was discussed earlier, the reason of such an anisotropy can be understood either from the spin-orbit splitting different for different direction of the carrier motion, or from the anisotropic spin relaxation times $\tau_0$.

Equations (14) and (15) show that measuring of the spin polarization for current flowing in particular crystallographic directions one can map the spin–orbit constants and deduce their magnitudes. To find the absolute values of the spin–orbit constants one needs to know the carrier effective mass $m^*$ and quasi-particle life time $\tau_0$. The latter can be roughly estimated from the carrier mobility. Indeed, though the band structure described by the Hamiltonian [10] is anisotropic, the electrical conductivity remains isotropic that can be verified directly computing the electrical current

$$j = -e \sum_s \int \frac{d^2 k}{(2\pi)^2} v_s g_1(s, k).$$

Taking this integral in the same manner as in Eq. (1) one can see that the anisotropy of the group velocity $v_s$ is compensated by the one stemming from the distribution function $g_1(s, k)$. Therefore, the electrical conductivity is described by the Drude-like formula $\sigma = e^2 n_e \tau_0 / m^*$ with

$$n_e = \frac{m^* E_F}{\pi \hbar^2} + \left( \frac{m^*}{\hbar^2} \right) \frac{\alpha^2 + \beta^2}{\pi},$$

being the carrier concentration. Using this Drude-like relation one can estimate the quasiparticle life time as $\tau_0 \sim m^* \mu / e$. To give an example, an n-type InAs quantum well [117] with $\mu = 2 \cdot 10^{13} \text{cm}^2/(V \cdot \text{s})$ and $m^* \sim 0.03 m_0$ with $m_0$ being the bare electron mass yields the quasiparticle life time $\tau_0 \sim 4 \cdot 10^{-13} \text{s}$.

Above we considered the regime linear in the electric current. Stronger electric fields provide a needle shape electron distribution known as “streaming” regime, in which each free charge carrier accelerates quasiballistically in the “passive” region until reaching the optical-phonon energy, then emits an optical phonon and starts the next period of acceleration [135]. The inclusion of spin degree of freedom into the streaming-regime kinetics gives rise to rich and interesting spin-related phenomena. In particular, the current-induced spin-orientation remarkably increases, reaching a high value $\simeq 2\%$ in the electric field $\sim 1 \text{kV/cm}$. The spin polarization enhancement is caused by squeezing of the electron momentum distribution in the direction of drift [73, 100]. Note that further increase in the field spin polarization falls.

Finally we would like to address another mechanism of the current-induced spin polarization and the spin-galvanic effect proposed in Refs. [69, 136] and [137], respectively. It does not require the spin splitting of electron spectrum and is based on spin-dependent electron scattering by static defects or phonons which is asymmetric in the momentum space in gyrotropic structures [116, 138]. The spin polarization is then occurs due to asymmetric spin-dependent scattering followed by the processes of spin relaxation which can be of both the Elliott-Yafet and the Dyakonov-Perel types. The scattering-related mechanism is expected to dominate at room temperature and/or electron gas of high density. It may be responsible for the observed current-induced spin polarization in n-doped InGaAs epilayers [54], where the anisotropy of both, current-induced spin polarization and spin splitting, was studied in the same structure and the smallest spin polarization was surprisingly observed for the electric current applied in the crystal directions corresponding to larger spin splitting. While might be important in some particular cases, a detailed consideration of this mechanism is out of scope of our chapter.

**CONCLUDING REMARKS**

We have given an overview of current-induced spin polarization in gyrotropic semiconductor nanostructures. Such a spin polarization as response to a charge current, may be classified as the inverse of the spin-galvanic effect, and sometimes is called as magneto-electrical effect or Edelstein (Rashba-Edelstein) effect. Apart from reviewing the experimental status of affairs, we have provided a detailed theoretical description of both effects in terms of a phenomenological model of spin-dependent relaxation processes, and an alternative theoretical approach based on the quasi-classical Boltzmann equation. Two microscopic mechanisms of this effect, both involving k-linear band spin splitting, are known so far: Scattering mechanism based on Elliott-Yafet spin relaxation and precessional mechanism due to D’yakonov-Perel’ spin relaxation. We note, that recently, another mechanism of the current-induced spin polarisation [136] and spin-galvanic effect [137] which may dominate at room temperature has been proposed. It is based on spin-dependent asymmetry of electron scattering and out of the scope of the present chapter. The relative direction between electric current and nonequilibrium spin for all mechanisms is
determined by the crystal symmetry. In particular, we have discussed the anisotropy of the inverse spin-galvanic effect in (001)-grown zinc-blende structure based QWs in the presence of spin-orbit interaction of both the Rashba and the Dresselhaus type. Combined with the theoretical achievements derived from the Boltzmann approach, the precise measurement of this anisotropy allows in principal to determine the absolute values of the Rashba and the Dresselhaus spin-orbit coupling parameter. Moreover, these interactions can be used for the manipulation of the magnitude and direction of electron spins by changing the direction of current, thereby enabling a new degree of spin control. We focused here on the fundamental physics underlying the spin-dependent transport of carriers in semiconductors, which persists up to room temperature [39, 40, 46], and, therefore, may become useful in future semiconductor spintronics.

---

[15] We remind that the gyrotropic point group symmetry makes no difference between certain components of polar vectors, like electric current or electron momentum, and axial vectors, like a spin or magnetic field, and is described by the gyration tensor \[ \mathbf{R} \]. Gyrotropic media are characterized by the linear in light or electron wavevector \( \mathbf{k} \) spatial dispersion resulting in optical activity (gyrotropy) or Rashba/Dresselhaus band spin-splitting in semiconductor structures \[ \mathbf{R} \] \[ \mathbf{D} \], respectively. Among 21 crystal classes lacking inversion symmetry, 18 are gyrotropic, from which 11 classes are enantiomorphic (chiral) and do not possess a reflection plane or rotation-reflection axis \[ \mathbf{R} \] \[ \mathbf{D} \]. Three nongyrotropic noncentrosymmetric classes are \( T_d, C_{3h} \) and \( D_{3h} \). We note that it is often, but misleading, stated that gyrotropy (optical activity) can be obtained only in non-centrosymmetric crystals having no mirror reflection plane. In fact 7 non-enantiomorphic classes groups (\( C_s, C_{2v}, C_{3v}, S_4, D_{2d}, C_{4v} \) and \( C_{6v} \)) are gyrotropic also allowing spin orientation by the electric current.
