Abstract. Model checking and automated theorem proving are two pillars of formal methods. This paper investigates model checking from an automated theorem proving perspective, aiming at combining the expressiveness of automated theorem proving and the complete automaticity of model checking. The focus of this paper is on the verification of temporal logic properties of Kripke models. The main contributions of this paper are: first the definition of an extended computation tree logic that allows polyadic predicate symbols, then a proof system for this logic, taking Kripke models as parameters, then, the design of a proof-search algorithm for this calculus and a new automated theorem prover to implement it. The verification process is completely automatic, and produces either a counterexample when the property does not hold, or a certificate when it does. The experimental result compares well to existing state-of-the-art tools on some benchmarks, including an application to air traffic control and the design choices that lead to this efficiency are discussed.

1 Introduction

Model checking [12,6,2] and automated theorem proving [18,21,8] are two pillars of formal methods. They differ by the fact that model checking often uses decidable logics, such as propositional modal logics, while automated theorem proving mostly uses undecidable ones, such as first-order logic. Nevertheless, model checking and automated theorem proving have a lot in common, in particular, both of them are often based on a recursive decomposition of problems, through the application of rules.

Links between model checking and automated theorem proving have been investigated for long. For instance, Bounded Model Checking (BMC) [4,32,5] is based a reduction of model checking to satisfiability of boolean or quantified boolean formulae.

This paper investigates model checking from an automated theorem proving perspective, but instead of using a reduction, it directly provides a proof system to solve model checking problems. This permits to combine the expressiveness of automated theorem proving and the complete automaticity of model checking.
The first contribution of this paper is to propose a slight extension of CTL\cite{15,16}, called CTL\_P. In this extension, we may refer explicitly to states of the model. The proposition \( P(s) \), for instance, expresses what is usually expressed with the judgment \( s \models P \). Thus \( P \) here is not an proposition symbol, but a unary predicate symbol. This transformation can be compared to the introduction of adverbial phrases in natural languages, where we can say not only “The sky will be blue in the future” but also “The sky will be blue on Monday”. A proposition such as \( EX(P)(s) \) must then be written \( EX_x(P(x))(s) \). Indeed, as the symbol \( P \) is now a unary predicate symbol, it must be applied to a state variable, which is bound by the modality \( EX \). This allows to introduce polyadic predicate that do not only express properties of states, but also relations between states. For instance, we can express the existence of a sequence of states \( s = s_0, s_1, ... \) starting from \( s \) such that for all \( i, s_i \rightarrow s_{i+1} \) and one can buy a left shoe at some state \( s_n \) and then the right shoe of the same pair at a later state \( s_p \). This property is expressed by the formula \( EF_x(EF_y(P(x,y))(x))(s) \).

The second contribution of this paper is to propose a proof system for CTL\_P in the style of a sequent calculus. The proof search in SCTL coincides with checking the validity of a formula in a Kripke model. Using such a proof system has several advantages. First, it permits to give a certificate, a formal proof, for the property when it succeeds. Such a certificate can be verified by an independent proof checker, increasing the confidence in the proved property, and can also be combined with proofs built by other means.

Secondly, when the verification of the given property fails, it permits to generate a counterexample as a proof of the negation of the formula, instead of a sequence of states or trees labeled with states, as in traditional model checkers. In particular, when providing a counterexample for a formula containing nested modalities, such as \( EG_x(EG_y(P(x,y))(x))(s) \), we need to provide a tree labeled with states, in such a way that for each state \( a \) labeling a leaf of this tree, the formula \( EG_y(P(a,y))(a) \) does not hold. That is for each of these states, we need to provide another tree. As we shall see, such a hierarchical tree can be represented as a proof of the formula \( AF_x(AF_y(\neg P(x,y))(x))(s) \).

Different proof systems for temporal logic have been proposed (see, for instance, \cite{16,17,19,27,29,7}). When designing such a proof system, one of the main issues is to handle co-inductive modalities, for instance, asserting the existence of an infinite sequence of which all elements satisfy some property. It is tempting to reflect this infinite sequence as an infinite proof and then use the finiteness of the model to prune the search-tree in a proof search method. Instead, we use the finiteness of the model to keep our proofs finite, like in the usual sequent calculus. This is the purpose of the merge rules of SCTL in Figure 4.

SCTL is shown to be decidable, and proof search in this calculus always terminates.

The third contribution of this paper is an implementation of a proof search method for SCTL. Instead of translating the temporal formulae to Quantified Boolean Formulae (QBFs) \cite{32} or to the format of an existing theorem prover \cite{20}, we develop a new automated theorem prover tailored for SCTL, called SCTLProV, in the programming
The source code of SCTLProV is available online. Designing our own system gives us a lot of freedom to optimize it. For example, the visited states are stored globally in order to avoid visiting repeatedly states during the verification process of SCTLProV. In addition, the set of visited states can be stored as a Binary Decision Diagram (BDD) in order to reduce space occupation. These strategies are commonly used in traditional model checkers, but cannot be realized in usual theorem provers like iProver Modulo. On the other hand, when formally verifying a system, theorem provers usually output proof trees as a diagnosis of the system, while in traditional model checkers, only sequences of states representing the counterexample of properties can be produced. Like usual theorem provers, SCTLProV produces proof trees when verifying a system. Thus, when solving CTL model checking problems, SCTLProV can produce more instructive information than traditional model checkers, and can use more optimization strategies than traditional theorem provers.

To illustrate the efficiency of SCTLProV, we compare it with an automated theorem prover iProver Modulo, a QBF-based bounded model checker Verds, and two BDD-based symbolic model checker NuSMV and NuXMV on several benchmarks. The experimental results show that SCTLProV compares well with these four tools.

The efficiency of SCTLProV depends on the following design choices: the first is that, unlike traditional symbolic model checkers or bounded model checkers, SCTLProV searches states in a doubly on-the-fly (both the transition relation and the formula are unfolded on-the-fly) style. Thus, the state space is usually not needed to be fully generated. This avoids enumerating unneeded states during the verification procedure. The second is that, unlike traditional on-the-fly model checking algorithms for CTL, our proof search algorithm is in continuation-passing style, in order to reduce stack operations.

SCTLProV provides a more expressive input language than most traditional model checkers: it provides both readable notations for the definition of data structures such as records or lists with unbounded length, and arbitrary algorithms for the definitions of transition rules and of properties.

The rest of the paper is organized as follows. In Section 2, we introduce the logic system CTL_P. In Section 3, we introduce the proof system SCTL. In Section 4, we describe the proof search algorithm for SCTL and the prover SCTLProV, which is an implementation of SCTL. In Section 5, we show the verification of properties under fairness constraints in SCTL. In Section 6, we compare, on several benchmarks, SCTLProV with iProver Modulo, Verds, NuSMV, and NuXMV, respectively. We also present an application of SCTLProV to model and analyze a concept of operations for air traffic control.
the detailed proof of the soundness and completeness of the SCTL system. D shows the detailed proof of the correctness of the proof search method.

2 CTL$_P$

In this section, we present the logic CTL$_P(M)$ taking a Kripke model $M$ as the parameter.

**Definition 1 (Kripke model).** A Kripke model $M$ is given by

- a finite non-empty set $S$, whose elements are called states,
- a binary relation $\rightarrow$ defined on $S$, such that for each $s$ in $S$, there exists at least one $s'$ in $S$, such that $s \rightarrow s'$,
- and a family of relations, each being a subset of $S^n$ for some natural number $n$.

We write $\text{Next}(s)$ for the set $\{s' \mid s \rightarrow s'\}$ which is always finite. A path is a finite or infinite sequence of states $s_0, ..., s_n$ or $s_0, s_1, ...$ such that for each $i$, if $s_i$ is not the last element of the sequence, then $s_{i+1} \in \text{Next}(s_i)$. A path-tree is a finite or infinite tree labeled by states such that for each internal node labeled by a state $s$, the children of this node are labeled by the elements of $\text{Next}(s)$.

Properties of such a model are expressed in a language tailored for this model that contains a constant for each state $s$, also written $s$; and a predicate symbol for each relation $P$, also written $P$.

The grammar of CTL$_P(M)$ formulae is displayed below:

$$
\phi :: \{ \top \mid \perp \mid P(t_1, ..., t_n) \mid \neg P(t_1, ..., t_n) \mid \phi \land \phi \mid \phi \lor \phi \mid
\hspace{1cm}
\begin{array}{l}
\text{AX}_x(\phi)(t) \mid \text{EX}_x(\phi)(t) \mid \text{AF}_x(\phi)(t) \mid \text{EF}_x(\phi)(t) \mid
\text{AR}_{x,y}(\phi_1, \phi_2)(t) \mid \text{EU}_{x,y}(\phi_1, \phi_2)(t)
\end{array}
\}
$$

where $x$, $y$ are variables, and each of $t$ and $t_1 ... t_n$ is either a constant or a variable.

Note that in this language, modalities are applied to formulae and states, binding variables in these formulae. More explicitly, modalities $\text{AX}$, $\text{EX}$, $\text{AF}$, and $\text{EF}$ bind the variable $x$ in $\phi$, and modalities $\text{AR}$ and $\text{EU}$ bind respectively the variable $x$ in $\phi_1$ and $y$ in $\phi_2$. Also, the negation is applied to atomic formulae only, so, as usual, negations must be pushed inside the formulae. We use the notation $(t/x)\phi$ for the substitution of $t$ for $x$ in $\phi$. As usual, in presence of binders, substitution avoids captures.

The following abbreviations are used.

- $\phi_1 \Rightarrow \phi_2 \equiv \neg \phi_1 \lor \phi_2$,
- $\text{EF}_x(\phi)(t) \equiv \text{EU}_{x,z}(\top, \phi)(t)$,
- $\text{ER}_{x,y}(\phi_1, \phi_2)(t) \equiv \text{EU}_{y,z}(\phi_2, ((z/x)\phi_1 \land (z/y)\phi_2))(t) \lor \text{EG}_y(\phi_2)(t)$, where $z$ is a variable that occurs neither in $\phi_1$ nor in $\phi_2$,
- $\text{AG}_x(\phi)(t) \equiv \neg (\text{EF}_x(\neg \phi)(t))$,
- $\text{AU}_{x,y}(\phi_1, \phi_2)(t) \equiv \neg (\text{ER}_{x,y}(\neg \phi_1, \neg \phi_2)(t))$.

Hereafter, a formula starting with one of the modalities $\text{AF}$, $\text{EF}$, $\text{AU}$ and $\text{EU}$ will be called an inductive formula; and a formula starting with one of the modalities $\text{AR}$, $\text{ER}$, $\text{AG}$ and $\text{EG}$ will be called a co-inductive formula.
The spatial property that the distance between state the unmanned vehicle, i.e., the initial state; and atomic formula $D$ formula $\phi$

Let $AG$ From the definition above, we obtain

Remark 1. From the definition above, we obtain $M \models EF_x(\phi)(s)$, if there exists an infinite path $s_0, s_1, \ldots$ starting from $s$ and a natural number $j$ such that $M \models (s_j/x)\phi$, etc.

Example 1. This example is motivated from the example presented in [25], where the specification of the motion planning of multi-robot [13] system is characterized by CTL formulae. The specification states that in a partitioned map, each robot starting from an initial section in the map will eventually move to its destination section; at the same time, each robot should avoid reaching some section along the movement steps.

In our example, however, we focus on a "spatial" property (i.e., a property that characterize a relation between states) that can not be easily expressed in CTL, but rather straightforward in CTL-$\rho$.

Consider a special robot: an unmanned vehicle that is designed to move on the surface of a planet, which are partitioned into finite pieces of small areas. The unmanned vehicle moves from one area to another at a time, and the position of the unmanned vehicle is considered to be a state. Thus, the set of possible positions of the unmanned vehicle forms the set of the states, and the moves from one position to another form the transition relation. There is a very basic property that the design of the unmanned vehicle must hold: the unmanned vehicle must not stay in a small set of areas infinitely long, to be more precise, for a given distance $\sigma$, at any state $s$, the unmanned vehicle will eventually move to some state $s'$ such that the distance (not the number of moves) between $s$ and $s'$ is larger than $\sigma$. This property can be easily characterized by the CTL-$\rho$ formula $AG_x(AF_y(D_\sigma(x, y))(x))(s_0)$ (Figure 3), where $s_0$ is the landing position of the unmanned vehicle, i.e., the initial state; and atomic formula $D_\sigma(x, y)$ characterize the spatial property that the distance between state $x$ and state $y$ is larger than $\sigma$.

**Definition 2 (Validity).** Let $M$ be a model and $\phi$ be a closed formula, the validity of a formula $\phi$ in the model $M$ is defined by induction on $\phi$ in Figure 1.

**Remark 1.** From the definition above, we obtain $M \models EF_x(\phi)(s)$, if there exists an infinite path $s_0, s_1, \ldots$ starting from $s$ and a natural number $j$ such that $M \models (s_j/x)\phi$, etc.

**Example 1.** This example is motivated from the example presented in [25], where the specification of the motion planning of multi-robot [13] system is characterized by CTL formulae. The specification states that in a partitioned map, each robot starting from an initial section in the map will eventually move to its destination section; at the same time, each robot should avoid reaching some section along the movement steps.

In our example, however, we focus on a "spatial" property (i.e., a property that characterize a relation between states) that can not be easily expressed in CTL, but rather straightforward in CTL-$\rho$.

**Definition 2 (Validity).** Let $M$ be a model and $\phi$ be a closed formula, the validity of a formula $\phi$ in the model $M$ is defined by induction on $\phi$ in Figure 1.

**Remark 1.** From the definition above, we obtain $M \models EF_x(\phi)(s)$, if there exists an infinite path $s_0, s_1, \ldots$ starting from $s$ and a natural number $j$ such that $M \models (s_j/x)\phi$, etc.

**Example 1.** This example is motivated from the example presented in [25], where the specification of the motion planning of multi-robot [13] system is characterized by CTL formulae. The specification states that in a partitioned map, each robot starting from an initial section in the map will eventually move to its destination section; at the same time, each robot should avoid reaching some section along the movement steps.

In our example, however, we focus on a "spatial" property (i.e., a property that characterize a relation between states) that can not be easily expressed in CTL, but rather straightforward in CTL-$\rho$.

Consider a special robot: an unmanned vehicle that is designed to move on the surface of a planet, which are partitioned into finite pieces of small areas. The unmanned vehicle moves from one area to another at a time, and the position of the unmanned vehicle is considered to be a state. Thus, the set of possible positions of the unmanned vehicle forms the set of the states, and the moves from one position to another form the transition relation. There is a very basic property that the design of the unmanned vehicle must hold: the unmanned vehicle must not stay in a small set of areas infinitely long, to be more precise, for a given distance $\sigma$, at any state $s$, the unmanned vehicle will eventually move to some state $s'$ such that the distance (not the number of moves) between $s$ and $s'$ is larger than $\sigma$. This property can be easily characterized by the CTL-$\rho$ formula $AG_x(AF_y(D_\sigma(x, y))(x))(s_0)$ (Figure 3), where $s_0$ is the landing position of the unmanned vehicle, i.e., the initial state; and atomic formula $D_\sigma(x, y)$ characterize the spatial property that the distance between state $x$ and state $y$ is larger than $\sigma$.
Such a temporal and spatial property cannot be elegantly expressed in traditional temporal logics, as there are no mechanisms to speak about specific states in the syntax of these logics. Even in the semantics, only one state is under consideration at a time, it is hard to express relationships between two states or among tuples of states.

![Fig. 2. Possible positions of a unmanned vehicle.](image)

3 SCTL

In this section, we present $\text{SCTL}(\mathcal{M})$, a proof system for $\text{CTL}_P(\mathcal{M})$. Unlike the usual proof systems, where a formula is provable if and only if it is valid in all models, a formula is provable in $\text{SCTL}(\mathcal{M})$ if and only if it is valid in the model $\mathcal{M}$.

First, consider the formula $AF_x(P(x))(s)$. This formula is valid if there exists a finite tree $T$ whose root is labeled by $s$, such that the children of an internal node labeled by a state $a$ are labeled by the elements of $\text{Next}(a)$, and all the leaves are in $P$. Such a tree can be called a proof of the formula $AF_x(P(x))(s)$.

Now, consider $AF_x(AF_y(P(x,y))(x))(s)$ that contains nested modalities. To justify the validity of this formula, one needs to provide a tree whose root is labeled by $s$, where at each leaf $a$, the formula $AF_y(P(a,y))(a)$ is valid. And to justify the validity of the formula $AF_y(P(a,y))(a)$, one needs to provide other trees. These hierarchical trees can be formalized with the proof rules

\[
\begin{align*}
\vdash (s/x)\phi & \quad \text{AF-R}_1 \\
\vdash AF_x(\phi)(s) & \\
\vdash AF_x(\phi)(s_1) \ldots \vdash AF_x(\phi)(s_n) & \quad \text{AF-R}_2 \\
\vdash AF_x(\phi)(s) & \quad \{s_1, \ldots, s_n\} = \text{Next}(s)
\end{align*}
\]
Example 2. Consider the model formed with the relation

\[
\begin{array}{ccc}
  a & \leftrightarrow & b \\
  & \wedge & \\
  c & \leftrightarrow & d
\end{array}
\]

and the set \( P = \{b, c\} \). A proof of the formula \( \AF_x(P(x))(a) \) is

\[
\frac{\vdash P(b)}{\vdash AF_x(P(x))(b)} \quad \frac{\vdash P(c)}{\vdash AF_x(P(x))(c)}
\]

where besides the rules \( \AF\text{-}R_1 \) and \( \AF\text{-}R_2 \), we use the rule

\[
\frac{\vdash P(s_1, \ldots, s_n)}{\vdash AF_x(P(x))(a)} \quad (s_1, \ldots, s_n) \in P
\]

Example 3. Consider the model formed with the same relation as in Example 2 and the set \( Q = \{(b, d), (c, d)\} \). A proof of the formula \( \AF_x(\AF_y(Q(x, y))(x))(a) \) is given in Figure 3.

\[
\frac{\vdash Q(b, d)}{\vdash AF_y(Q(b, y))(d)} \quad \frac{\vdash AF_y(Q(b, y))(b)}{\vdash AF_x(AF_y(Q(x, y))(x))(b)}
\]

\[
\frac{\vdash Q(c, d)}{\vdash AF_y(Q(c, y))(d)} \quad \frac{\vdash AF_y(Q(c, y))(c)}{\vdash AF_x(AF_y(Q(x, y))(x))(b)}
\]

Fig. 3. A proof of \( \AF_x(\AF_y(Q(x, y))(x))(a) \)

Note that \( \text{SCTL} \) needs neither contraction rules nor multiplicative \( \vee\text{-}R \) rules, because for each atomic formula \( P \), either \( P \) is provable or \( \neg P \) is. Therefore the sequent \( \vdash \neg P \vee P \) is proved by proving either the sequent \( \vdash \neg P \) or the sequent \( \vdash P \). As we have neither multiplicative \( \vee\text{-}R \) rules nor structural rules, if we start with a sequent \( \vdash \phi \), then each sequent in the proof has one formula on the right of \( \vdash \) and none on the left. So, as all sequents have the form \( \vdash \phi \), the left rules and the axiom rule can be dropped as well. In other words, unlike the usual sequent calculus and like Hilbert systems, \( \text{SCTL} \) is tailored for deduction, not for hypothetical deduction.

As the left-hand side of sequents is not used to record hypotheses, we will use it to record a different kind of information, that occur in the case of co-inductive modalities, such as the modality \( \EG \).

Indeed, the case of the co-inductive formula, for example \( \EG_x(P(x))(s) \), is more complex than that of the inductive one, such as \( \AF_x(P(x))(s) \). To justify its validity, one needs to provide an infinite sequence, that is an infinite tree with only one branch, such that the root of the tree is labeled by \( s \), the child of a node labeled by a state \( a \) is
labeled by an element of Next(s), and each node of the tree verifies P. However, as the model is finite, we can always restrict to regular trees and use a finite representation of such trees. This leads us to introduce a rule, called **EG-merge**, that permits to prove a sequent of the form \( \Gamma \vdash EG_x(P(x))(s) \), provided such a sequent already occurs lower in the proof. To make this rule local, we re-introduce hypotheses \( \Gamma' \) to record part of the history of the proof. The sequent have therefore the form \( \Gamma \vdash \phi \), with a non empty \( \Gamma' \) in this particular case only, and the **EG-merge** rule is then just an instance of the axiom rule, that must be re-introduced in this particular case only. The contexts of our sequents can be compared to the notion of history of [7], although our contexts are global while histories are attached to modalities.

The rules of SCTL are depicted in Figure 4.

**Fig. 4. SCTL(M)**

**Theorem 1 (Soundness and Completeness).** If \( \phi \) is closed, then the sequent \( \vdash \phi \) has a proof in SCTL(M) if and only if \( M \models \phi \) for the given Kripke model \( M \).

**Proof.** The soundness and completeness are guaranteed by the finiteness of the Kripke model. The details are presented in [7].
4 SCTLProV

In this section, the system SCTLProV\footnote{https://github.com/terminatorlxj/SCTLProV} that is an implementation of SCTL, is presented and compared with other model checking tools.

4.1 Implementation

We develop, in the programming language OCaml, a new automated theorem prover SCTLProV (Figure 5) to implement SCTL.

SCTLProV reads and interprets an input file containing a description of a Kripke model and a finite number of formulae—the properties to be verified on the model. It searches for a proof of these formulae and outputs a certificate (resp. True) when the verification succeeds, and a counterexample, that is a proof of the negation of the formula, (resp. False) when it does not.

![Fig. 5. A general work flow of SCTLProV.](image)

The basic idea of the proof search procedure in SCTLProV is as follows: first we give an order over the inference rules of SCTL with the same conclusion (if any) and, for each root under consideration of a Continuation Passing Tree (Definition 3), we give an order over the children of this node. Then, to prove an SCTL sequent \( \Gamma \vdash \phi \), we need to find an inference rule of SCTL such that this sequent matches the conclusion of the rule, and then find successively a proof of each premise, according to the given orders. Thus, the proving procedure of sequent \( \Gamma \vdash \phi \) transforms into the proving procedure of all its premises with some specific order. The major techniques used in this implementation are the use of continuations and of memorization.

The use of continuations One of the major techniques for the implementation of SCTL is based on the concept of continuation, usually used in compiling and programming \cite{1,30}. Basically, a continuation is an explicit representation of “the rest of the computation”, which will happen next.

Definition 3 (Continuation Passing Tree). A Continuation Passing Tree (CPT) is a binary tree such that
Fig. 6. Rewritings over CPTs.

- every leaf is labeled by either \( t \) or \( \tilde{t} \), where \( t \) and \( \tilde{t} \) are two different symbols;
- every internal node is labeled by an SCTL sequent.

For each internal node in a CPT, the left subtree is called its \( t \)-continuation, and the right one its \( \tilde{t} \)-continuation. A CPT \( c \) with an SCTL segment \( \Gamma \vdash \phi \) as its root is often denoted by \( \text{cpt}(\Gamma \vdash \phi, c_1, c_2) \), or visually by

\[
\Gamma \vdash \phi \\
\overline{\hspace{1cm}} \\
\vdash c_1 \ c_2
\]

where \( c_1 \) is the \( t \)-continuation of \( c \), and \( c_2 \) the \( \tilde{t} \)-continuation.

CPTs are evaluated to \( t \) or \( \tilde{t} \) using the conditional rewrite rules presented in Figure 6, where conditions are put in brackets, which implement the rules of SCTL.

Note that there is no congruence rule to allow the application of a rewrite rule to a subexpression of a CPT. So reductions always occur at the root of the CPTs.

The aim of the rewrite rules is to decide, for a given sequent \( \Gamma \vdash \phi \), if the CPT \( \text{cpt}(\Gamma \vdash \phi, t, \tilde{t}) \) reduces to \( t \) or \( \tilde{t} \). To do so, we analyze the form of the formula \( \phi \).

If, for instance, it is \( t \vdash \phi_1 \wedge \phi_2 \), we transform, using one of the rewrite rules, the tree.
\[ \text{cpt}(\vdash \phi_1 \land \phi_2, t, f) \] into \[ \text{cpt}(\vdash \phi_1, \text{cpt}(\vdash \phi_2, t, f), f) \] expressing that if the attempt to prove \( \vdash \phi_1 \) succeeds then we attempt to prove \( \vdash \phi_2 \), otherwise it just returns a negative result. The CPT \( \text{cpt}(\vdash \phi_1, \text{cpt}(\vdash \phi_2, t, f), f) \) is in turn transformed according to the form of \( \phi_1 \).

**Proposition 1 (Termination).** \( \text{cpt}(\vdash \phi, t, f) \) always rewrites to \( t \) or \( f \) in finite many steps.

**Proof.** Let \( n \) be the cardinal of \( M \), let \( |\phi| \) be the size of \( \phi \) defined in the usual way, and \( |\Gamma| \) be the length of a merge \( \Gamma \). We define the size of a sequent \( \Gamma \vdash \phi \) as

\[ |\Gamma \vdash \phi| = (|\phi|, (n - |\Gamma|)) \]

We then define the set of operators \( F = \{ t, f, \text{cpt} \} \cup \text{Seq} \), where \( \text{Seq} \) is the set of sequents. The arity of \( \text{cpt} \) is 3, while other elements in \( F \) have arity 0. The partial ordering \( \succ \) over \( F \) is defined as follows:

- \( \text{cpt} \succ t \);
- \( \text{cpt} \succ f \);
- \( \Gamma \vdash \phi \succ \text{cpt} \) for each sequent \( \Gamma \vdash \phi \);
- \( \Gamma \vdash \phi \succ \Gamma' \vdash \phi' \) if \( |\Gamma \vdash \phi| > |\Gamma' \vdash \phi'| \), where \( \succ \) is the lexicographic ordering of natural numbers.

Let \( T(F) \) be the set of terms constructed by operators in \( F \), and \( \succ^* \) be the recursive path ordering on \( T(F) \) proposed by Dershowitz [14], which is restated here.

The recursive path ordering \( \succ^* \) on the set \( T(F) \) of terms over \( F \) is defined recursively as follows:

\[ s = f(s_1, ..., s_m) \succ^* g(t_1, ..., t_n) = t \]

iff one of the following cases holds:

- \( f = g \), and \( \{s_1, ..., s_m\} = \{t_1, ..., t_n\} \);
- \( f \succ g \), and \( \{s\} = \{t_1, ..., t_n\} \);
- \( f \not\succ g \), and either \( \{s_1, ..., s_m\} \succ^* \{t\} \) or \( \{s_1, ..., s_m\} = \{t\} \);

where \( \succ^* \) is the extension of \( \succ \) to multisets. \( \succ^* \) is well-founded since \( \succ \) is well-founded [14].

To prove the termination of the rewriting system, it is sufficient to prove that for each rewriting \( c \rightarrow c' \), \( c \succ^* c' \).

Then we analyze each case of \( c \rightarrow c' \) in the rewriting system. Assume that \( c \) is of the form \( \text{cpt}(\Gamma \vdash \phi_1, c_1, c_2) \).

- If \( \Gamma \vdash \phi = \top \), \( \bot \), \( P(s_1, ..., s_m), \neg P(s_1, ..., s_m) \), or \( \neg P(s_1, ..., s_m) \), and given that \( \{\Gamma \vdash \phi, c_1, c_2\} \succ^* \{c_1\} \) and \( \{\Gamma \vdash \phi, c_1, c_2\} \succ^* \{c_2\} \), then \( c \succ c' \) by the definition of recursive path ordering on \( T(F) \);
- If \( \Gamma \vdash \phi = \phi_1 \land \phi_2 \), and given that \( \{\vdash \phi_1 \land \phi_2, c_1, c_2\} \succ^* \{\vdash \phi_1, \text{cpt}(\vdash \phi_2, c_1, c_2), c_2\} \), we have \( c \succ c' \) by the definition of the recursive path ordering on \( T(F) \);
- If $\Gamma \vdash \phi = \vdash \phi_1 \lor \phi_2$, and given that $\{\vdash \phi_1 \lor \phi_2, c_1, c_2\} \nrightarrow^* \{\vdash \phi_1, c_1, \text{cpt}(\vdash \phi_2, c_1, c_2)\}$, we have $c \nrightarrow^* c'$ by the definition of the recursive path ordering on $T(F)$;
- If $\Gamma \vdash \phi = \text{AX}_x(\phi_1)(s)$, and given that $\{\Gamma \vdash \text{AX}_x(\phi_1)(s), c_1, c_2\} \nrightarrow^* \{\vdash (s_1/x)\phi_1, \text{cpt}(\vdash (s_2/x)\phi_1, \text{cpt}(\ldots\text{cpt}(\vdash (s_m/x)\phi_1, c_1, c_2), \ldots, c_2)\ldots, c_2)\}$ where $\text{Next}(s) = \{s_1, \ldots, s_m\}$, we have $c \nrightarrow^* c'$ by the definition of the recursive path ordering on $T(F)$;
- The $\text{EX}$ case is analogous to the $\text{AX}$ case;
- If $\Gamma \vdash \phi = \text{EG}_x(\phi_1)(s)$,
  - when $\text{EG}_x(\phi_1)(s) \in \Gamma$, then analogous to the first case, $c \nrightarrow^* c'$;
  - when $\text{EG}_x(\phi_1)(s) \notin \Gamma, \text{Next}(s) = \{s_1, \ldots, s_m\}$, and given that $\{\Gamma \vdash \text{EG}_x(\phi_1)(s), c_1, c_2\} \nrightarrow^* \{\vdash (s/x)\phi_1, \text{cpt}(\Gamma' \vdash \text{EG}_x(\phi_1)(s_1), c_1, \text{cpt}(\ldots\text{cpt}(\Gamma' \vdash \text{EG}_x(\phi_1)(s_m), c_1, c_2), \ldots, c_2)\ldots, c_2)\}$, we have $c \nrightarrow^* c'$ by the definition of the recursive path ordering on $T(F)$;
- The cases of $\text{AF}, \text{AR}$, and $\text{EU}$ are analogous to the $\text{EG}$ case.

The correctness of this algorithm is ensured by the proposition below.

**Proposition 2 (Correctness of the Proof Search Algorithm).**

*Given a formula $\phi$, $\text{cpt}(\vdash \phi, t, f) \nrightarrow^* t$ iff $\vdash \phi$ is provable."

**Proof.** Induction on the structure of $\phi$. The details are presented in [3].

Moreover, for a given CPT $\text{cpt}(\vdash \phi, t, f)$, when we memorize the already visited states to avoid visiting them again during the proof of each modality, each sub-formula of $\phi$ appears, in the worst case, $|\mathcal{M}|$ times in the root of all CPTs in the rewriting steps, where $|\mathcal{M}|$ is the number of states in the Kripke model under consideration. Therefore, the time complexity of our proof search algorithm is $O(|\phi| \times |\mathcal{M}|)$, where $|\phi|$ is the size of the formula $\phi$ to be proved and $|\mathcal{M}|$ that of the model.

The pseudo code of the proof search algorithm is depicted in Figure 7.

In addition, the rewriting steps are memorized to build a proof tree after the end of the proof search.

![Fig. 7. The main algorithm](image)

**Example 4.** The use of rules in Figure 6 are illustrated in Figure 8 on the proof of Example 2.
Fig. 8. An illustration of CPT rewrtings.

Step 1. At this step, on the left side of $\frac{1}{3}$, the root of the CPT is $\vdash A F_x(P(x))(a)$. We need to decide whether $\vdash A F_x(P(x))(a)$ is provable, which is not known at that moment yet. So we have to decide first whether $P(a)$ is provable, and then both $A F_x(P(x))(b)$ and $A F_x(P(x))(c)$ are successively provable, corresponding applying the $A F$-$R_1$ rule and the $A F$-$R_2$ rule, respectively. We encode those two steps in a single CPT, which is the one on the right side of $\frac{1}{3}$.

Step 2. Since the atomic formula $P(a)$ is not provable, the CPT on the left side of $\frac{2}{3}$ reduces to its right subtree (f-continuation), which is the CPT on the right side of $\frac{2}{3}$.

Step 3. Like at step 1, we need to decide whether $A F_x(P(x))(a) \vdash A F_x(P(x))(b)$ is provable, which is not known at that moment yet. So we encode the left subtree (t-continuation) of the CPT which is on the left side of $\frac{3}{3}$, and, by the $A F$-$R_1$ rule and the $A F$-$R_2$ rule, the two steps to find successively the proofs of $\vdash P(b)$ and of $A F_x(P(x))(a)$, $A F_x(P(x))(b) \vdash A F_x(P(x))(d)$ into the CPT which is on the right side of $\frac{3}{3}$.

Step 4. Like at step 2, we can judge the atomic formula $P(b)$ is provable immediately. So the CPT on the left side of $\frac{4}{3}$ reduces to its left subtree (t-continuation) which is on the right side of $\frac{4}{3}$.

Step 5. Like at step 1 and 3, we can not judge whether the sequent $A F_x(P(x))(a) \vdash A F_x(P(x))(c)$ is provable immediately, so we encode the two steps to find successively the proofs of $\vdash P(c)$ and $A F_x(P(x))(a)$, $A F_x(P(x))(b) \vdash A F_x(P(x))(d)$ into the CPT which is on the right side of $\frac{5}{3}$.
Step 6. Like at step 2 and 4, as the atomic formula $P(c)$ is provable, so the CPT on the left side of $\xrightarrow{6}$ reduces to its left subtree (t-continuation) which is $t$. Now, the proof search of $\vdash AF_x(P(x))(a)$ terminates, and we can judge that this sequent is provable.

Memorization In the proof search of sequents with co-inductive formulae (formulae with modality $EG$ or $AR$), the merge rules are used to assert that some property holds on an infinite path of states. For every merge rule, the formulae need to be memorized are with the same modality, whereas the only differences are the states appearing in the formulae. Thus, it is sufficient to memorize only the states, not the whole formulae, in the implementation of every merge (i.e., $\Gamma$). Essentially, each construction of a merge is implemented by memorizing an infinite path where all states verify some property.

What is worth mentioning is the proof search of sequents with inductive formulae (formulae with modality $AF$ or $EU$). Although there are no merge rules for the proof of this kind of sequents, merges are also helpful to avoid infinite proof search, when the formula is not provable, that is when its (co-inductive) negation is. For instance, for the proof search of the sequent $\vdash EU_{x,y}(\phi_1,\phi_2)(s)$, we need to find a finite path where in the last states $\phi_2$ holds, and in all other states $\phi_1$ holds. Although we are not finding infinite paths, we still need to avoid our proof search falling into an infinite path. Thus, as an optimization in the proof search of inductive formulae, we also keep merges in the rewriting rules. Note that merges are not reflected in the proof rules for the $AF$ and $EU$ cases. The reason is that, in the proof rules, we only care about the shape of the proof tree, not how the proof tree is constructed. It is only in the construction of proof trees where merges for $AF$ and $EU$ are mentioned.

As another optimization of the proof search algorithm, we use a global memory to remember, for each sub-formula $\phi$, the states visited during the proof search of this formula, and avoid visiting states that are already in this memory. This memory can either be a hash table or a BDD, each having advantages and disadvantages. This memory helps to avoid constructing the same merges repeatedly. This optimization does not break the correctness property of the proof search algorithm, as we are only omitting repeatedly rewriting steps on CPTs.

4.2 Relations with some model checking techniques

In this section, we discuss the relations of the techniques adopted in SCTLProV with those in some other CTL model checking approaches.

BDD-based symbolic model checking When a Kripke model contains mostly boolean variables, for instance in model checking for hardware problems, using BDDs to memorize states is an effective way to reduce space during verification procedure. The best known BDD-based symbolic model checker is NuSMV [23][11], and its extension NuXMV [10]. To illustrate verification procedure in a BDD-based symbolic model checker, let us consider, for instance, a Kripke model with the initial state $s_0$ and a transition relation $T$. To check whether $M, s_0 \models EF\phi$ holds in such a model checker, say NuSMV, first one needs to calculate the least fixed point $\text{lfp} = \mu Y.(\phi \lor EXY)$,
then check whether $s_0 \in \text{lfp}$ \cite{22,11}. Calculating the lfp corresponds to unfolding the transition relation $T$, where states that are not reachable from $s_0$ may be involved.

The verification procedure in SCTLProV differs from traditional CTL symbolic model checkers. For instance, unlike in NuSMV, there is no need for SCTLProV to calculate a fixed point of the transition relation. Instead, unfolding of the transition relation stops as soon as the given property is proved or its negation is proved. Moreover, SCTL-ProV can memorize visited states either directly when there are many non-boolean variables in the model, or using BDDs when the model contains mostly boolean variables. In the latter case, unlike NuSMV that encodes models and properties into BDDs before searching state space, SCTLProV searches states directly on the Kripke model under consideration, using BDDs to memorize the visited states only.

**On-the-fly model checking**  The on-the-fly style of searching state space helps avoid exploring unneeded states. Indeed, in on-the-fly model checking, usually, there is no need to generate the full state space. Traditional on-the-fly CTL model checking algorithms \cite{31,3} are usually recursive, i.e., the unfolding of the formula and the transition rules are performed recursively. These recursive based algorithms usually involve a lot of stack operations when verifying properties over big size Kripke models. These stack operations may consume much time during the verification processes.

In SCTLProV, the proof search of a formula mimics a double on-the-fly style model checking, that is, unfolding on demand both transition relations and the formulae. However, unlike traditional on-the-fly model checking algorithms, our algorithm is in continuation-passing style, which contains only constant stack operations \cite{30}. In the programming language theory, a continuation is an explicit representation of the rest of the computation. A function is said in continuation-passing style (CPS), if it takes an extra argument, the continuation, which decides what will happen to the result of the function. This method, usually used in compiling and programming, can help, among others, to reduce considerably the size of the stacks \cite{17,130}.

We would like to compare our algorithm in SCTLProV to those given in \cite{31} and \cite{3}, respectively. However, as far as we know, there are no tools based on these algorithms that can fully solve CTL model checking problems. To show that using continuation-passing style is not a trivial improvement, we designed therefore a recursion variant of SCTLProV, called SCTLProV$_R$ \cite{22,11}. The difference between SCTLProV$_R$ and SCTLProV is that, instead of using continuations, SCTLProV$_R$ uses recursion calls to prove sub-formulae and search state space. We will compare the experimental results of SCTLProV and SCTLProV$_R$ in Section \ref{sec:experiments}.

**Bounded model checking**  For traditional BMC tools, where the temporal formulae under proving are unfolded on a set of traces with limited length once for all. For example, in model checking $M, s_0 \models_{k+1} EF\phi$, one unfolding step of the $EF$ formula involves $k + 1$ unfolding steps of the transition relation $T$, that is, BMC tools need to deal with the bulky formula $\phi$.

\footnote{https://github.com/terminatorlxj/SCTLProV$_R$}
\[ |M, EF\phi|_{k+1} := \bigwedge_{i \geq 0} T(s_i, s_{i+1}) \land \bigvee_{j \geq 0} \phi(s_j) \]

To avoid exploring unnecessary states in \( M \), SCTLProV unfolds on demand the transition relation \( T \). Thus, in SCTL, one unfolding step of a formula involves at most one unfolding step of the transition relation. In fact, to verify transition relation \( T \) and the formula \( EF_\phi(s_0) \) as
\[
\text{unfold}(S, EF_\phi(s_0)) := \phi(s_0) \land (s_0 \notin S) \land T(s_0, s_{i+1}) \land \text{unfold}(S \cup \{s_i\}, EF_\phi(s_{i+1}))
\]
where \( S \) is a set representing the visited states during the proof search, which is in fact our implementation of the merge rule of Figure 4.

5 SCTL with fairness constraints

Fairness is an important aspect in verifying concurrent systems. Fairness assumptions often rule out unrealistic behaviors, and are often necessary to establish liveness properties [2]. For instance, in a mutual exclusion algorithm of two processes, we usually need to consider a fair scheduling of the execution of the processes, i.e., no process waits infinitely long. Such fairness constraints can also be defined in SCTL. Our definition of fairness coincides with that in [22], i.e., the path quantifiers apply to those paths along which each formula in a set \( C \) holds infinitely often. For instance, \( EF \) means that there exists a path such that each formula in \( C \) is true infinitely often and \( f \) is true in this path.

We define the fairness constraint \( C \) as a set of SCTL formulae; an infinite path is fair under fairness constraint \( C \) if and only if for each SCTL formula \( \phi \in C \), \( \phi \) is valid infinitely often on this path. Formula \( EG_\phi(t) \) is valid if and only if there exists an infinite path, fair under \( C \), starting from state \( t \) such that for all state \( s \) in this path, \((s/x)\phi \) is valid. Similarly, formula \( AF_\phi(t) \) is valid if and only if for each infinite path, fair under \( C \), starting from state \( t \) such that there exists a state \( s \) on this path and \((s/x)\phi \) is valid.

Similar to [22], other SCTL formulae with fairness constraints can be characterized in terms of \( EG_\phi \) formulae and \( AF_\phi \) formulae:
\[
\begin{align*}
E_C X_\phi(t) &= EX_\phi(t) \land E_C G_\phi(\top)(t) \\
A_C X_\phi(t) &= AX_\phi(t) \lor A_C F_\phi(\bot)(t) \\
E_C U_{x,y}(\phi_1, \phi_2)(t) &= EU_{x,y}(\phi_1, \phi_2 \land E_C G_\phi(\top)(y))(t) \\
A_C R_{x,y}(\phi_1, \phi_2)(t) &= AR_{x,y}(\phi_1, \phi_2 \lor A_C F_\phi(\bot)(y))(t)
\end{align*}
\]

Given that SCTL is sound and complete, to prove \( EG_\phi(t) \) is equivalent to prove \( EF_\phi(t) \) where only fair paths are considered, i.e., to prove the existence of a fair path on which \( \phi \) is always provable. Similarly, to prove \( AF_\phi(t) \) is equivalent to prove \( AF_\phi(t) \) where only fair paths are considered, i.e., to prove the absence of
a fair path on which \( \phi \) is always not provable. Thus, to prove SCTL formulae with fairness constraints, we need a mechanism to decide the existence of fair paths.

According to Proposition 3 and Proposition 4 shown below, we can decide the existence of a fair path in finite steps, which is exactly the purpose of our merges. To be more precise, when the merge rule is applied, we check the fairness of the path constructed and discard those that are not fair: i.e., we only consider merges where each formula in \( C \) is provable in some state of a loop.

**Proposition 3.** For a set \( C \) of SCTL formulae and an infinite sequence of states \( \sigma = s_0, s_1, \ldots \) such that for all \( i, s_i \rightarrow s_{i+1}, \) if each element of \( C \) is valid infinitely often in \( \sigma \), then there exists a finite sequence of states \( \sigma_f = s_0', s_1', \ldots, s_n' \) such that for all \( 0 \leq j \leq n - 1 \), \( s'_j \rightarrow s'_{j+1} \), and there exists \( 0 \leq p \leq n - 1 \) such that \( s_n' = s_p' \), all the \( s'_j \) are among \( \sigma \), and for each element \( f \in C, f \) is valid in some state \( s'_p \) where \( p \leq q \leq n \).

**Proof.** As the number of states is finite, there exists a set of states \( S \), such that each state \( s \in S \) appears infinitely often in \( \sigma \), and each formula \( f \in C \) is valid in some state in \( S \). Otherwise, if for each set \( S' \) of states that occur infinitely often in \( \sigma \), there exists some formula \( f \in C \) such that \( f \) is not valid in any element of \( S' \), then \( f \) is not valid in any state of \( \sigma \) that occur infinitely often, and thus \( f \) is not valid infinitely often. Assume \( S = \{s_{i_1}, s_{i_2}, \ldots, s_{i_k}\} \) such that \( i_1 \leq i_2 \leq \ldots \leq i_k \), then let \( s_{i_p} = s_{i_1} \), and \( s_{i_k} = s_{i_k} \), such that \( i_k' \geq i_k \) and \( s_{i_k'} = s_{i_k} \).

**Proposition 4.** For a set \( C \) of SCTL formulae and a finite sequence of states \( \sigma_f = s_0, s_1, \ldots, s_n \) such that for all \( 0 \leq i \leq n - 1 \), \( s_i \rightarrow s_{i+1} \), there exists \( 0 \leq p \leq n, s_p = s_n \), and every formula in \( C \) is valid in some states between \( s_p \) and \( s_n \) in the sequence, then there exists an infinite sequence of states \( \sigma = s_0', s_1', \ldots \) such that for all \( i, s_i' \rightarrow s_{i+1}' \), all the \( s'_j \) are among \( s_0, s_1, \ldots, s_n \), and every formula in \( C \) is valid infinitely often in the infinite sequence.

**Proof.** The sequence \( \sigma = s_0, \ldots, s_{p-1}, s_p, \ldots, s_{n-1}, \ldots \) verifies the properties above.

### 6 Example and Experimental Evaluation

To illustrate the feasibility and the efficiency of SCTLProV, we first use an example (Subsection 6.1) to show an application of SCTLProV, and then evaluate several benchmarks (benchmark #1, #2 and #3 in Subsection 6.2) and benchmark #4 in Subsection 6.3 to show the efficiency of SCTLProV, and compare the experimental results with four other verification tools: the Resolution-based theorem prover iProver based on BDDs, the QBF-based theorem prover Verds version 1.49, the unbounded model checker NuSMV version 2.6.0 and its extension NuXMV version 1.0.0. All examples and benchmarks are tested on a Linux platform with 3.0 GB memory and a 2.93GHz × 4 CPU, and the time limit is 20 minutes.

All benchmarks used in this paper are available online.\( ^\text{13} \)\[https://github.com/terminatorlxj/ctl_benchmarks\]
6.1 An illustrative example

**Example 5 (A Mutual Exclusion Problem).**

This example is a mutual exclusion algorithm of two concurrent processes (process \( A \) and process \( B \)) described in [26]. Mutual Exclusion means that both two processes can not enter the critical section at the same time. This problem is addressed in several model checkers. In our formulation of this problem, a shared variable \( mutex \) is used to remember the number of processes that have entered the critical section. A violation of Mutual Exclusion means that in some state of the program, the value of the shared variable \( mutex \) is 2.

Model mutual()

```
Var {
    flag : Bool; mutex : (0 .. 2);
    a : (1 .. 6); b : (1 .. 6);
}
Init {
    flag := false; mutex := 0; a := 1; b := 1;
}
Transition {
    a = 1 && flag = false : {a := 2;};
    a = 2 : {a := 3; flag := true;};
    /*A has entered the critical section*/
    a = 3 : {a := 4; mutex := mutex + 1;};
    /*A has left the critical section*/
    a = 4 : {a := 5; mutex := mutex - 1;};
    a = 5 : {a := 6;};
    b = 1 && flag = false : {b := 2;};
    b = 2 : {b := 3; flag := true;};
    /*B has entered the critical section*/
    b = 3 : {b := 4; mutex := mutex + 1;};
    /*B has left the critical section*/
    b = 4 : {b := 5; mutex := mutex - 1;};
    b = 5 : {b := 6;};
}
Atomic {bug(s) := s(mutex) = 2;}
Spec{find_bug := EU(x, y, TRUE, bug(y), ini);}
```

**Fig. 9.** The input file “mutual.model”.

In the input file (Figure 9), variable \( flag \) is a signal indicating whether there exists a process is running; Variables \( a \) and \( b \) indicate the program counters of the two processes, respectively. The property to be checked is that whether both processes are in the critical section at the the same time. We check this property in SCTLProV using the following command:

```
sctl -output output.out mutual.model
```

The result is as follows, which indicates that there is a bug in the mutual exclusion problem, i.e., the mutual exclusion property is violated.

```
verifying on the model mutual...
find_bug: EU(x,y, TRUE, bug(y), ini)
find_bug is true.
```
According to the output above, we can find that after process $A$ have entered the critical section, process $B$ can also enter the critical section.

6.2 Randomly generated programs

We consider three benchmarks in this part. The original description of benchmark #1 is in [32] and also restated here. Based on benchmark #1, we extend the number of variables to tens, hundreds, and even thousands in benchmark #2 and benchmark #3. The randomness of the test cases in three benchmarks makes it rather fair for different CTL model checking approaches, and helps us recognize the strengths and weaknesses of each tool.

Benchmark #1 Benchmark #1 chosen in this subsection is originally introduced by Zhang [32] in the evaluation of model checkers Verds and NuSMV. Later, Ji [20] also uses this benchmark in the evaluation of the theorem prover iProver Modulo and the model checker Verds. This benchmark consists of 2880 randomly generated test cases where two types of random Boolean programs are considered—Concurrent Processes and Concurrent Sequential Processes. In programs with Concurrent Processes, the parameters of the first set of random Boolean programs are as follows.
The shared variables are initially set to a random value in \( \{0, 1\} \), and the local variables are initially set to 0. For each process, the shared variables and the local variables are assigned the negation of a variable randomly chosen from these variables. We test different sizes of the programs with 3 processes \((a = 3)\), and let \( b \) vary over the set of values \( \{12, 24, 36\} \), then set \( c = b/2 \), \( d = c/a \). Each of the 24 properties is tested on 20 test cases for each value of \( b \).

In programs with Concurrent Sequential Processes, in addition to \( a, b, c, d \) specified above, the parameters of the second set of random Boolean programs are as follows.

\[
\begin{align*}
  t : & \text{ number of transitions in a process} \\
  p : & \text{ number of parallel assignments in each transition}
\end{align*}
\]

For each concurrent sequential process, besides the \( b \) Boolean variables, there is a local variable representing program locations, with \( c \) possible values. The shared variables are initially set to a random value in \( \{0, 1\} \), and the local variables are initially set to 0. For each transition of a process, \( p \) pairs of shared variables and local variables are randomly chosen among the shared variables and the local variables, such that the first element of such a pair is assigned the negation of the second element of the pair. Transitions are numbered from 0 to \( t - 1 \), and are executed consecutively, and when the end of the sequence of the transitions is reached, it loops back to the execution of the transition numbered 0. For this type of programs, we test different sizes of the programs with 2 processes \((a = 2)\), and let \( b \) vary in the set of values \( \{12, 16, 20\} \), and then set \( c = b/2 \), \( d = c/a \), \( t = c \), and \( p = 4 \). Similarly, each property is tested on 20 test cases for each value of \( b \).

Twenty-four properties are to be checked in this benchmark: properties \( P_{01} \) to \( P_{12} \) are depicted in Figure 10, and \( P_{13} \) to \( P_{24} \) are simply the variations of \( P_{01} \) to \( P_{12} \) by replacing \( \land \) and \( \lor \) by \( \lor \) and \( \land \), respectively.

\[
\begin{align*}
  P_{01} & : AG(v_{1} \lor v_{2}) \\
  P_{02} & : AF(v_{1} \lor v_{2}) \\
  P_{03} & : AG(v_{1} \Rightarrow AF(v_{2} \lor \bigvee_{i=3}^{c} v_{i})) \\
  P_{04} & : AG(v_{1} \Rightarrow EF(v_{2} \lor \bigvee_{i=3}^{c} v_{i})) \\
  P_{05} & : EG(v_{1} \Rightarrow AF(v_{2} \lor \bigvee_{i=3}^{c} v_{i})) \\
  P_{06} & : EG(v_{1} \Rightarrow EF(v_{2} \lor \bigvee_{i=3}^{c} v_{i})) \\
  P_{07} & : AU(v_{1}, AU(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{08} & : AU(v_{1}, EU(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{09} & : AU(v_{1}, ER(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{10} & : AU(v_{1}, EU(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{11} & : P_{12} \text{ AU}(v_{1}, EU(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{13} & : AR(Axv_{1}, AXAU(v_{2}, \bigvee_{i=3}^{c} v_{i})) \\
  P_{14} & : AR(EXv_{1}, EXEU(v_{2}, \bigvee_{i=3}^{c} v_{i}))
\end{align*}
\]

Fig. 10. Properties \( P_{01}, P_{02}, \ldots, P_{12} \) to be checked in benchmark #1, #2, and #3.
Benchmark #2 and #3 In benchmark #2, we increase the number of state variables in benchmark #1 to 48, 60, or 72 for Concurrent Processes, and 24, 28, or 32 for Concurrent Sequential Processes. The 2880 test cases are also randomly generated. The properties to be checked are the same as in benchmark #1.

In benchmark #3, we increase the number of state variables in benchmark #1 to 252, 504, and 1008 for both Concurrent Processes and Concurrent Sequential Processes, and check the same properties as benchmark #1 and #2.

Experimental data The experimental results are shown below, and the detailed data is in A.

Experimental data for benchmark #1. For 2880 test cases in this benchmark, iProver Modulo can solve 1816 (63.1%) cases, Verds can solve 2230 (77.4%) cases, SCTL-ProV can solve 2862 (99.4%) cases, and both NuSMV and NuXMV can solve all (100%) test cases. The numbers of test cases where SCTLProV runs faster are 2823 (98.2%) comparing with iProver Modulo, 2858 (99.2%) comparing with Verds, 2741 (95.2%) comparing with NuSMV, and 2763 (95.9%) comparing with NuXMV. According to Figure [1] and Figure [2], SCTLProV uses less time and space than the other four tools.

Experimental data for benchmark #2. For 2880 test cases in this benchmark, iProver Modulo can solve 1602 (55.6%) cases, Verds can solve 1874 (65.1%) cases, NuSMV can solve 728 (25.3%) cases, NuXMV can solve 736 (25.6%) cases, and SCTLProV can solve 2597 (90.2%) cases. The numbers of test cases where SCTLProV runs faster are 2597 (90.2%) comparing with iProver Modulo, 2594 (90.1%) comparing with Verds, and 2588 (89.9%) comparing both with NuSMV and NuXMV. According to Figure [3] and Figure [4], SCTLProV uses less time and space than the other four tools.

Experimental data for benchmark #3. For 2880 test cases in this benchmark, iProver Modulo can solve 1146 (39.8%) cases, Verds can solve 352 (12.2%) cases, SCTLProV can solve 1844 (64.0%) cases, while neither NuSMV nor NuXMV can solve any case.

Continuation vs. recursion. To show the importance of using continuation-passing style, we have implemented a recursive version of our tool and compared the time efficiency. In benchmark #1, #2, and #3, SCTLProV solves about 10% more test cases than SCTLProV_R, and it outperforms SCTLProV_R in almost all solvable cases (Table 1). SCTLProV_R is more sensitive to the number of variables than SCTLProV (Figure [5]).

| Bench | SCTLProV solvable | SCTLProV_R solvable | | t(SCTLProV) - t(SCTLProV_R) |
|---|---|---|---|
| #1 | 2862(99.4%) | 2682(93.1%) | 2598(90.2%) |
| #2 | 2597(90.2%) | 2306(80.1%) | 2406(83.5%) |
| #3 | 1844(64.0%) | 1520(52.8%) | 1735(60.2%) |

Table 1. SCTLProV vs. SCTLProV_R
Remark 2. In the comparison of average verification time of SCTLProV and SCTLProV_R, we extend the number of variables in Concurrent Sequential Processes to 72, which is the same as in Concurrent Processes.
6.3 Programs with fairness constraints

In this part, we evaluate benchmark #4, which models mutual exclusion algorithms and ring algorithms. Then, we compare the evaluation results of SCTLProV, Verds, NuSMV, and NuXMV, and we do not consider iProver Modulo because iProver Modulo cannot handle CTL properties with fairness constraints.

Mutual exclusion and ring algorithms. This benchmark consists of two sets of concurrent programs: the mutual exclusion algorithms and the ring algorithms. Both kinds of algorithms consist of a set of concurrent processes running in parallel.

In the mutual exclusion algorithms, the scheduling of processes is simple: for all \( i \) between 0 and \( n - 2 \), process \( i + 1 \) performs a transition after process \( i \), and process 0 performs a transition after process \( n - 1 \). Each formula in the algorithms needs to be verified under the fairness constraint that each process does not starve, i.e., no process waits infinitely long.

Each process in the mutual exclusion algorithms has three internal states: noncritical, trying, and critical. The number of processes vary from 6 to 51. There are five properties specified by CTL formulae are to be verified in mutual exclusion algorithms, as in Table 16. In these formulae, \( non_i(try_i, crit_i) \) indicates that process \( p_i \) has internal state noncritical (trying, critical). Note that because of the scheduling algorithm, processes 0 and 1 are not symmetric, as exemplified by the difference in performance between the properties \( P_4 \) and \( P_5 \).

Each process in the ring algorithms consists of 5 Boolean internal variables indicating the internal state, and a Boolean variable indicating the output. Each process receives a Boolean value as the input during its running time. For a ring algorithm with processes \( p_0, p_1, ..., p_n \), the internal state of \( p_i \) depends on the output of process \( p_{i-1} \), and the output of \( p_{i-1} \) depends on its internal state, where \( 1 \leq i \leq n \). The internal state of \( p_0 \) depends on the output of process \( p_n \), and the output of \( p_n \) depends on the internal state of its own. The number of processes vary from 3 to 10. There are four properties specified by CTL formulae are to be verified in ring algorithms, as in Figure 16. In these formulae, \( out_i \) indicates that the output of process \( p_i \) is Boolean value true.

The experimental results (Table 2 and Table 3) show that SCTLProV solves more test cases than Verds, NuSMV, and NuXMV. At the same time, SCTLProV is more

\[\text{http://ics.ios.ac.cn/~zwh/verds/verds_code/bp12.rar}\]
time and space efficiency in more than 75 percent of the test cases than the other three tools.

The detailed experimental data is shown in [B].

### 6.4 Discussion of the experimental results

In the evaluation of all benchmarks in this paper, the performances of the five tools in the comparisons are affected by two factors: the number of state variables, and the type of the property to be checked. The performances of NuSMV and NuXMV are mainly affected by the number of state variables, while the performances of iProver Modulo, Verds, and SCTLProV are mainly affected by the type of the property to be checked. When the number of state variables is rather small (such as test cases in benchmark #1), NuSMV and NuXMV solves more test cases than iProver Modulo, Verds, and SCTLProV, but when the number of state variables becomes larger (such as test cases in benchmark #2 and #3), they performs worse than the other three tools. When checking properties where nearly all states must be searched (such as AG properties), NuSMV and NuXMV usually perform better than iProver Modulo, Verds, and SCTLProV. However, for most properties, iProver Modulo, Verds, and SCTLProV usually search much less states than NuSMV and NuXMV to check them, and are more
time and space efficiency. Thus, iProver Modulo, Verds and SCTLProV scale up better than NuSMV and NuXMV when checking these properties. Moreover, SCTLProV scales up better than both iProver Modulo and Verds, and outperforms these two tools in most solvable cases.

6.5 An application to the analysis of Air traffic control protocols

As an application to an engineering problem, we present a concept of operations for the Small Aircraft Transportation System (SATS) in SCTLProV.

In this concept of operation, the airspace volume surrounding an airport facility, called the self controlled area, is divided into 15 zones (Figure 17). For instance, the zone holding3(right) is a holding pattern at 3000 feet on the right of the self controlled area. Each zone contains a list of aircraft and 24 transition rules specify different SATS-procedures. For instance, the rule Vertical Entry (right) specifies the vertical entry of an aircraft in the zone holding3(right).

The model is non-deterministic, that is, for a given state, several transitions are possible and all must be considered. As there are no a priori bounds on the number of aircraft in each zone, the number of states in the model is potentially infinite. However, the number of states that are reachable from the initial state is finite: an enumeration of the model shows that there are 54221 such states (and around 3000 in the simplified model where departure operations are not considered).

There are eight properties of the model that we want to verify with SCTLProV, for instance that the SATS concept does not allow more than four simultaneous landing
operations and none of the 15 zones contains too many aircraft (each zone is assigned a maximum number of aircraft and the actual number of aircraft is never higher than this number). The safety property is thus conjunction of these eight properties.

The verification problem is to check that this property holds on every reachable state from the initial state (the state where there are no aircraft on each zone of the self controlled area), so the formula to be checked is $AG_x(\phi)(e)$ where $\phi$ is the conjunction of the eight properties and $e$ is the initial state.

This is a typical model checking problem, but this problem is known to be cumbersome for traditional model checkers [23] because:

- Each state of the model is represented by a complex data structure. For instance, a number of state variables are represented by lists of aircraft with unbounded length.
- The transition rules of the model are complex algorithms. For instance, some transitions rules involve recursive operations on lists of aircraft.
- The properties to be verified in the model are also represented by complex algorithms. For instance, some of the properties are inductively defined over lists of aircraft.

However, this example fits well in SCTLProV that provides a more expressive input language than most traditional model checkers. Indeed, SCTLProV provides both readable notations for the definition of data structures such as records or lists with unbounded length, and arbitrary algorithms for the definitions of transition rules and of properties. So we have been able to check in SCTLProV that the safety property holds on the model, and the verification was executed in less than 30 seconds on the same machine as which the benchmarks are evaluated.

7 Conclusion and future work

This paper provides a first step towards combining model checking and proof checking.

We proposed a parameterized logic $CTL_P$, which extends CTL with polyadic predicate symbols, provided a proof system $SCTL$ for $CTL_P$ in the style of a sequent calculus, and developed a new automated theorem prover SCTLProV from scratch, tailored for SCTL. The particular aspects of SCTLProV are as follows: (1) It performs verification automatically and directly over any given Kripke model. (2) In addition of generating counterexamples when the verification of the given property fails, SCTLProV permits to give a certificate for the property when it succeeds. (3) It performs verification in a continuation-passing style and a doubly on-the-fly style, thanks to the syntax and inference rules of SCTL.

As comparisons to other CTL model checking tools, we consider four other tools: an automated theorem prover iProver Modulo, a QBF-based bounded model checker Verds, and two BDD-based symbolic model checker NuSMV and its extension NuXMV.

There are four benchmarks considered in the comparisons. Benchmark #1 is originally introduced by Zhang [32] in the evaluation of Verds and NuSMV. Later, Ji [20] also uses this benchmark in the evaluation of iProver Modulo and Verds. Based on benchmark #1, we extend the number of state variables into tens, hundreds, and even thousands in benchmark #2 and benchmark #3. In benchmark #4, we verify properties with...
fairness constraints on test cases that models mutual exclusion algorithms and ring algorithms. The experimental results show that SCTLProV has a good performance in terms of time and space consuming, compared to existing tools and, SCTLProV outperforms these four tools in the verification of many kinds of CTL properties, and can be considered complementary to model checkers such as NuSMV and NuXMV, which are among the best CTL model checkers up-to-date. As a matter of fact, NuSMV and NuXMV perform better than SCTLProV in proving some AG properties, while SCTLProV usually performs better with other kinds of properties. Note also that the tool SCTLProV can be seen either as a theorem prover, or a model checker that can produce more information than traditional ones.

The fairness constraints have been added in the implementation, but not yet in CTL_p nor in SCTL. This is left for future work.

Until now, SCTLProV is single-threaded, it is also our future work to write a parallel version to improve efficiency.

A Detailed Experimental data in benchmark #1, #2 and #3

We show the detailed experimental data in benchmark #1, #2 and #3 in the following three subsections.

A.1 Benchmark #1 (Table 4 and 5)

Table 4 shows that SCTLProV outperforms iProver Modulo and Verds, and is almost as good as NuSMV and NuXMV: NuSMV and NuXMV solve all the 2880 problems, while SCTLProV solves 2862 problems (99.4%).

Let us now turn to the efficiency. SCTLProV is much faster than the four other tools (Table 5). Among the problems that can be solved by SCTLProV and iProver Modulo, SCTLProV is faster in 98.2% of these problems, 99.2% when compared with Verds, 95.2% when compared with NuSMV and 95.9% when compared with NuXMV.

Table 5. Cases where SCTLProV runs faster.

A.2 Benchmark #2 (Table 6 and 7)

Our benchmark #2 investigates the performances of iProver Modulo, Verds, NuSMV, NuXMV, and SCTLProV when the size of the model increases.

To do so, we increase the number of variables in the random Boolean programs to 48, 60, or 72 for concurrent processes, and 24, 28, or 32 for concurrent sequential processes. The 2880 test cases are also randomly generated. The properties to be checked are the same as in benchmark #1.

Counting the number of problems that can be solved in 20 minutes, we see that SCTLProV scales up better (Table 6, 7) than the other four tools: SCTLProV solves
more test cases than the other tools and, outperforms the other tools in most solvable test cases.

A.3 Benchmark #3 (Table 8)

We increase, in our benchmark #3, the number of variables to 252, 504 and 1008 for both concurrent and concurrent sequential processes.

We compare the evaluation results of iProver Modulo, Verds, NuSMV, NuXMV, and SCTLProV as in Table 8 and find that, in 20 minutes, SCTLProV can still solve 64.0% of the test cases, while iProver Modulo and Verds solve 39.8% and 12.2% test cases, respectively; moreover, NuSMV and NuXMV solve none.

Table 10. Time and memory usage in benchmark #4 (Ring algorithms).

C Proof of soundness and completeness of SCTL

Proposition 5 and 6 below permit to transform finite structures into infinite ones and will be used in the Soundness proof, while Proposition 7 and 8 permit to transform infinite structures into finite ones and will be used in the Completeness proof.

Proposition 5 (Finite to infinite sequences). Let $s_0, \ldots, s_n$ be a finite sequence of states such that for all $i$ between 0 and $n - 1$, $s_i \rightarrow s_{i+1}$, and $s_n = s_p$ for some $p$ between 0 and $n - 1$. Then there exists an infinite sequence of states $s_0', s_1', \ldots$ such that $s_0 = s_0'$ and for all $i$, $s_i' \rightarrow s_{i+1}'$, and all the $s_i'$ are among $s_0, \ldots, s_n$.

Proof. Take the sequence $s_0, \ldots, s_{p-1}, s_p, \ldots, s_{n-1}, s_p, \ldots$, where $s_0 = s_0'$.

Proposition 6 (Finite to possibly infinite trees). Let $\Phi$ be a set of states and $T$ be a finite tree labeled by states such that, for each internal node $s$, the immediate successors of $s$ are the elements of $\text{Next}(s)$ and each leaf is labeled with a state which is either in $\Phi$ or a label of a node on the branch from the root of $T$ to this leaf. Then, there exists an possibly infinite tree $T'$ labeled by states such that for each internal node $s$ the successors of $s$ are the elements of $\text{Next}(s)$, all the leaves are labeled by elements of $\Phi$, and all the labels of $T'$ are the labels $T$.

**Table 10.** Time and memory usage in benchmark #4 (Ring algorithms).
Proof. Consider for $T'$ the tree whose root is labeled by the root of $T$ and such that for each node $s$, if $s$ is in $\Phi$, then $s$ is a leaf of $T'$, otherwise the successors of $s$ are the elements of $\text{Next}(s)$. It is easy to check that all the nodes of $T'$ are labeled by labels of $T$.

Proposition 7 (Infinite to finite sequences). Let $s_0, s_1, \ldots$ be an infinite sequence of states such that for all $i$, $s_i \rightarrow s_{i+1}$. Then there exists a finite sequence of states $s'_0, \ldots, s'_n$ such that for all $i$ between 0 and $n-1$, $s'_i \rightarrow s'_{i+1}$, $s'_n = s'_p$ for some $p$ between 0 and $n-1$, and all the $s'_j$ are among $s_0, s_1, \ldots$

Proof. As the number of states is finite, there exists $p$ and $n$ such that $p < n$ and $s_p = s_n$. Take the sequence $s_0, \ldots, s_n$.

Proposition 8 (Possibly infinite to finite trees). Let $\Phi$ be a set of states and $T$ be an possibly infinite tree labeled by states such that for each internal node $s$ the successors of $s$ are the elements of $\text{Next}(s)$ and each leaf is labeled by a state in $\Phi$. Then, there exists a finite tree labeled by states such that for each internal node $s$ the successors of $s$ are the elements of $\text{Next}(s)$ and each leaf is labeled with a state which is either in $\Phi$ or also a label of a node on the branch from the root of $T$ to this leaf.

Proof. As the number of states is finite, on each infinite branch, there exists $p$ and $n$ such that $p < n$ and $s_p = s_n$. Prune the tree at node $s_n$. This tree is finitely branching and each branch is finite, hence, by König’s lemma, it is finite.

Theorem 2 (Soundness). Let $\phi$ be a closed formula. If the sequent $\vdash \phi$ has a proof $\pi$, then $\models \phi$.

Proof. By induction on the structure of the proof $\pi$.

- If the last rule of $\pi$ is $\text{atom-R}$, then the proved sequent has the form $\vdash P(s_1, \ldots, s_n)$, hence $\models P(s_1, \ldots, s_n)$.
- If the last rule of $\pi$ is $\neg-R$, then the proved sequent has the form $\vdash \neg P(s_1, \ldots, s_n)$, hence $\models \neg P(s_1, \ldots, s_n)$.
- If the last rule of $\pi$ is $T-R$, the proved sequent has the form $\vdash T$ and hence $\models T$.
- If the last rule of $\pi$ is $\wedge-R$, then the proved sequent has the form $\vdash \phi_1 \wedge \phi_2$. By induction hypothesis $\models \phi_1$ and $\models \phi_2$, hence $\models \phi_1 \wedge \phi_2$.
- If the last rule of $\pi$ is $\vee-R_1$ or $\vee-R_2$, then the proved sequent has the form $\vdash \phi_1 \vee \phi_2$. By induction hypothesis $\models \phi_1$ or $\models \phi_2$, hence $\models \phi_1 \vee \phi_2$.
- If the last rule of $\pi$ is $\text{AX-R}$, then the proved sequent has the form $\vdash \text{AX}_x(\phi_1)(s)$. By induction hypothesis, for each $s'$ in $\text{Next}(s)$, such that $\models (s'/x)\phi_1$, hence $\models \text{AX}_x(\phi_1)(s)$.
- If the last rule of $\pi$ is $\text{EX-R}$, then the proved sequent has the form $\vdash \text{EX}_x(\phi_1)(s)$. By induction hypothesis, for each $s'$ in $\text{Next}(s)$, $\models (s'/x)\phi_1$, hence $\models \text{EX}_x(\phi_1)(s)$.
- If the last rule of $\pi$ is $\text{AF}_1$ or $\text{AF}_2$, then the proved sequent has the form $\vdash \text{AF}_x(\phi_1)(s)$. We associate a finite tree $[\pi]$ to the proof $\pi$ by induction in the following way.
  - If the proof $\pi$ ends with the $\text{AF}_1$ rule with a subproof $\rho$ of the sequent $\vdash (s/x)\phi_1$, then the tree contains a single node $s$. 

SCTL: Towards Combining Model Checking and Proof Checking
• If the proof \( \pi \) ends with the AF-R\(_2\) rule, with subproofs \( \rho_1, \ldots, \rho_n \) of the sequent

\[ \vdash AF_x(\phi_1)(s_1), \ldots, \vdash AF_x(\phi_1)(s_n), \]

respectively, then \( |\pi| \) is the tree \( s(|\pi_1|, \ldots, |\pi_n|) \).

The tree \( |\pi| \) has root \( s \); for each internal node \( s' \), the children of this node are labeled by elements of \( \text{Next}(s') \); and for each leaf \( s' \) the sequent \( \vdash (s'/x)\phi_1 \) has a proof smaller than \( \pi \). By induction hypothesis, for each leaf \( s' \) of \( |\pi| \), \( \models (s'/x)\phi_1 \).

Hence \( \models AF_x(\phi_1)(s) \).

– If the last rule of \( \pi \) is EG-R, then the proved sequent has the form \( \vdash EG_x(\phi_1)(s) \).

We associate a finite sequence \( |\pi| \) to the proof \( \pi \) by induction in the following way.

• If the proof \( \pi \) ends with the EG-merge rule, then the sequence contains a single element \( s \).

• If the proof \( \pi \) ends with the EG-R rule, with subproofs \( \rho_1 \) and \( \pi_1 \) of the sequents

\[ \vdash (s/x)\phi_1 \quad \text{and} \quad \Gamma, EG_x(\phi_1)(s) \vdash EG_x(\phi_1)(s'), \]

respectively, then \( |\pi| \) is the sequence \( s|\pi_1| \).

The sequent \( |\pi| = s_0, s_1, \ldots, s_n \) is such that \( s_0 = s \); for all \( i \) between 0 and \( n \), \( s_i \rightarrow s_{i+1} \); and for all \( i \) between 0 and \( n \), the sequent \( \vdash (s'_i/x)\phi_1 \) has a proof smaller than \( \pi \); and \( s_n \) is equal to \( s \) for some \( p \) between 0 and \( n \). By induction hypothesis, for all \( i \), we have \( \models (s_i/x)\phi_1 \).

Using Proposition 5, there exists an infinite sequence \( s'_0, s'_1, \ldots \) such that for all \( i \), we have \( s'_i \rightarrow s'_{i+1} \), and \( \models (s'_i/x)\phi_1 \).

Hence, \( \models EG_x(\phi_1)(s) \).

– If the last rule of \( \pi \) is AR-R\(_1\) or AR-R\(_2\), then the proved sequent has the form

\[ \vdash AR_x(\phi_1, \phi_2)(s) \]

We associate a finite tree \( |\pi| \) to the proof \( \pi \) by induction in the following way.

• If the proof \( \pi \) ends with the AR-R\(_1\) rule with subproofs \( \rho_1 \) and \( \rho_2 \) of the sequents

\[ \vdash (s/x)\phi_1 \quad \text{and} \quad \vdash (s/x)\phi_2, \]

respectively, or with the AR-merge rule, then the tree contains a single node \( s \).

• If the proof \( \pi \) ends with the AR-R\(_2\) rule, with subproofs \( \rho, \pi_1, \ldots, \pi_n \) of the sequents

\[ \vdash (s/y)\phi_2, \Gamma, AR_x,y(\phi_1, \phi_2)(s) \vdash AR_x,y(\phi_1, \phi_2)(s_1), \ldots, \Gamma, AR_x,y(\phi_1, \phi_2)(s) \vdash AR_x,y(\phi_1, \phi_2)(s_n), \]

respectively, then \( |\pi| \) is the tree \( s(|\pi_1|, \ldots, |\pi_n|) \).

The tree \( |\pi| \) has root \( s \); for each internal node \( s' \), the children of this node are labeled by the elements of \( \text{Next}(s') \); for each node \( s' \) of \( |\pi| \), the sequent \( \vdash (s'/y)\phi_2 \) has a proof smaller than \( \pi \); and for each leaf \( s' \), either the sequent \( \vdash (s'/x)\phi_1 \) has a proof smaller than \( \pi \), or \( s' \) is also a label of a node on the branch from the root of \( |\pi| \) to this leaf. By induction hypothesis, for each node \( s' \) of this tree \( \models (s'/y)\phi_2 \) and for each leaf \( s' \), either \( \models (s'/x)\phi_1 \) or \( s' \) is also a label of a node on the branch from the root of \( |\pi| \) to this leaf. Using Proposition 6 there exists a possibly infinite tree \( T' \) labeled by states such that for each internal node \( s \) the successors of \( s \) are the elements of \( \text{Next}(s) \), for each node \( s' \) of \( T' \), \( \models (s'/y)\phi_2 \), and for each leaf \( s' \) of \( T' \), \( \models (s'/x)\phi_1 \). Thus, \( \models AR_{x,y}(\phi_1, \phi_2)(s) \).

– If the last rule of \( \pi \) is EU-R\(_1\) or EU-R\(_2\), then the proved sequent has the form

\[ \vdash EU_{x,y}(\phi_1, \phi_2)(s) \]

We associate a finite sequence \( |\pi| \) to the proof \( \pi \) by induction in the following way.

• If the proof \( \pi \) ends with the EU-R\(_1\) rule with a subproof \( \rho \) of the sequent

\[ \vdash (s/y)\phi_2, \]

then the sequence contains a single element \( s \).
By induction over the size of $\pi$, if $\pi$ has root $s$, for each internal node $s'$, the children of this node are labeled by the elements of $\text{Next}(s')$, and for each leaf $s', \varphi(s'/x)$. By induction hypothesis, for every leaf $s'$, the sequent $\vdash (s'/x)\varphi_1$ is provable. This way, each subtree $T'$ of $T$, we associate a proof $[T']$ of the sequent $\vdash AF_x(\varphi_1)(s')$ where $s'$ is the root of $T'$, by induction, as follows.

- If $T'$ contains a single node $s'$, then the proof $[T]$ is built with the $AF$-$R_2$ rule from the proof of $\vdash (s'/x)\varphi_1$ given by the induction hypothesis.
- If $T' = s'(T_1, \ldots, T_n)$, then the proof $[T]$ is built with the $AF$-$R_2$ rule from the proofs $[T_1], \ldots, [T_n]$ of the sequents $\vdash AF_x(\varphi_1)(s_1), \ldots, \vdash AF_x(\varphi_1)(s_n)$, respectively, where $s_1, \ldots, s_n$ are the elements of $\text{Next}(s')$. This way, the proof $[T]$ is a proof of the sequent $\vdash AF_x(\varphi_1)(s)$.
If $\phi = EG_x(\phi_1)(s)$, as $\models EG_x(\phi_1)(s)$, there exists a path $s_0, s_1, \ldots$ such that $s_0 = s$ and for all $i$, $\models (s_i/x)\phi_1$. By induction hypothesis, all the sequents $\frac{1}{\phi} (s_i/x)\phi_1$ are provable. Using Proposition 7, there exists a finite sequence $T = s_0, s_1, \ldots, s_n$ such that for all $i$, $s_i \rightarrow s_{i+1}$, the sequent $\frac{1}{\phi} (s_i/x)\phi_1$ is provable and $s_n$ is some $s_p$ for $p < n$. We associate a proof $[s_1, \ldots, s_n]$ of the sequent $EG_x(\phi_1)(s_0), \ldots, EG_x(\phi_1)(s_{i-1}) \frac{1}{\phi} EG_x(\phi_1)(s_i)$ to each suffix of $T$ by induction as follows.

- **The proof $[s_n]$ is built with the EG-merge rule.**
- **If $i \leq n - 1$, then the proof $[s_1, \ldots, s_n]$ is built with the EG-R rule from the proof of $\frac{1}{\phi} (s_i/x)\phi_1$ given by the induction hypothesis and the proof $[s_{i+1}, \ldots, s_n]$ of the sequent $EG_x(\phi_1)(s_0), \ldots, EG_x(\phi_1)(s_i) \frac{1}{\phi} EG_x(\phi_1)(s_{i+1})$.**

This way, the proof $[s_0, \ldots, s_n]$ is a proof of the sequent $\frac{1}{\phi} EG_x(\phi_1)(s)$. If $\phi = AR_{x,y}(\phi_1, \phi_2)(s)$, as $\models AR_{x,y}(\phi_1, \phi_2)(s)$, there exists an possibly infinite tree such that the root of this tree is $s$, for each internal node $s'$, the children of this node are labeled by the elements of Next($s'$), for each node $s'$, $\models (s'/y)\phi_2$ and for each leaf $s'$, $\models (s'/x)\phi_1$. By induction hypothesis, for each node $s'$ of the tree, the sequent $\frac{1}{\phi} (s'/y)\phi_2$ is provable and for each leaf $s'$ of the tree, the sequent $\frac{1}{\phi} (s'/x)\phi_1$ is provable. Using Proposition 8, there exists a finite tree $T$ such that for each internal node $s'$ the successors of $s'$ are the elements of Next($s'$), for each node $s'$, the sequent $\frac{1}{\phi} (s'/y)\phi_2$ is provable, and for each leaf $s'$, either the sequent $\frac{1}{\phi} (s'/x)\phi_1$ is provable or $s'$ is also a label of a node on the branch from the root of $T$ to this leaf. Then, to each subtree $T'$ of $T$, we associate a proof $[T']$ of the sequent $AR_{x,y}(\phi_1, \phi_2)(s_1), \ldots, AR_{x,y}(\phi_1, \phi_2)(s_m) \frac{1}{\phi} AR_{x,y}(\phi_1, \phi_2)(s')$ where $s'$ is the root of $T'$ and $s_1, \ldots, s_m$ is the sequence of nodes in $T'$ from the root of $T$ to the root of $T'$.

- **If $T'$ contains a single node $s'$, and the sequent $\frac{1}{\phi} (s'/x)\phi_1$ is provable then the proof $[T']$ is built with the AR-R$_1$ rule from the proofs of $\frac{1}{\phi} (s'/x)\phi_1$ and $\frac{1}{\phi} (s'/y)\phi_2$ given by the induction hypothesis.**
- **If $T'$ contains a single node $s'$, and $s'$ is among $s_1, \ldots, s_m$, then the proof $[T']$ is built with the AR-merge rule.**
- **If $T' = s'(T_1, \ldots, T_n)$, then the proof $[T']$ is built with the AR-R$_2$ rule from the proofs $\frac{1}{\phi} (s'/y)\phi_2$ given by the induction hypothesis and the proofs $[T_1], \ldots, [T_n]$ of the sequents $AR_{x,y}(\phi_1, \phi_2)(s_1), \ldots, AR_{x,y}(\phi_1, \phi_2)(s_m), AR_{x,y}(\phi_1, \phi_2)(s')$**

This way, the proof $[T]$ is a proof of the sequent $\frac{1}{\phi} AR_{x,y}(\phi_1, \phi_2)(s)$.

If $\phi = EU_{x,y}(\phi_1, \phi_2)(s)$, as $\models EU_{x,y}(\phi_1, \phi_2)(s)$, there exists a finite sequence $T = s_0, \ldots, s_n$ such that $\models (s_i/x)\phi_1$ and for all $i$ between 0 and $n - 1$, $\models (s_i/y)\phi_2$. By induction hypothesis, the sequent $\frac{1}{\phi} (s_i/y)\phi_2$ is provable and for all $i$ between 0 and $n - 1$, the sequent $\frac{1}{\phi} (s_i/x)\phi_1$ is provable. We associate a proof $[s_1, \ldots, s_n]$ of the sequent $\frac{1}{\phi} EU_{x,y}(\phi_1, \phi_2)(s_i)$ to each suffix of $T$ by induction as follows.
• The proof $[s_n]$ is built with the EG-R$_3$ rule from the proof of $\vdash (s_n/y)\phi_2$
given by the induction hypothesis.

• If $i \leq n - 1$, then the proof $[s_i, ..., s_n]$ is built with the EG-R$_2$ rule from the
proof of $\vdash (s_i/x)\phi_1$ given by the induction hypothesis and the proof $[s_{i+1}, ..., s_n]$
of the sequent $\vdash EU_{x,y}(\phi_1, \phi_2)(s_{i+1})$.

This way, the proof $[s_0, ..., s_n]$ is a proof of the sequent $\vdash EU_{x,y}(\phi_1, \phi_2)(s)$.

D Proof of the correctness of the proof search algorithm

Proposition 9. Given a formula $\phi$, $\text{cpt}(\vdash \phi, t, f) \leadsto^* t$ iff $\phi$ is provable.

Proof. We prove, more generally, by induction on the structure of $\phi$, that given a se-
quent $\Gamma \vdash \phi$ and distinct CPTs $c_1$ and $c_2$, $\text{cpt}(\Gamma \vdash \phi, c_1, c_2) \leadsto^* c_1$ iff $\Gamma \vdash \phi$ is
provably.

– If $\phi = T$ or $\bot$, trivial.

– If $\phi = P(s_1, ..., s_n)$ where $P(s_1, ..., s_n)$ is atomic, then $\text{cpt}(\vdash P(s_1, ..., s_n), c_1, c_2) \leadsto$
c_1 iff $\langle s_1, s_2, ..., s_n \rangle \in P$ iff $\vdash P(s_1, s_2, ..., s_n)$ is provable.

– If $\phi = \neg P(s_1, ..., s_n)$ where $P(s_1, ..., s_n)$ is atomic, then $\text{cpt}(\vdash \neg P(s_1, ..., s_n), c_1, c_2) \leadsto$
c_1 iff $\langle s_1, s_2, ..., s_n \rangle \notin P$ iff $\vdash \neg P(s_1, s_2, ..., s_n)$ is provable.

– If $\phi = \phi_1 \land \phi_2$, then $\text{cpt}(\vdash \phi_1 \land \phi_2, c_1, c_2) \leadsto^* c_1$ iff $\text{cpt}(\vdash \phi_1 \land \phi_2, c_1, c_2) \leadsto$
$c_1$ and $\text{cpt}(\vdash \phi_2, c_1, c_2) \leadsto^* c_1$ and $\phi_1$ and $\phi_2$ are provable (by induction hypothesis) iff $\vdash \phi_1 \land \phi_2$ are provable.

– If $\phi = \phi_1 \lor \phi_2$, then $\text{cpt}(\vdash \phi_1 \lor \phi_2, c_1, c_2) \leadsto^* c_1$ iff either $\text{cpt}(\vdash \phi_1 \lor \phi_2, c_1, c_2) \leadsto$
cpt$(\vdash \phi_1, c_1, \text{cpt}(\vdash \phi_2, c_1, c_2)) \leadsto^* c_1$ or $\text{cpt}(\vdash \phi_1 \lor \phi_2, c_1, c_2) \leadsto$ cpt$(\vdash \phi_1, c_1, \text{cpt}(\vdash \phi_2, c_1, c_2)) \leadsto^* c_1$ iff either $\vdash \phi_1$, or $\vdash \phi_2$ is provable (by
induction hypothesis) iff $\vdash \phi_1 \lor \phi_2$ is provable.

– If $\phi = AX_x(\psi)(s)$ and $\{s_1, ..., s_n\} = \text{Next}(s)$, then $\text{cpt}(\vdash AX_x(\psi)(s), c_1, c_2) \leadsto^* c_1$ iff $\text{cpt}(\vdash AX_x(\psi)(s), c_1, c_2) \leadsto$
cpt$(\vdash (s_1/x)\psi, c_1, \text{cpt}(\vdash (s_2/x)\psi, \text{cpt}(\vdots \text{cpt}(\vdash (s_n/x)\psi, c_1, c_2), c_2), c_2), c_2) \leadsto^* c_1$ iff $\vdash (s_1/x)\psi, (s_2/x)\psi, ..., (s_n/x)\psi$ are all
provably (by induction hypothesis) iff $\vdash AX_x(\psi)(s)$ is provable.

– If $\phi = EX_x(\psi)(s)$ and $\{s_1, ..., s_n\} = \text{Next}(s)$, then $\text{cpt}(\vdash EX_x(\psi)(s), c_1, c_2) \leadsto^* c_1$ iff $\text{cpt}(\vdash EX_x(\psi)(s), c_1, c_2) \leadsto$
cpt$(\vdash (s_1/x)\psi, c_1, \text{cpt}(\vdash (s_2/x)\psi, c_1, \text{cpt}(\vdots \text{cpt}(\vdash (s_n/x)\psi, c_1, c_2), c_2)) \leadsto^* c_1$ iff $\vdash (s_1/x)\psi$ is provable (by induction hypothesis)
iff $\vdash EX_x(\psi)(s)$ is provable, where $1 \leq i \leq n$, and $c_2$ is either $c_2$ when $i = n$ or
$c_2$ when $i = n$. \text{cpt}(\vdash (s_{i+1}/x)\psi, c_1, \text{cpt}(\vdots \text{cpt}(\vdash (s_n/x)\psi, c_1, c_2))$ when $i \neq n$.

– If $\phi = AF_x(\psi)(s)$ and $\{s_1, ..., s_n\} = \text{Next}(s)$, then $\text{cpt}(\Gamma \vdash AF_x(\psi)(s), c_1, c_2) \leadsto^* c_1$ iff either $\text{cpt}(\Gamma \vdash AF_x(\psi)(s), c_1, c_2) \leadsto$
cpt$(\vdash (s/x)\psi, c_1, \text{cpt}(\vdash (\Gamma' \vdash AF_x(\psi)(s_1), \text{cpt}(\vdots \text{cpt}(\Gamma' \vdash AF_x(\psi)(s_n), c_1, c_2), c_2), c_2)) \leadsto^* c_1$, or $\text{cpt}(\Gamma \vdash AF_x(\psi)(s), c_1, c_2) \leadsto$
\[ \text{cpt}(\vdash s/x \psi, c_1, \text{cpt}(\Gamma' \vdash AF_x(\psi) (s_1)), \text{cpt}(\ldots \text{cpt}(\Gamma'' \vdash AF_x(\psi) (s_i), c_1, c_2), \ldots, c_2)) \rightsquigarrow^* \]
\[ \text{cpt}(\Gamma'' \vdash AF_x(\psi) (s_i), \text{cpt}(\ldots \text{cpt}(\Gamma'' \vdash AF_x(\psi) (s_n), c_1, c_2), \ldots, c_2)) \rightsquigarrow^* c_1, \]
where \( 1 \leq i \leq n \) and \( \Gamma' = \Gamma, AF_x(\psi) (s) \). We are going to prove that the second condition holds iff \( \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_1), \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_2), \ldots, \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_n) \) are all provable. This will be sufficient to conclude as The first condition holds iff \( \vdash (s/x) \psi \) is provable (by induction hypothesis). So, we will get that both conditions hold if and only if \( \Gamma' \vdash AF_x(\psi) (s) \) is provable.

Let us prove, as announced, that the second condition holds iff \( \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_1), \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_2), \ldots, \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_n) \) are all provable:

- \((\Rightarrow)\) if the second condition holds, then \( \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_1), \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_2), \ldots, \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_n) \) are all provable. That is because otherwise, if \( 1 \leq j \leq n \) such that \( \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_j) \) is the first sequent that is not provable, then there exists an infinite path \( s_{j_0}, s_{j_1}, s_{j_2}, \ldots \) and \( s_{j_k} = s_j \) such that \( \vdash (s_{j_k}/x) \psi \) is not provable for all \( k \geq 0 \), then by induction hypothesis,

\[ \text{cpt}(\Gamma' \vdash AF_x(\psi) (s_1), \text{cpt}(\ldots \text{cpt}(\Gamma'' \vdash AF_x(\psi) (s_j), c_1, c_2), \ldots, c_2)) \rightsquigarrow^* \]
\[ \text{cpt}(\Gamma' \vdash AF_x(\psi) (s_j), c_1, c_2) \rightsquigarrow^* \ldots \rightsquigarrow^* \text{cpt}(\Gamma_m \vdash AF_x(\psi) (s_{j_m}), c_1^m, c_2) \rightsquigarrow^* c_2, \]
where
\[ AF_x(\psi) (s_{j_m}) \in \Gamma_m, \]
\[ \Gamma'' = \Gamma, AF_x(\psi) (s), \]
\[ \Gamma_m = \Gamma'', AF_x(\psi) (s_{j_0}), \ldots, AF_x(\psi) (s_{j_m}), \text{ and the shape of } c_1^m, \ldots, c_2^m \text{ have no impact on the transformations of CPTs here. Note that such } m \geq 0 \text{ exists because our Kripke model is finite. So, the second condition holds implies that } \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_1), \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_2), \ldots, \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_n) \text{ are all provable, and thus } \Gamma' \vdash AF_x(\psi) (s) \text{ are provable.} \]

- \((\Leftarrow)\) if \( \forall i \in \{1, 2, \ldots, n\}, \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_i) \) is provable, to prove that the second condition holds, it is sufficient to prove that

\[ \text{cpt}(\Gamma' \vdash AF_x(\psi) (s_j), c_1^j, c_2^j) \rightsquigarrow^* c_1 \text{ for all } 1 \leq j \leq n \text{ and all } c_1^j, c_2^j, \text{ and that } \Gamma'' = \Gamma, AF_x(\psi) (s). \] This is easily proved by induction on the structure of the proof tree of \( \Gamma, AF_x(\psi) (s) \vdash AF_x(\psi) (s_1). \)

- if \( \phi = EG_x(\psi) (s) \) and \( \{s_1, \ldots, s_n\} = \text{Next}(s) \), then for \( \Gamma' \vdash EG_x(\psi) (s) \),

  - if \( EG_x(\psi) (s) \in \Gamma, \text{ trivial;} \)
  - if \( EG_x(\psi) (s) \notin \Gamma, \text{ then}
    \[ \text{cpt}(\Gamma \vdash EG_x(\psi) (s), c_1, c_2) \rightsquigarrow^* c_1 \text{ iff} \]
    \[ \text{cpt}(\Gamma \vdash EG_x(\psi) (s), c_1, c_2) \rightsquigarrow^* \text{cpt}(\Gamma \vdash (s/x) \psi, c_1, c_2) \]
    \[ \text{cpt}(\Gamma' \vdash EG_x(\psi) (s), c_1, c_2)) \rightsquigarrow^* \]
    \[ \text{cpt}(\Gamma' \vdash EG_x(\psi) (s), c_1, c_2)) \rightsquigarrow^* \]
    \[ \text{cpt}(\Gamma_1 \vdash EG_x(\psi) (s_1), c_1, c_2)) \rightsquigarrow^* \]
    \[ \text{cpt}(\Gamma_2 \vdash EG_x(\psi) (s_1), c_1, c_2)) \rightsquigarrow^* \]
\(\text{cpt}(\Gamma_m \vdash EG_x(\psi)(s_{i_1i_2\ldots i_m1}), c_1, \text{cpt}(\ldots \text{cpt}(\Gamma_m \vdash EG_x(\psi)(s_{i_1i_2\ldots i_mn_m}), c_1, c_2^{m})\ldots)) \Rightarrow^* \text{cpt}(\Gamma_m \vdash EG_x(\psi)(s_{i_1i_2\ldots i_mn_m+1}), c_1, \text{cpt}(\ldots \text{cpt}(\Gamma_m \vdash EG_x(\psi)(s_{i_1i_2\ldots i_mn_m}), c_1, c_2^{m})\ldots))\)

iff there exists an infinite path

\[s, s_{i_1i_2\ldots i_m1}, s_{i_1i_2\ldots i_m2}, \ldots \]

such that for all state \(s'\) in this path, \(\vdash \psi(s')\) is provable, where \(\Gamma' = \Gamma, EG_x(\psi)(s), \Gamma_m = \Gamma', EG_x(\psi)(s_{i_1}), \ldots, EG_x(\psi)(s_{i_1i_2\ldots i_m})\), and \(EG_x(\psi)(s_{i_1i_2\ldots i_mn_m+1}) \in \Gamma_m\). By induction hypothesis, this holds iff \(\Gamma \vdash EG_x(\psi)(s)\) is provable.

- if \(\phi = AR_x, y(\phi_1, \phi_2)(s)\), as are both co-inductive modalities, the analysis is analogous to \(EG\).
- if \(\phi = EU_x, y(\phi_1, \phi_2)(s)\), as are both inductive modalities, the analysis is analogous to \(AF\).
