Families of Regular Polygons and their Mutations

G.H. Hughes

Abstract

Every regular N-gon generates a canonical ‘family’ of regular polygons which are conforming to the bounds of the ‘star polygons’ determined by N. These star polygons are formed from truncated extended edges of the N-gon and the intersection points determine a scaling which defines the parameters of the family. Based on a 1949 letter from Carl Siegel to S. Chowla, it follows that this scaling forms a basis for \( \mathbb{Q}_N^+ \) the maximal real subfield of the cyclotomic field \( \mathbb{Q}_N \). The traditional generator for this subfield is \( \lambda_N = 2\cos(2\pi/N) \) so it has order \( \varphi(N)/2 \) where \( \varphi \) is the Euler totient function. This order is known as the ‘algebraic complexity’ of N. The family of regular polygons shares this same scaling and complexity, so members of this family are an intrinsic part of any regular polygon - and we call them the First Family of N.

Because the First Family members are also regular polygons, their First Families can be used to define a recursive nesting with known scaling. This scaling would typically lead to a multi-fractal topology for the star polygons of N, and the scaling parameters would be algebraic units in \( \mathbb{Q}(\lambda_N) \) so calculations would be efficient and exact.

This scenario actually exists under a piecewise isometry such as the outer-billiards map \( \tau \) because the ‘singularity set’ W is formed by iterating the extended edges of N under \( \tau \) and this iteration is compatible with the First Family of N. For N-gons with complexity that is linear or quadratic (N = 3,4,5,6,8,10,12), the First Family evolution is sufficient to describe the resulting topology of W because in these cases there is never more than one effective scale. Therefore the topology is linear for N = 3, 4 and 6 and simple fractal for N = 5,8,10 and 12.

When there are multiple non-trivial scaling parameters, the topology of W may be multi-fractal and there is no guarantee that the First Family scaling will be sufficient to determine the geometric scaling of W - but we conjecture that this scaling is always sufficient. In all cases the First Family geometry can provide insight into the actual scaling (which is typically very complex). Of course the topology of W depends also on the ‘temporal’ scaling – which is the limiting growth of the periods of ‘tiles’ in the complement of W. We will concentrate here on the geometric scaling of W and show examples of the type of calculations that are possible using the geometric properties of the First Families. In the Appendix we show how these same calculations can be carried out with the Digital Filter map of Chua and Lin [CL] and a complex-valued ‘dual center’ map of Arek Goetz [Go] - so the geometry of W may be inherent in N.

Note: This paper is part of the subject matter of ‘piecewise rotations’. For simplicity, most published studies are based on rotations of the form \( 2\pi/2N \) with N odd – because the matching cyclotomic field \( \mathbb{Q}_{2N} \) is equal to \( \mathbb{Q}_N \). This algebraic equivalence explains why N = 11 and N = 22 have equivalent scaling and singularity sets, but the relationship between geometry and dynamics is poorly understood. In Section 2, we will show that it is natural to regard N = 11 as embedded in the First Family of N = 22, but there are important differences between the ‘in-situ’ dynamics of N = 11 and the ‘in-vitro’ dynamics – when N = 11 is at the origin. This applies to most N-gons.
Introduction

In a 1978 article called “Is the Solar System Stable?” Jurgen Moser [M2] used the landmark KAM Theorem – named after A. Kalmogorov, V. Arnold and Moser – to show that there is typically a non-zero measure of initial conditions that would lead to a stable solar system – but these initial conditions are unknown and this is still an open question. Since the KAM Theorem was very sensitive to continuity, Moser suggested a ‘toy model’ based on orbits around a polygon – where continuity would fail. This is called the ‘outer-billiards’ map and in 2007 Richard Schwartz [S1] showed that if the polygon was in a certain class of ‘kites’, orbits could diverge and stability failed. The special case of a regular polygon was settled earlier in 1989 when F. Vivaldi and A. Shaidanko [VS] showed that all orbits are bounded.

The author met with Moser at Stanford University in that same year to discuss the ‘canonical’ structures that always arise in the regular case - and Moser suggested that a study of these structures would be an interesting exercise in ‘recreational’ mathematics. This is exactly what it became over the years - but the evolution of these canonical ‘First Families’ proved to be a difficult issue except for regular the N-gons with linear or quadratic complexity.

It has lately become clear that these families are an intrinsic part of the geometry of N and the outer-billiards map may be just one way to uncover this geometry – so the singularity set W on the right could be ‘generic’ for piecewise isometries acting on N = 14.

Organization of the Paper (see the Table of Contents)

- Section 1 introduces star polygons and their scaling. The main results are the Scaling Lemma for nested regular N-gons and the Two-Star Lemma for construction of regular N-gons.

- Section 2 contains a geometric and algebraic derivation of the S[k] tiles which make up the First Families. The main results are the First Family Theorem and the First Family Scaling Lemma which says that hS[1]/hS[k] = scale[k] – so the S[1] tile is a reference for scaling.

- Section 3 is devoted to GenScale[N] – which is the scaling of the S[1] tile of the maximal D tile of N. We show that all regular N-gons have the potential to support ‘generations’ of First Families on the edges of D – and this can be continued recursively. The main result is the Unit Basis Lemma which shows that the scale[k] with gcd(k,N) = 1 are a unit basis for $\mathbb{Q}_N^\times$. Therefore this ‘scaling’ field can be generated by GenScale[N] or GenScale[N/2] for N twice-odd.

- Sections 4 and 5 are devoted to the outer-billiards map. The main results are the existence of canonical orbits of the S[k] tiles, the Twice-odd Lemma, possible mutations of the S[k], and the multi-step web evolution of the S[k] - which has many consequences including the Rule of 4 and the 4k + 1 conjecture which attempt to describe the evolution of S[2] and S[1] on the edges of N. Section 5 has examples of singularity sets and the Appendix has sample calculations comparing three different piecewise isometries.
Section 1. Star Polygons and Star Points

‘Star’ polygons or ‘stellated’ polygons were first studied by Thomas Bradwardine (1290-1349), and later by Johannes Kepler (1571-1630).

The vertices of a regular \( N \)-gon with radius \( r \) are \( \{r \cos \left( \frac{2\pi k}{N} \right), r \sin \left( \frac{2\pi k}{N} \right)\} \) for \( \{k, 1, N\} \). A ‘star polygon’ \( \{p, q\} \) generalizes this by allowing \( N \) to be rational of the form \( p/q \) so the vertices are given by \( \{p, q\} = \{r \cos \left( \frac{2\pi kq}{p} \right), r \sin \left( \frac{2\pi kq}{p} \right)\} \) for \( \{k, 1, p\} \).

Using the notation of H.S. Coxeter [Co] a regular heptagon can be written as \( \{7, 1\} \) (or just \( \{7\} \)) and \( \{7, 3\} \) is a ‘step-3’ heptagon formed by joining every third vertex of \( \{7\} \) so the exterior angles are \( 2\pi/(7/3) \) instead of \( 2\pi/7 \).

By the definition above, \( \{14, 6\} \) would be the same as \( \{7, 3\} \), but there are two heptagons embedded in \( N = 14 \) and a different starting vertex would yield another copy of \( \{7, 3\} \) - so a common convention is to define \( \{14, 6\} \) using both copies of \( \{7, 3\} \) as shown below. This convention guarantees that all the star polygons for \( \{N\} \) will have \( N \) vertices.

</tbody>
</table>

The number of ‘distinct’ star polygons for \( \{N\} \) is the number of integers less than \( N/2 \) – which we write as \( \langle N/2 \rangle \). So for a regular \( N \)-gon, the ‘maximal’ star polygon is \( \{N, \langle N/2 \rangle\} \).

Our default convention for the ‘parent’ \( N \)-gon will be centered at the origin with ‘base’ edge horizontal, and the matching \( \{N, 1\} \) will be assumed equal to \( N \). In general \( sN \), \( rN \) and \( hN \) will denote the side, radius and height (apothem). Typically we will use \( hN \) as the lone parameter.

**Definition 1.1** The *star points* of a regular \( N \)-gon are the intersections of the edges of \( \{N, \langle N/2 \rangle\} \) with a single extended edge of the \( N \)-gon (which will be assumed horizontal). By convention the star points are numbered from \( \text{star}[1] \) (a vertex of \( N \)) outwards to \( \text{star}[\langle N/2 \rangle] \) – which is called \( \text{GenStar}[N] \) – so every \( \text{star}[k] \) is a vertex of \( \{N,k\} \) embedded in \( \{N,\langle N/2 \rangle\} \).

The star points could equally be defined on the positive side of \( N \), but this ‘left-side’ convention is sometimes convenient. The symmetry of these choices makes it irrelevant which convention is used. In general, the star points of a regular \( N \)-gon with apothem \( hN \) are:

\[
\text{star}[k] = \pm hN \cdot (s_k, 1) \quad \text{where} \quad s_k = \tan(k\pi/N) \quad \text{for} \quad 1 \leq k < N/2.
\]
The primitive star[k] and s_k are those with (k,N) = 1, where (k,N) is gcd(k,N). Sometimes we will loosely refer to the s_k as ‘star’ points.

Note: There is a long history of interest in trigonometric functions of rational multiples of π. Niven [N] shows that these ‘trigonometric numbers’ are also algebraic numbers. In 1949 C.L. Siegel (see chronology) communicated to S. Chowla [Ch] a proof that the primitive s_k for the cotangent function are linearly independent. This was a non-trivial result in algebraic number theory and Siegel only proved it for prime N. In 1970 Chowla generalized this result using character theory and Dirichlet’s L-series, but the general tangent case was only settled recently in [Gi] (1997). Therefore the set of primitive star points is linearly independent and it follows that any non-primitive s_k must be a Q-linear combination of the primitive s_k.

Section 3 is devoted to scaling, but here we present the basic definitions and prove the Scaling Lemma. In Section 3 we will use these scales as a basis for the maximal real subfield of \( \mathbb{Q}_N \).

**Definition 1.2** The (canonical) scales of a regular N-gon are scale[k] = s_1/s_k for 1 ≤ k < N/2. The co-scales are of the form s_k/s_1. The primitive scales or coscales are those with (k,N) = 1. GenScale[N] is scale[<N/2>].

By definition scale[1] is always 1 and GenScale is the minimal scale. Since these scales are independent of height, to compare scales for an N-gon and an N/k-gon, the later can be regarded as circumscribed about the N-gon with shared center and height – so the sides can be compared.

**Definition 1.3** If N and M are regular polygons with M = N/k, then ScaleChange(N,M) = (s_1 of N)/(s_1 of M) ≤ 1. This is abbreviated SC(N,M) or just SC(N) < ½ , when M is N/2.

**Lemma 1.1** (Scaling Lemma) Suppose N and M are regular polygons and M = N/k, then scale[j] of N/k = scale[kj] /scale[k] of N

Proof: There is no loss of generality in assuming that N and N/k are in ‘standard position’ at the origin with equal heights so N/k will be a ‘circumscribed factor polygon’ of N. If s is the side of N, then s/SC(N,N/k) will be the side of N/k. The external angle of N/k is 2πk/N so in this position, every kth edge will coincide with an edge of N. Therefore it will share every kth star point with N and by definition the corresponding scales are related by the ratio of the sides of N and N/k, so scale[j] of N/k = (scale[kj] of N)/SC(N,N/k). Since scale[1] of N/k = 1 = scale[k]/SC(N,N/k), it follows that scale[k] of N is SC(N,N/k). □

Therefore scale[k] of N = 7 is the same as scale[2k]/scale[2] for N = 14 and this twice-odd case is the only nesting where the GenStar points coincide, so GenScale[7] = GenScale[14]/scale[2].

**Lemma 1.2** When N is even, GenScale[N] = Tan^2[π/N] = s_1^2 and when N is odd GenScale[N] = Tan[π/2N]-Tan[π/N] = s_1s_2 of 2N.

Proof: For N even, the star points inherit the reflective symmetry of N under tan[π/2 - θ] = cot[θ], so s_{N/2-k} = 1/s_k. Setting k = <N/2> = N/2-1, GenScale[N] = s_1/(1/s_1) = s_1^2. When N is odd The Scaling Lemma says that GenScale[N] = GenScale[2N]/scale[2] = s_1^2/(s_1/s_2) = s_1s_2 of 2N. □
To define a regular N-gon in a given coordinate system, it is sufficient to know its height (apothem) and its center, but both of these are determined by knowing the co-ordinates of two star points – as any cartographer would know.

**Lemma 1.3** (Two-Star Lemma) If P is a regular N-gon, any two star points are sufficient to determine the center and height.

**Proof.** By definition, the star points lie on an extended edge of P. There is no loss of generality in assuming that this extended edge is parallel to the horizontal axis of a known coordinate system with arbitrary center.

Since all points on this extended edge will have a known second coordinate, we will just need the horizontal coordinates of the star points – which we will call p₁ and p₂ with p₂ > p₁, so d = p₂ - p₁ will be positive. Relative to P, p₁ = ± star[j][[1]] = ±hP·Tan[jπ/N] and p₂ = ± star[k][[1]] = ±hP·Tan[kπ/N] (where p[[1]] is the horizontal coordinate of p). These indices j and k must be known. There are only two cases to consider:

(i) If p₁ and p₂ are on the same side of P, there is no loss of generality in assuming that it is the right-side of P because star points always exist in their symmetric form with respect to P. In this case we can assume that 1 ≤ j < k < N/2 so hP = d/(Tan[kπ/N] - Tan[jπ/N]).

(ii) If p₁ and p₂ are on opposite sides hP = d/ (Tan[kπ/N] + Tan[jπ/N]) and it does not matter whether j ≤ k or not.

Now that hP is known, the horizontal displacement of p₁ and p₂ relative to P are:

x = hP·Tan[jπ/N] and (x + d) = hP·Tan[kπ/N] if both are on the same side
or x = hP·Tan[jπ/N] and (d - x) = hP·Tan[kπ/N] if they are on opposite sides

Of course only one of these displacements is needed to define the center of P. □

**Example 1.1** (The one-elephant case) P below shares two star points with the elephant N = 14 – which defines the coordinate system. The shared star points are star[3] and star[6] of P which we abbreviate as starP[3] and starP[6].
Because of the symmetry between P and N, either one could be used as reference to construct the other – but here we assume that \( h_N \) is known and it is desired to find \( h_P \) (and \( c_P \)) relative to \( N \).

By the Two-Star Lemma \( h_P = \frac{p_2 - p_1}{\tan(6\pi/14) - \tan(3\pi/14)\tan(\pi/14)} = \frac{\tan(\frac{4\pi}{14}) - \tan(\frac{\pi}{14})}{\tan(\frac{6\pi}{14}) - \tan(\frac{3\pi}{14})} \).

Therefore \( \frac{h_P}{h_N} = \frac{\tan(\frac{4\pi}{14}) - \tan(\frac{\pi}{14})}{\tan(\frac{6\pi}{14}) - \tan(\frac{3\pi}{14})} \approx 0.286208264215 \).

This trigonometric reduction implies that \( h_P \tan(\frac{3\pi}{14}) = h_N \tan(\frac{\pi}{14}) \). Therefore the displacement of \( c_P \) from \( \text{star}N[4] \) must be the same as the (known) displacement of \( c_N \) from \( \text{star}N[1] \) as illustrated above. This follows from the symmetry between P and N. Since P can construct N (by setting \( p_1 = -p_2 \)), the two displacements must be negatives of each other.

\( P \) here is known as \( S[4] \) because it was constructed using \( \text{star}[4] \) (and \( \text{star}[1] \)) of \( N \). Clearly this same construction can be carried out for the remaining \( \text{star}[k] \) points of \( N = 14 \) – and we will do this below for arbitrary \( N \). Since each \( S[k] \) will have a symmetric relationship with \( N \), the displacements will always be \(-s_N/2\). (And each \( S[k] \) will have a natural embedding in \( N \).)

Algebraically the \( S[k] \) and \( N \) are closely related because \( h_P/h_N \) will always be an element of the ‘scaling field’ defined by \( N = 14 \) (or \( N = 7 \)). This is the number field generated by \( 2 \cos(2\pi/7) \) or \( \text{GenScale}[7] = \tan(\pi/7) \cdot \tan(\pi/14) \). See Section 3. Using Mathematica:

\[
\text{AlgebraicNumberPolynomial}[\text{ToNumberField}[h_S[4]/h_N, \text{GenScale}[7]], x] = \frac{x^2 - x + 1}{2}
\]

So \( h_S[4]/h_N = \frac{x^2 - x + 1}{2} \) where \( x = \tan(\pi/7) \cdot \tan(\pi/14) \) and this scale is an algebraic number.

Since \( N = 14 \) and the matching \( N = 7 \) have \( \phi(N)/2 = 3 \) where \( \phi \) is the Euler totient function, they are classified as ‘cubic’ polygons. This means that any generator of the scaling field will have minimal degree 3, so the scaling polynomials will be at most quadratic.

**Example 1.2** (The two-elephant case) The tiles below exist in the coordinate space of \( N = 11 \). This is a ‘quintic’ \( N \)-gon so the algebra is much more complex than \( N = 14 \). \( P_x \) and DS5 share a star point which is off the page at the right, but they do not share any other star points so it was a challenge to find a second defining star point of \( P_x \) – even though the parameters and star points of DS5 are known from the First Family Theorem to follow. Since these two elephants are only distantly related, it is unusual for them to share a third tile – which we call \( S_x \). This \( S_x \) tile shares extended edges with both \( P_x \) and DS5.
These tiles share the ‘base’ edge of N = 11. The calculations below assume a radius of 1 for N, so $h_N = \cos(\pi/11)$ and this defines the vertical coordinate of the star points shown here. For the Two-Star Lemma all that is required are the horizontal coordinates $p_1$ and $p_2$:

$$p_1 = \star DS5[4][1] = -\cos(\pi/11)\cot(\pi/22) + 2\sin(\pi/11) - \sin(\pi/11)\tan(5\pi/22) - \cot(3\pi/22)\sin(\pi/11)\tan(\pi/11)\tan(5\pi/22)$$

$$p_2 = -\star Px[3][1] = -\frac{-5i + 8(-1)^{3/2} - 15(-1)^{1/2} - 5(-1)^{5/2} + 5(-1)^{7/2} + 5(-1)^{13/2} + 5(-1)^{19/2} - 8(-1)^{17/2} + 3(-1)^{9/2} + 3(-1)^{11/2}}{4(1 + (-1)^{4/11})(1 + (-1)^{3/11})(\cos(\pi/11) - \sin(5\pi/22))}$$

(Because $Px$ does not share any scaling with the First Family for N = 11, its parameters are algebraically far more complex than $DS5$. The form shown here for $p_2$ is a simplification of the trigonometric form – which would fill this page. Mathematica prefers to do these calculations in ‘cyclotomic’ form as shown here. Of course $p_2$ will have vanishing complex part.)

By the Two-Star Lemma, $h_Sx = (p_2-p_1)/(\tan(3\pi/11) + \tan(4\pi/11)) = \frac{-2i - 11(-1)^{5/2} + (-1)^{5/2} - 15(-1)^{1/2} - 4(-1)^{7/2} + 4(-1)^{13/2} - 2(-1)^{9/2} - 12(-1)^{11/2}}{2(1 + (-1)^{4/11})(2 + (-1)^{3/11} - (-1)^{3/11} + (-1)^{5/11} - (-1)^{5/11} + (-1)^{5/11} + (-1)^{5/11} - (-1)^{5/11})(\cos(3\pi/22) + \cos(5\pi/22))(\cos(\pi/11) - \sin(5\pi/22))}$

The ratio $h_Sx/h_N$ will be in the scaling field $S_{11}$ which is generated by $x = GenScale[11] = \tan(\pi/11)\cdot\tan(\pi/22)$. $\text{AlgebraicNumberPolynomial[ToNumberField[hSx/hN, GenScale[11]]}$ yields $p(x) = \frac{-9}{4} + 52x + \frac{62x^2}{2} + x^3 - \frac{5x^4}{4}$. This is the ‘characteristic’ or ‘fundamental’ polynomial for $h_Sx$. It will be unchanged for any other $h_N$. Here $h_Sx = p(x)\cdot h_N \approx .00150329$

These are the steps to construct $Sx$: (i) Using $p_2$, the displacement is $x = h_Sx\cdot\tan(3\pi/11)$ so $\text{MidpointSx} = \{-\star Px[3][1]\cdot x, -h_N\} \approx \{-6.201044900, -\cos(\pi/11)\}$. (ii) $cSx = \text{MidpointSx} + \{0, h_Sx\}$. (iii) $rSx = \text{RadiusFromHeight[hSx, 11]}$. (iv) $Sx = \text{RotateVertex}[cSx + \{0, rSx\}, 11, cSx]$

Under the outer- billiards map $\tau$, the edges of tiles such as $Sx$ are part of the singularity set $W$ – also known as the ‘web’. This set will be defined in Section 4. For a regular N-gon it can be obtained by mapping the extended edges of N under $\tau$ or $\tau^1$. Below is a portion of $W$ in the vicinity of $Sx$. Note that $Sx$ has a clone obtained by rotation about the center of $Px$. In the limit this web is probably multi-fractal. See Example 5.3 and [H6]. (Click on the main image or $Sx$ to download larger versions.)
It is our contention that all the polygonal ‘tiles’ (regular or not) which arise from the outer billiards map of N are defined by scales which lie in the scaling field of N. For N = 11, knowing the exact parameters of ‘third-generation’ tiles like Sx allow us to probe deeper into the small-scale structure of N = 11 – which is almost a total mystery. But algebraic results like this point to the fact that each new ‘generation’ will tend to involve a significant increase in the complexity of any algebraic analysis. Therefore it may be impossible at this time to probe deeper than 10 or 12 generations for N = 11. Since the generations scale by \( \text{GenScale}[11] = \tan\frac{\pi}{11} \cdot \tan\frac{\pi}{22} \approx 0.0422171 \), the 25th generation would be on the order of the Plank scale of \( 1.6 \cdot 10^{-35} \text{ m} \). In the words of R. Schwartz, “A case like N = 11 may be beyond the reach of current technology.”

Section 2. Conforming Regular Polygons

The S[4] tile from Example 1.1 is ‘conforming’ to the bounds of the star polygon of N = 14 because they share the same ‘base’ edge and the right-side GenStar of S[4] is star[1] of N as shown below. Clearly there are an infinite number of such conforming N-gons for N = 14, but S[4] also shares star[4] (and star[5]) of N and there are only 6 such ‘strongly conforming’ tiles for N = 14. These will constitute the nucleus of the First Family of N = 14.

When N is odd, we will define the conforming tiles to be 2N-gons since there will be algebraic and geometric compatibility issues with N-gons. Because the exterior angle of N is twice that of 2N, conforming tiles like S[2] shown here will need to share their ‘penultimate’ star point with N. Note that the matching magenta N-gon will have the same GenStar point as P, but it will have a different penultimate star point- so it will not be conforming. Therefore all of the S[k] for N odd will be 2N-gons.

**Definition 2.1**

(i) If N is even and P is a regular N-gon, P is *conforming* relative to N if P shares the same base edge as N and star[<N/2>] = star[N/2-1] = GenStar of P is ± star[1] of N.

(ii) If N is odd and P is a regular 2N-gon then P is *conforming* relative to N if P shares the same base edge as N and star[N-2] of P is ± star[1] of N. In both cases P is said to be strongly conforming if it is conforming and also shares another star point with N.

**Lemma 2.1** (Conformal Replication) Every regular N-gon has a strongly conforming D_N tile which is identical to N for N even and a regular 2N-gon with same side as N for N odd.

Proof: Set -starD_N[1] = GenStar[N] and center offset -sN/2. When N is even this center and side length defines a regular N-gon D_N which is identical to N. By the reflective symmetry of N, D_N
must have \(-\text{GenStar}[D_N]\) equal to \(\text{star}[1]\) of \(N\). When \(N\) is odd, use \(\text{GenStar}[N]\) and the same offset of \(-sN/2\) to construct a regular \(2N\)-gon \(D_N\). Because the exterior angle of \(D_N\) is half of the exterior angle of \(N\), \(D_N\) will have \(\text{star}[N-2]\) equal to \(\text{star}[1]\) of \(N\) so it is strongly conforming. □

**Example 2.1** When \(N\) is odd, the matching \(D_N\) is a \(2N\)-gon, so it can also serve as the \(D\) for a \(2N\)-gon, as shown here for \(N = 13\) and \(N = 26\).

This means that \(N = 13\) will be a natural part of the First Family of \(N = 26\), and we will call them an ‘M-D’ pair (Definition 2.3). Since \(sN = sD\), \(hN/hD = \text{scale}[2]\) of \(D\) which is also \(\text{SC}(D)\).

It should be clear that \(D_N\) will be the largest possible strongly conforming tile relative to \(N\) as shown below for \(N = 14\). In the outer-billiards world the \(D\) tiles are globally maximal.

**Corollary 2.1** For a regular \(N\)-gon, there is a conforming regular \(N\)-gon or \(2N\)-gon \(P\) with \(hP \leq hD_N\).

**Proof.** By the Conformal Replication Lemma, there is a conformal \(D_M\) for any regular \(N\)-gon \(M\) embedded in \(N\) which shares the base edge and \(\text{star}[1]\) of \(N\). This \(D_M\) will also be conformal relative to \(N\) because \(N\) and \(M\) have the same exterior angle. Therefore a conforming \(D_M\) must exist for any \(hD_M \leq hD_N\). □

**Theorem 2.1** (First Family) For a regular \(N\)-gon every \(\text{star}[k]\) point defines a unique \(S[k]\) tile which is strongly conforming and has horizontal center displacement \(-sN/2\) relative to \(\text{star}[k]\).

**Proof:** (i) Suppose that \(N\) is even with \(p_1 = \text{star}N[k]\). Let \(P\) be the conforming regular \(N\)-gon with center displacement \(-sN/2\) relative to \(p_1\) as shown here. Such a \(P\) must exist by Corollary 2.1 of the Conformal Replication Lemma. We will show that \(P\) must have \(\text{star}[k]\) as a star point and \(-\text{star}P[j] = \text{star}N[k]\) for \(j = N/2-k\).

This graphic matches Example 1.1, so \(k = 4\) and \(j = 3\). Every conforming \(P\) has \(-\text{star}P[N/2-1] = \text{star}[1]\) of \(N\), so they all share a global ‘index’ of \(N/2-1\), and here we claim
that \(-\star P[N/2-k] = \star[k]\) of \(N\), so the ‘local’ index of \(P\) is \(N/2-k\). When \(k = 1\) this local index matches the global index but the diagram above is still valid with \(p_1 = p_2\). On the other extreme, when \(k = N/2-1\), the local index is 1 and \(P\) is the \(D_N\) from the Replication Lemma. (This ‘retrograde’ form of the local index is due to the numbering convention of the \(S[k]\).)

As indicated in Example 1.1, the relationship between \(N\) and \(P\) is symmetric so setting \(p_1 = -p_2\) will move the origin to \(P\) and allow \(P\) to construct \(N\). Therefore the center displacements of \(P\) and \(N\) must be the negative of each other. It remains only to prove that the local index of \(P\) is \(N/2-k\).

The magenta displacement from \(p_2\) to \(\text{Mid}P\) can be written from the two different perspectives:
(a) Relative to \(N\), it is the same as the displacement of \(\star[k]\), namely \(-hN \cdot \tan[k \pi / N]\).
(b) Relative to \(P\) and \(\star N[1]\), this displacement is \(-hP \cdot \tan[(N/2-1) \pi / N]\).

Therefore \(hN \cdot \tan[k \pi / N] = hP \cdot \tan[(N/2-1) \pi / N]\), so
\[
\frac{hP}{hN} = \frac{\tan[k \pi / N]}{\tan[(N/2-1) \pi / N]} = \frac{\tan[\pi / N]}{\tan[(N/2-k) \pi / N]}.
\]

But for \(1 \leq k < N/2\),
\[
\frac{\tan[k \pi / N]}{\tan[(N/2-1) \pi / N]} = \frac{\tan[\pi / N]}{\tan[(N/2-k) \pi / N]} = 1.
\]

Therefore \(hS[k] = \frac{\tan[\pi / N]}{\tan[(N/2-k) \pi / N]}\) and \(\star S[k][N/2-k]\) has displacement \(sN/2\) as desired.

For \(k > 1\) all the \(S[k]\) will be strongly conforming because they share two distinct star points with \(N\). When \(k = 1\) the local index is the same as the global index but the calculations above are valid when \(p_1 = p_2\), so \(hS[1] = \frac{\tan[\pi / N]}{\tan[(N/2-1) \pi / N]} = \tan[\pi / N]^2\) because \(1/\tan[(N/2-1) \pi / N] = \tan[\pi / N]\) when \(N\) is even. This is known as GenScale\([N]\) (when \(N\) is even). Therefore \(S[1]\) can be constructed without the help of \(\star[2]\), but we will show that the illustration below for \(N = 14\) is canonical and \(S[1]\) always has index 2 relative to \(\star[2]\).

To see this, apply the Two-Star Lemma with opposite sides and (hypothetical) local index 2. This yields
\[
\frac{hS[1]}{hN} = \frac{\tan[2 \pi / N] - \tan[\pi / N]}{\tan[(N/2-1) \pi / N] + \tan[2 \pi / N]} = \tan[\pi / N]^2\] as above.

Therefore for \(N\) even all of the \(S[k]\) tiles are strongly conforming and share the same offset.

(ii) Suppose \(N\) is odd and \(P\) is the conforming regular \(2N\)-gon with center displacement \(-sN/2\) from \(\star N[k]\) and \(\star P[N-2] = \star N[1]\) as shown below for \(N = 11\) (and \(S[3]\)).
The P-N symmetry of the N-even case is unchanged and this justifies the displacement of sN/2. All the S[k] will have global index N-2 and we will show that the local index is N-2k - which is twice the index for N even. This makes sense because the S[k] are now 2N-gons. Once again the magenta displacement from p2 to MidP can be measured from two different perspectives so

\[
\frac{hP}{hN} = \frac{\tan(k\pi/N)}{\tan((N-2)\pi/2N)}
\]

which is equivalent to

\[
\frac{hP}{hN} = \frac{\tan(\pi/N)}{\tan((N-2k)\pi/2N)}
\]

Therefore \( hP \cdot \tan((N-2k)\pi/2N) = -sN/2 \) and the ‘local’ index of P is N-2k as desired.

This shows that all the S[k] are strongly conforming except S[1] – which has local index equal to the global index. The formula above is still valid so

\[
\frac{hS[1]}{hN} = \frac{\tan(\pi/N)}{\tan((N-2)\pi/2N)} = \tan(\pi/N) \cdot \tan(\pi/2N) \quad \text{(which is GenScale[N] for N odd)}
\]

This is exactly the ratio that will result from using starN[2] and local index 4 as can be observed from N= 11 above. As expected, this is twice the index of the N-even case. Therefore S[1] is strongly conforming and Theorem 2.1 is valid for all S[k] with 1 < k < N/2. □

In summary, the formulas for the S[k] are:

For N even:

\[
\frac{hS[k]}{hN} = \frac{\tan(\pi/N)}{\tan((N/2-k)\pi/N)} = s_1/s_{N/2-k} = \text{scale}[N/2-k] \text{ of } N
\]

For N odd:

\[
\frac{hS[k]}{hN} = \frac{\tan(\pi/N)}{\tan((N-2k)\pi/2N)} = \frac{\tan(2\pi/2N)}{\tan((N-2k)\pi/2N)} = s_2/s_{N-2k} = \text{scale}[N-2k]/\text{scale}[2] \text{ of } 2N
\]

Therefore the indices are just doubled when N is odd. By the Scaling Lemma, this means that the S[2k] for N twice-odd will be congruent to the S[k] for N odd. In both cases it is clear that D = D_N is S[<N/2>]. When N is even, <N/2> is N/2-1 so hD/hN = s_1/s_1 = 1 as expected. The penultimate S[N-2-2] of D will be called M, and hM/hD = s_1/s_2 of D = scale[2] of D = SC(D).

**Lemma 2.2** (First Family Scaling) For all regular N-gons, \( hS[1]/hS[k] = \text{scale}[k] \text{ of } N \).

Proof: For N even \( hS[1]/hN = s_1^2 \) and \( hS[k]/hN = s_1/s_{N/2-k} = s_1s_k \) so \( hS[1]/hS[k] = s_1/s_k \text{ of } N \).

For N odd, \( hS[1]/hS[k] = hS[2]/hS[2k] \text{ of } 2N \). By part(i), \( hS[1]/hS[2] = \text{scale}[2] \) and \( hS[1]/hS[2k] = \text{scale}[2k] \), so \( hS[2]/hS[2k] = \text{scale}[2k]/\text{scale}[2] \text{ of } 2N = \text{scale}[k] \text{ of } N \). □

**Example 2.2** (The First Family of N = 7) By convention for N odd, we will merge the S[k] of N with the (right-side) S[k] of D, which we call DS[k]. Since \( hS[1]/hS[2] = \text{scale}[2] \text{ of } N = \tan(\pi/7)/\tan(2\pi/7) \approx 0.38404 \) this provides a relative scaling of S[1] and S[2]. Recall that they are congruent to DS[2] and DS[4] so they are only distantly related. Lemma 2.2 says that \( hDS[1]/hDS[2] = \text{scale}[2] \text{ of } D = SC(14) \). This is the same ratio as hN/hD as noted earlier, so DS[1] and DS[2] are also an M-D pair and this is why they are called M[1] and D[1]. They will be the basis for a (hypothetical) ‘2nd–generation’ at GenStar[7].

![Diagram](https://via.placeholder.com/150)
The plot above was an attempt to reconcile the First Families of $N = 7$ and $D$ - acting as $N = 14$. Since these two have equivalent cyclotomic fields, the First Families should be algebraically equivalent. There is an issue with this combined plot because the First Family Theorem says that all the $DS[k]$ should be 14-gons, so $DS[5]$ cannot be $N = 7$. This is not an algebraic issue because $hN/hD$ is indeed $SC(14)$ – which is the correct scale for $DS[5]$ – the penultimate tile of $D$.

We will show that $DS[5]$ (and all the odd $DS[k]$) can be either ‘gender’ without violating any results of the First Family Theorem. This will help to restore some of the even-odd parity of the $S[k]$ from the First Family Theorem, and now it makes sense that $DS[1]$ could be regarded as a 2nd generation $N = 7$. We will explain in Secion 4 why this gender change occurs in the web of the outer-billiards map – and why this issue is important in the dynamics of $\tau$.

**Definition 2.2** For $N$ even, a regular $N/2$-gon is the *outer-dual* of $N$ if the $N/2$-gon is circumscribed about the $N$-gon with matching ‘base’ edge, center and height. In this case $sN/s(N/2)$ will be $SC(N) = s_1/s_2$ of $N$. When $N$ is twice-odd, this outer-dual will be called the *parity-dual* or *gender-dual* of $N$. This the only case where GenStar$[N] = GenStar[N/2]$.

**Example 2.3** Below are the outer-duals for $N = 12$ and $N = 14$.

![Outer-duals for N = 12 and N = 14](image)

**Lemma 2.3** When $N$ is odd, the First Family Theorem implies that the even $S[k]$ of $D_N$ are congruent to the $S[k/2]$ of $N$. Here we show that the odd $S[k]$ of $D_N$ can be replaced by their gender duals and the resulting $N$-gons are still strongly conforming.

Proof: Suppose $P$ is the gender-dual of an $S[k]$ of $D$. $P$ will an $N$-gon with the same center and height as $S[k]$ and GenStar$[P]$ will be GenStar$[S[k]]$ iff $N$ is odd. Therefore $P$ will be conforming. In addition star$[j]$ of $P$ will be star$[2j]$ of $S[k]$. By the First Family Theorem, the local index of $S[k]$ of $N$ is $N-k$ and this will be even iff $k$ is odd, so $P$ will have local index $(N-k)/2$ and hence be strongly conforming. □

Since $N = 9$ is the penultimate tile of $D$, it is also called $M$. As with $N = 7$, $DS[1]$ and $DS[2]$ are scaled copies of $M$ and $D$ so they are known as $M[1]$ and $D[1]$. $DS[8]$ is not shown here. It is the right-side $D$ tile for $N = 9$.

**Definition 2.3** (M tiles) If $P$ is a regular $N$-gon with $N > 4$ even, the ‘penultimate’ $S[N/2-2]$ of $P$ is called the $M$-tile of $P$. Note that $h_M/h_P$ will be scale$^2$ of $P = SC(P)$.

**Definition 2.4** (First Family) For any regular $N$-gon, the First Family Theorem defines the strongly conforming $S[k]$ tiles for $1 \leq k \leq \langle N/2 \rangle$. These tiles will be called the First Family Nucleus and $S[\langle N/2 \rangle]$ will be $D_N$ (a.k.a. D). Based on the definition above, the penultimate tile of $D$ will be called $M$ and for $N > 4$, $DS[1]$ and $DS[2]$ will be called $M[1]$ and $D[1]$.

(i) For $N$ twice-even, the First Family will consist of the $S[k]$ in the First Family Nucleus together with the (right-side) First Family Nucleus of $D$ – called the $DS[k]$. sM here is not sD.

(ii) For $N$ twice-odd, the odd $S[k]$ in the First Family Nucleus will be replaced with their N/2 counterparts, and the First Family will consist of this revised First Family Nucleus together with the (right-side) revised First Family nucleus of $D$ – called the $DS[k]$.

(iii) For $N$ odd, the First Family will consist of the First Family Nucleus together with the (right-side) revised First Family Nucleus of $D$ – called the $DS[k]$ (with $DS[\langle N/2 \rangle]$ usually omitted).

Since the M tile of $N = 14$ can be regarded as a scaled copy of $N = 7$, case (iii) is essentially half of case (ii) and we will make this relationship precise in the Twice-odd Lemma of Section 4. As indicated in the introduction, most of the algebraic and geometric complexity for a regular $N$-gon can be traced to the cyclotomic field $\mathbb{Q}_N$, which is defined below. For $N$ twice-odd, $\mathbb{Q}_N = \mathbb{Q}_{N/2}$, so the scaling and singularity sets of $N = 11$ and $N = 22$ are interchangeable and there are
computational advantages to regarding N = 11 as embedded in N = 22. For example the extra symmetry of N even allows the outer-billiards map to be replaced with the simpler toral Digital Filter map – as explained in the Appendix. The singularity set local to Sx in Example 1.2 was generated in this fashion – but it still required billions of iterations.

Section 3. Evolution of First Families - Generation Scaling

Since the First Family tiles are regular polygons, they have well-defined secondary families and this is an invitation to recursion. For the quadratic polygons N = 5, 8, 10 and 12, these secondary families appear to exist on all scales under the outer-billiards map τ and the resulting topology is fractal with geometric scale given by GenScale[N] – as described in Sections 4 and 5. We will show later in this section that for all N-gons, GenScale[N] (or GenScale[N/2]) generates the scaling field $S_N$ so it should play an important role in the topology of τ. Here we will present evidence that this GenScale scaling is actually inherent in the star polygons of N – and hence would be expected to influence the geometry and dynamics of τ.

**Lemma 3.1** For all regular N-gons, hDS[1]/hN = GenScale[N]

Proof: DS[1] is S[1] of D, so when N is even hDS[1]/hN = hS[1]/hD = hS[1]/hS[N/2-1] and this is scale[N/2-1] which is GenScale[N]. When N is odd, D is twice-odd so hDS[1]/hD = GenScale[D] as above, but this is a gender-mismatch which can be corrected by dividing both sides by scale[2] of D so hDS[1]/hN = GenScale[D]/scale[2] of D = GenScale[N]. □

Based on this Lemma, the S[1] tile of D will typically play the part of the ‘next generation’ N. This is called ‘generation’ scaling – and theoretically it could be continued to generate infinite (ideal) sequences of generations converging to GenStar[N] as in Definition 3.3 to follow. To show that this DS[1] scaling is inherent in the star polygons of N, there are 3 cases to consider.

(i) (N odd) Note that N = 7 can be regarded as the S[1] tile of a ‘parent’ D tile called D[-1]. One edge of D[-1] is shown here in dark blue. The scaling between DS[1] (M[1]) and M[0] must be the same as the scaling between the parents D[0] and D[-1]. Here sD = sN so sD[0]/sD[-1] = sN/sD[-1] = s/(2sx+s) = Tan[π/7]·Tan[π/14] = GenScale[7] = sM[1]/sN. Since the genders match, this ratio is also hM[1]/hN and this result agrees with Lemma 3.1.

This is what we call the (ideal) 2nd generation of N = 7 with M[1] and D[1] serving as N and D. The kth generation with M[k-1] and D[k-1] would be scaled by GenScale[7]^{k-1}.
(ii) (N twice-odd) This should be equivalent to case(i) above, but now N = 14 is at the origin playing the role of S[1] of the large D[-1]. Therefore sD[0]/sD[-1] = s/(2sx+s) = Tan^2[π/14] = GenScale[14]. This ratio is indeed sM[1]/sN as above, but now it is a gender mismatch, and not even an algebraic integer. This can be rectified by dividing both sides by scale[2] of N = 14, to get sM[1]/sM[0] = hM[1]/hM[0] = GenScale[14]/scale[2] = GenScale[7]. Geometrically this is the same as replacing N = 14 with its magenta gender-dual (and scaled-up D[0]’ which is omitted here).

Now sD[0]/sD[-1] = s/(2sy+s) where sy = star[2][[1]]-GenStar[[1]] and s' = -2star[2][[1]] (magenta). This yields scale[6]/scale[2] which is GenScale[7] = hM[1]/hM[0] as in case(i).

Therefore N = 14 has scaling compatible with N = 7 as long as the S[1] tiles on the edges of N = 14 are heptagons. Algebraically this compatibility is driven by the equivalence of their cyclotomic fields under ζ → -ζ where ζ = exp(2πi/N). The outer-billiards map and all rational piecewise mappings would be expected to preserve this equivalence.

(iii) (N twice-even) This resembles case(ii) but now there is no gender mismatch and N = 12 is the correct S[1] of D[-1]. By definition sD[0]/sD[-1] = s/(2sx+s) = Tan^2[π/12] = GenScale[12]. This is also sS[1]/sN = hS[1]/hN = 7- 4√3 – which is an algebraic unit (with inverse is 7+ 4√3). It is a generator of the scaling field S_{12} which can also be generated by 2Cos[2π/12] = √3.

As in case(ii), D[0] is congruent to N so DS[1] and DS[2] have the same dynamics as S[1] and S[2] of N. S[1] will still be the M[1] ‘penultimate’ tile in the First Family of S[2], but S[2] cannot be in the First Family of S[1] since they have the same gender. This means that the 2nd generation on the edges of N will be dominated by the family of S[1] – not S[2]. In Example 5.5 we will see that the dominant tiles in the 2nd generation of N = 12 are the M[k], not the D[k]. For any twice-even N-gon of the form 8k+4, this should be a similar issue – while the 8k cases would be expected to have 2nd generations with both S[1] families and S[2] families at D[1].

The singularity set W of the outer-billiards map will be defined in Section 4. It is formed by iterating the extended edges of N – so it is based on the star polygons of N. The examples here show that generation scaling is an intrinsic part of the star polygon geometry for a regular N-gon, so it would be expected that W shares this symmetry – and at least allows for the possibility of self-similar generations to exist at GenStar. This is part of the 4k+1 conjecture of Section 4.
Note: The results above show that any even N-gon can support these ideal families on its edges. When N is odd this is no longer true, and this why it is necessary rely on the matching D tile to support these families. The problem with N-odd is that the S[1] and S[2] tiles are now 2N-gons, so their evolution is not always compatible with N. S[1] and S[2] are now congruent to DS[2] and DS[4] so they are only distantly related, and the First Family of S[2] will typically not contain S[1]. Since the web of S[2] will always generate S[1] on the edges of N, these tiles are still related – but their relationship is not a simple First Family issue. The Edge Conjecture of Section 4 attempts to classify the types of dynamics that can occur on the edges of any N-gon, and for N-odd these dynamics tend to be much more complex that the N-even case.

The cyclotomic field of N

Definition 3.1 For a regular N-gon, the cyclotomic field $\mathbb{Q}_N$, is the algebraic number field which can be generated by $\zeta = \exp(2\pi i / N) = \cos(2\pi / N) + i\sin(2\pi / N)$. As a vector space $\mathbb{Q}_N$ is the direct sum of its real and imaginary parts, $\mathbb{Q}_N^+$ and $\mathbb{Q}_N^-$. Since $\zeta + \zeta^{-1} = 2\cos(2\pi / N)$, $\mathbb{Q}_N^+$ can be generated by $\lambda_N = 2\cos(2\pi / N)$. Since $\zeta$ has (minimal) degree $\phi(N)$ and complex conjugation in $\mathbb{Q}_N$ is always an automorphism of order 2, $\mathbb{Q}_N^+$ has degree $\phi(N)/2$. It is called the maximal totally real subfield of $\mathbb{Q}_N$. The full field $\mathbb{Q}_N$ is always a quadratic extension of $\mathbb{Q}_N^+$.

Because of the Lemma below $\mathbb{Q}_N^+$ is also called the ‘scaling field’ of N – written $S_N$. Since $\mathbb{Q}_N$ is equivalent to $\mathbb{Q}_{N/2}$ for N twice-odd, $S_N = S_{N/2}$.

Lemma 3.2 (Scaling Field Lemma) For any regular N-gon, the maximal real subfield $\mathbb{Q}_N^+$ has a unit basis consisting of the primitive (canonical) scales.

Proof: For a given N we have defined $s_k = \tan(k\pi / N)$ for $1 \leq k < N/2$. These ‘star points’ are classified as ‘primitive’ if $(k,N) = 1$ and ‘degenerate’ otherwise. Here we show that the set of primitive scales, $T = \{t_k = s_1/s_k: (k,N) = 1\}$ is a basis for $\mathbb{Q}_N^+ = \mathbb{Q}_N \cap \mathbb{R}$. $\mathbb{Q}_N$ can be generated by any ‘primitive’ N-th root of unity of the form $\zeta^k = \exp(2k\pi i / N)$ with $(k,N) = 1$ – so the indices of the primitive scales are also indices of primitive roots of unity.

Since $i\tan(\theta) = (e^{i2\theta}-1)/(e^{i2\theta}+1)$, $i s_k = (e^{i2k\pi i / N}-1)/(e^{i2k\pi i / N}+1) = (\zeta^k-1)/(\zeta^k+1)$ so $i s_k$ is in $\mathbb{Q}_N$ and $\text{scale}[k] = \tan(\pi / N) / \tan(k\pi / N) = i s_1 / i s_k = \left[ \begin{array}{c} \zeta-1 \\ \zeta+1 \end{array} \right] \left[ \begin{array}{c} \zeta^k+1 \\ \zeta^k-1 \end{array} \right]$ is in $\mathbb{Q}_N^+$. We will show that when $(k,N) = 1$, scale[k] is an algebraic integer in $\mathbb{Z}[\zeta]$ and its inverse coscale[k] = cot($\pi / N$)/cot($k\pi / N$) is also an integer. Regrouping terms, $\text{scale}[k] = \left[ \begin{array}{c} \zeta^k-1 \\ \zeta^k+1 \end{array} \right] \left[ \begin{array}{c} \zeta^{-1} \\ \zeta^{-1} \end{array} \right]$. The term on the left is called a ‘cyclotomic unit’ in $\mathbb{Z}[\zeta]$, but we will show from first principles that this product is a unit. Since $(k,N) = 1$, there is a (rational) integer j such that $kj = 1(\text{Mod}N)$. Therefore

$$\left[ \begin{array}{c} \zeta^{-1} \\ \zeta^{-1} \end{array} \right] = \left[ \begin{array}{c} (\zeta^k)^j - 1 \\ (\zeta^k)^j - 1 \end{array} \right] = \sum_{0}^{k-1} (\zeta^k)^j$$

and when k is odd

$$\left[ \begin{array}{c} \zeta^k+1 \\ \zeta+1 \end{array} \right] = \left[ \begin{array}{c} (-\zeta)^k - 1 \\ (-\zeta^k) - 1 \end{array} \right] = \sum_{0}^{k-1} (-\zeta)^j$$

If k is even N must be odd, so repeat the above with $k' = k+N$. This substitution leaves scale[k] and coscale[k] unchanged. Therefore scale[k] is an algebraic integer.
For coscale[k] replace $\zeta$ with $-\zeta$ so when $k$ is odd the two quotients are $\sum_{j=0}^{i-1} (-\zeta^k)^j$ and $\sum_{j=0}^{i-1} \zeta^j$.

When $k$ is even, again replace $k$ with $k'= k+N$ which will be odd, and the inverse $j$ can be chosen odd so that it will preserve the sign change. Therefore scale[k] is an algebraic unit in $\mathbb{Q}_N^+$ with inverse coscale[k].

To show that the set $T$ of primitive scales forms a basis for $\mathbb{Q}_N^+$, note that $|T| = \varphi(N)/2$ because $(k,N) = 1$ implies that $(N-k, N) = 1$. It only remains to show that the primitive scales are independent over $\mathbb{Q}$.

Suppose that $\sum_{15k<2N/2} a_t k = 0$ with $(k,N) = 1$ and $a_i \in \mathbb{Q}$, then $\frac{1}{s_i} \sum_{15k<2N/2} a_t k = \sum_{15k<2N/2} a_t r_k = 0$

where $r_k = \cot[k\pi/N]$ with $(k,N) = 1$. This contradicts the Siegel-Chowla result that the primitive $r_k$ are independent over $\mathbb{Q}$. Therefore the primitive scales are a unit basis for $\mathbb{Q}_N^+$. □

**Example 3.1** (N = 11) Set $\zeta = \zeta_{11}$ then scale[4] = $\frac{Tan[\pi/11]}{Tan[4\pi/11]} = \frac{\zeta - 1}{\zeta + 1} \frac{\zeta^4 + 1}{\zeta^4 - 1} = \frac{\zeta - 1}{\zeta^4 + 1} \frac{\zeta^4 - 1}{\zeta + 1}$

$\coscale[4] = \frac{Cot[\pi/11]}{Cot[4\pi/11]} = \frac{\sum_{j=0}^{2} (-\zeta^4)^j \sum_{j=0}^{14} (-\zeta)^j}{\sum_{j=0}^{14} (-\zeta^4)^j \sum_{j=0}^{14} \zeta^j} = (1 - \zeta^4 + \zeta^8) \cdot \sum_{j=0}^{14} \zeta^j$

Note that this shows a relationship between scale[4] and $\zeta^4$ -which goes back to star[4] and S[4].

Since all of the scales are in $\mathbb{Q}_N = \mathbb{Q}(\zeta_N)$, Mathematica will find a polynomial expression for any scale[k] in terms of $\zeta_N$ but there is no guarantee (except this Lemma) that scale[k] will be in $\mathbb{Z}[\zeta_N]$ when the scale is primitive. In Mathematica set $z = \text{Exp}[2*\pi*I/11]$, then

$$\text{AlgebraicNumberPolynomial[ToNumberField[scale[4], z],x]} = -\{3 + 4x^3 + 2x^4 + 2x^5 + 2x^6 + 2x^7 + 4x^9\}$$

Since all the $i_s$ are in $\mathbb{Q}_N$, the degenerate scales are still in $\mathbb{Q}_N^+$ and any such scale will be a linear combination of the primitive scales. The same is true for the degenerate $s_k$.

**Corollary 3.1** For a given N, every $s_j$ for $j < N$, is a linear combination of the primitive $s_k$.

Proof: Suppose $(j,N) = m \geq 1$, then $(j/m,N/m) = 1$ and $s_{j/m}$ of $N/m = s_j$ of N. Since $\mathbb{Q}_{N/m} \subseteq \mathbb{Q}_N$, $is_j \in \mathbb{Q}_N^-$ and the set $iS = \{is_k : (k,N) = 1, k < N/2 \}$ forms a (vector space) basis for $\mathbb{Q}_N^-$ because $|S| = \varphi(N)/2$ and the $is_k$ are independent over $\mathbb{Q}$. Therefore $is_j$ is a linear combination of the primitive $is_k$ which implies that $s_j$ is a linear combination of the $s_k$. □

**Example 3.2** For a case like N = 18, known summation formula such as those found in [P] can be used to find the coefficients. For example $\tan(\pi/18) + \tan(\pi/18 + \pi/3) + \tan(\pi/18 + 2\pi/3) = \tan(6\pi/18) = \sqrt{3}$. Note that all the factors on the left side are primitive in $N = 18$, with k values 1, 7 and 13 (= -5), so $\tan(\pi/18) + \tan(7\pi/18) - \tan(5\pi/18) = \sqrt{3}$. In general it can be very difficult to find these coefficients and the same applies to coefficients of the scales.
**Lemma 3.3** We have shown that GenScale[N] is \( \text{Tan}[\pi/N]^2 \) for \( N \) even and \( \text{Tan}[\pi/N] \cdot \text{Tan}[\pi/2N] \) for \( N \) odd. Here we show that GenScale[N] is primitive except when \( N \) is twice-odd – in which case GenScale[N/2] is primitive.

Proof: By definition \( \text{GenScale}[N] = \text{scale}[<N/2>] \) which is primitive iff \( (<N/2>,N) = 1 \), This is true iff \( N-1 < (2<N/2>) < N \). Since \( (N,N+1) = 1 \), \( (<N/2>,N) \) is either 1 or 2. When \( N \) is odd, \( <N/2> = (N-1)/2 \) is even so \( (<N/2>,N) = 1 \). When \( N = 2M, <N/2> = M-1 \) so \( (<N/2>,N) = (M-1,2M) \) which is only 1 when \( N \) is twice-even. \( \square \)

**Corollary 3.2** For a regular \( N \)-gon, GenScale[N] is a unit generator of the scaling field \( S_N \) except when \( N \) is twice-odd, in which case \( \text{GenScale}[N/2] \) is a unit generator of \( S_{N/2} \) and \( S_N \).

**Example 3.3** Continuing with Example 3.1 above, Lemma 3.3 says that scale[4] of \( N = 11 \) can also be expressed as a polynomial in \( x = \text{GenScale}[11] = \text{Tan}[\pi/11] \cdot \text{Tan}[\pi/22] \)

\[
\text{AlgebraicNumberPolynomial}[\text{ToNumberField}[\text{scale}[4],\text{GenScale}[11],x] = \\
\frac{1}{8}(-1+48x+26x^2-x^4)
\]

Note that when \( N \) is twice-odd, it is still true that \( \text{Tan}[\pi/N]^2 \) is a generator of \( S_N \) but it may no longer be a unit or even an integer. Therefore it would not be a good choice of generator. The First Family geometry shows clearly the gender issue discussed earlier in this section.

**Example 3.4** (The First Family for \( N = 6 \)) The First Family Theorem says that \( hS[1]/hN = \text{scale}[2] = \text{GenScale}[6] = \text{Tan}[\pi/6]^2 = 1/3 \), but this is not an algebraic integer, so a better choice of scaling is \( hS[2]/hN = \text{GenScale}[3] = \text{Tan}[\pi/6] \cdot \text{Tan}[\pi/3] = 1 \). This avoids the gender mismatch between \( N = 6 \) and \( S[1] \) and assigns the correct scaling to the web \( W \).

For \( N = 3, 4 \) and 6, \( \varphi(N)/2 = 1 \) so they have linear algebraic complexity. This means that there will be no accumulation points in the outer-billiards web \( W \) because the web consists of rays or segments parallel to the sides of \( N \) and under the outer-billiards map, these segments are bounded apart by linear combinations of the vertices. When \( N \) is regular the vector space determined by the vertices has the same rank as \( \mathbb{Q}_N \) - namely \( \varphi(N) \). Therefore the coordinate space of \( N \)-gons with linear complexity will have rank 2 over \( \mathbb{Q} \) and affinely rational coordinates. Since the outer-billiards map is itself an affine transformation these ‘rational’ coordinates are preserved and the web is also affinely rational – with no limit points.
Definition 3.2 (Canonical polygons) Every regular N-gon defines a coordinate system, and any line segment or polygon P (convex or not) that exists in this co-ordinate system will be called canonical relative to N if for every side s_P, the ratio s_P/s_N is in S_N. The Scaling Conjecture says that all tiles and line segments which arise in the web W of the outer-billiards map are canonical.

Example 3.5 Any line segment defined by a linear combination of star points of N is canonical because if T is such a linear combination T/s_1 is a linear combination of dual scales, so it is in S_N. Therefore every gender-change mutation or period-based mutation is canonical. In addition every star polygon based on N is canonical. Our convention for scaling N-gons is to scale them relative to another N-gon and in this case side scaling is the same a height scaling. The only mixed-gender case is with N twice-odd and the matching M tile can be used as reference for scaling N/2-gons. All the scales of N/2 are also scales of N, so any N/2 scaling has an equivalent scaling using N.

Lemma 3.4 For a regular N-gon, the First Family S[k] tiles are canonical.
Proof: For N even, 
\[
\frac{hS[k]}{hN} = \frac{\tan(\pi / N)}{\tan((N / 2 - k)\pi / N)} = \text{scale}[N-2k] \text{ of } N, \text{ which is in } S_N.
\]
For N odd 
\[
\frac{hS[k]}{hN} = \frac{\tan(2\pi / 2N)}{\tan((N-2k)\pi / 2N)} = \text{scale}[N-2k]/\text{scale}[2] \text{ of } 2N \text{ so it is in } S_{2N} = S_N. \quad \square
\]

Since the S[k] are canonical regular N-gons or N/2 gons, the First Families and subsequent families generated by the S[k] will also be canonical regular N-gons or N/2 gons. The linear or quadratic cases like N = 3,4,5,6, 8, 10, and 12 have webs consisting of only scaled First Family tiles with possible period-based mutations, so all tiles are canonical.

Definition 3.3 (Ideal generations at GenStar[N]) For any regular N-gon with N > 4 , define D[0] = D and M[0] = M (the penultimate tile of D). Then for any natural number k > 0, define M[k] and D[k] to be DS[1] and DS[2] of D[k-1] so for all k, M[k] will be the penultimate tile of D[k]. The (ideal) kth generation of N is defined to be the (ideal) First Family of D[k-1]. Therefore M[k] and D[k] will be ‘matriarch’ and ‘patriarch’ of the ‘next’ generation – which is generation k+1. By Lemma 3.1, hM[k]/hM[k-1] will be GenScale[N] or GenScale[N/2] if N is twice-odd.

Example 3.6 (Ideal generations at GenStar[N] for N = 9 – where by convention M[0] = N)

(The Mathematica code for these families is FFM1 = TranslationTransform[cM[1]][First Family*GenScale] and FFM2 = TranslationTransform[cM[2]][FirstFamily*GenScale^2].)
Section 4. The Outer-Billiards map

Except for motivation, the first three sections are independent of any mapping, and here we will show connections between the First Families and the outer-billiards map $\tau$. In terms of dynamics the $S[k]$ are known as ‘orbital resonances’ - of the type that exist between Jupiter and Saturn where 5 orbits of Jupiter is approximately 2 of Saturn. As shown by Lemma 4.1 below, the points inside each $S[k]$ tile will have constant step-k orbits around $N$ – which means the orbit will skip $k$ vertices on each iteration of the outer-billiards map $\tau$ as shown here for $S[2]$ of $N = 7$. This implies that the centers of the $S[k]$ will have period $N/(k,N)$.

**Definition 4.1** (The outer-billiards map $\tau$) Suppose that $P$ is a convex polygon in Euclidean space with origin internal to $P$. If $p$ is a point external to $P$ that does not lie on a blue ‘trailing edge’ of $P$, then the (clockwise) outer-billiards image of $p$ is $\tau(p) = 2c-p$ where $c$ is the nearest clockwise vertex of $P$.

The fact that $\tau$ is a reflection means that the even and odd cases are fundamentally different under the outer-billiards map. The points inside a polygonal tile such as $S[2]$ must all map together under $\tau$, so they will all have the same period $q$ - and it takes an even number of reflections to have a periodic orbit for the tile - so $q$ will be even. The one possible exception is the ‘center’ of the tile – which could have minimal period $q/2$.

**Example 4.1** (The orbit of $S[2]$ for $N = 7$). All points in $S[2]$ have step-2 period 14 orbits. The center also has period 14, but its prime period is 7.

For a regular $N$-gon, this ‘period doubling’ can only occur if $N$ is even because the dihedral symmetry group $D_N$ for $N$ even contains $N/2$ reflections based on pairs of opposite vertices, while $D_N$ for $N$ odd has all $N$ reflections based on vertices and opposite sides. The canonical equivalence of $Q_{N/2}$ and $Q_N$ maps $v$ to $-v$ for the vertices of $N/2$ to yield the vertices of $N$. The added symmetry of the $N$ even case was addressed in the introduction. In physics the ‘parity’ issue between even and odd functions is fundamental with scalars like mass, time and charge clearly ‘even’ under spatial inversion and vectors typically odd.

In Example 4.1 above, $\tau^2(cD[2]) = cD[2]$ but for any other point $p$ in $S[2]$, $\tau^2(p)$ will yield an offset from $cD[2]$ as shown on the right. Note that $\tau^k(p)$ will always have the form $2Q + (-1)^k p$. 
where $Q$ is an alternating sum of vertices of $N$, so $\tau^7(p) = 2Q - p$ for some $Q$. Therefore $p$ will have period 7 iff $2Q = 2p$ and here the only solution is $p = cS[2]$. For all points in $S[2]$, the ‘second round’ of 7 iterations has the same $Q$ (except for sign), so the concatenation yields $Q' = 0$ and $\tau^{14}(p) = p$. This is a ‘stable’ period 14 orbit.

**Lemma 4.1** (Canonical Orbits of $\tau$) For all regular $N$-gons, $cS[k]$ has a constant step-$k$ outer-billiards orbit about $N$ with period $N/(k,N)$

Proof: We will show that there is a ‘duality’ between the $cS[k]$ and the star[$k$] defined by $cS[k] =$ **OuterDual[star[$k$],N] = RotationTransform[-Pi/N][star[$k$]*rN/hN]**, so that any edge-based orbit of star[$k$] defines a vertex-based orbit of $cS[k]$.

Every star[$k$] point is a vertex of an $\{N,k\}$ star polygon embedded in $\{N,<N/2>\}$. Therefore it defines a ‘edge-orbit’ which coincides with the edges of $N$. By definition this orbit skips $k$ edges so it has period $N/(k,N)$ as shown below in magenta for star[4] of $N = 14$. Because $\{N,k\}$ has rotational symmetry, this orbit will extend equal distance on either side of the midpoint of each edge. Therefore it can be converted to an outer-billiards orbit by swapping edges and vertices of $N$ – and rotating by $\pi/N$. This is exactly what the OuterDual map does, so the only remaining issue is to show that OuterDual[star[$k$],N] = cS[k].

The First Family Theorem maps star[$k$] to $cS[k]$ by displacing star[$k$] horizontally by $sN/2$ and vertically by $hS[k]$. Measured from star[1], the horizontal displacement of $cS[k]$ will be simply $hN*s_k$, so the slope determined by $cS[k]$ is $hS[k]/s_k$. For even $N$, this is $scale[N/2-k]/s_k = (s_1/sN/2-k)/s_k = s_1$. For $N$ odd, the $S[k]$ are even and this ratio is unchanged. This $s_1$ rotation relative to the star[1] vertex of $N$ is identical to the Outer Dual rotation after first translating the origin to star[1] under the height-radius exchange. □

Note that this implies that the $cS[k]$ are colinear – which must be true to preserve the rotational symmetry of the star polygons. See Example 4.2 below and Table 4.1 for $N = 24$.

**Example 4.2** ($N = 14$ and $N = 9$) Note that star[5] of $N = 14$ is primitive so $S[5]$ will have a period 14 orbit – which will visit both heptagons embedded in $N = 14$. By contrast $D = S[6]$ will only visit one heptagon and have period 7, so the ring of 14 $D$’s will decompose. This occurs only for $N$ twice-odd where $<N/2>,N) = 2$. For $N = 9$, $cS[3]$ only ‘sees’ one triangle embedded in $N = 9$ and $cS[3]$ will have period 3 which will cause a ‘mutation’ in $S[3]$ - as explained below.
Definition 4.2 (The outer-billiards singularity set (web) of a convex polygon P)
Let $W_0 = \bigcup E_j$ where the $E_j$ are the (open) extended edges of $P$. The level-$k$ (forward) web is $W_k = \bigcup_{j=0}^{k} \tau^{-j}(W_0)$ and the level-$k$ (inverse) web is $W^i_k = \bigcup_{j=0}^{k} \tau^j(W'_0)$. The limiting webs are $W = \lim_{k \to \infty} W_k$ and $W^i = \lim_{k \to \infty} W^i_k$.

Example 4.3: (The star polygon webs of $N = 7$ and $N = 14$) For a regular polygon $N$, $\tau^{-1}$ is $\tau$ applied to a horizontal reflection of $N$, so the $W^i_k$ can be generated by mapping the forward extended edges of $N$ under $\tau$ - and if desired a reflection gives $W_k$ also. Here we choose the level-0 set $W_0$ to be the edges of the (maximal) star polygon of $N$. Below are $W_k$ for $k = 0, 1, 2$ and 10 for $N = 7$ and $N = 14$. These ‘generalized star polygons’ will have symmetry group $D_N$.

It is easy to show that these ‘inner-star’ regions are invariant. In [VS], the authors give evidence for the fact that these regions bounded by $D$ tiles, can serve as a ‘template’ for the global dynamics. When $N$ is even, symmetry allows this template to be reduced to half of the magenta rhombus shown above. This will be our default region of interest for $N$ even, and for $N$ odd it will extend from $D$ to the matching right side $D$ as shown here for $N = 7$.

When $N$ is twice-odd, the geometry of these two default regions should be equivalent because the equivalence of cyclotomic fields implies that the $M$ tile of $N$ can be regarded as $N/2$ under a scaling and change of origin. The Scaling Lemma gives the equivalence of scales under $\text{scale}[k]$ of $N/2 = \text{scale}[2k]/\text{scale}[2]$ of $N = \text{scale}[2k]/\text{SC}(N)$.

Lemma 4.2 (Twice-odd Lemma) For $N$ twice-odd the First Families and webs of $N$ and $N/2$ are related by $T[x] = \text{TranslationTransform}[0,0]-cS[N/2-2][x]/\text{SC}[N,N/2]$. 

Proof: $T$ maps $M = S[N/2-2]$ to the origin and then scales it to be a gender change of $N$ and Lemma 2.3 shows that this is consistent with the First Family Theorem since $M$ is an odd $S[k]$. Because $T$ and $T^{-1}$ are affine transformations they will commute with the affine transformation $\tau$ and hence preserve the web $W$, so $T[W(N)] = W(N/2)$ and conversely. □

As noted in the introduction, there should be a matching dynamical conjugacy.
Example 4.4 (The extended First Family of N = 22) Using the rotational symmetry of W, the First Family of N= 22 can be extended as shown here. By the Twice-odd Lemma, it is valid to import a scaled version of the First Family of N = 11 and these will match up perfectly with the First Family of N = 22, but it is not clear whether this can be extended to the remaining S[k]. To answer this question we will need more information about the evolution of W.

Evolution of W and mutations in the S[k] tiles

Example 4.5 (The web evolution of N = 14). Note the mutations in the cyan odd S[k]. In each case the result is a magenta heptagon with the same center and height as in Lemma 2.3.

The (clockwise) outer-billiards map $\tau$ is defined for ‘most’ points on the forward edges of the N-gon - but it is discontinuous at the star points. This is a ‘shear’ discontinuity of horizontal magnitude $sN$ as the ‘target’ vertex changes abruptly. On each iteration of the web this shear is followed by a position-dependent rotation because every edge of N is being iterated and the 14 domains map to each other under $\tau$.

This ‘shear and rotate’ scenario is common for any piecewise isometry acting on a polygon because it is also a recipe for constructing N from sN. See also the dual-center map in the Appendix. In the example above, the 14 domains are partitioned by the star polygon edges and for N even, the rotation angles are the ‘star-angles’ $k\varphi$ where $\varphi = 2\pi/N$. (Note that this shear and rotation is consistent with the $sN/2$ center displacement of the S[k].)

D is constructed by a repetition of this ‘shear and rotate’ process. Since the rotation angle is $\varphi$, D is a clone of N. D is the only tile formed in a ‘normal’ step-1 fashion. In general S[k] will have edges formed by rotations of step N/2-k, because the numbering of the S[k] is ‘retrograde’ relative to the increase of the star angles.

By symmetry, the S[k] are formed from two competing shears, one relative to N and the other relative to D. These shears are $\varphi$ apart because they occur on consecutive edges of N.
For \( N \) twice-odd as shown here, it takes an even number of iterations to go from the bottom edge to the top shear. For \( S[k] \) with \( k \) odd, each step is \( j\phi \) with \( j \) even, so the top shear and bottom shear are a perfect match and either one would form \( S[k] \) independently - so the \( S[k] \) are \( N/2 \)-gons. This can be regarded as a ‘mutation’ or ‘resonance’ relative to the even \( S[k] \).

This step-2 evolution of the \( M \) tile would have to be consistent with the local First Family of \( N/2 \), and indeed this family is always step-2 with respect to \( D \) and \( N \) as shown in the First Family Theorem. For \( S[4] \) shown here, the step-size is 3, so the edge numbering will be 0,3,6,9,etc and this will be period 14 with no resonance with the top sequence, so \( S[4] \) will be a 14-gon, but formed in a redundant step-3 fashion. As with \( S[5] \), this will have an effect on the local ‘in-situ’ family of \( S[4] \). Note that with \( S[5] \) (\( N = 7 \)) at the origin, this \( S[4] \) tile would be called \( S[2] \) but it will still have a step-3 relationship with \( N = 7 \), so the webs of \( N = 7 \) and \( N = 14 \) are compatible – but they are only identical in the limit.

For \( N \) twice-even the star angle and shears are unchanged but now it takes an odd number of steps to go from the bottom edge to the top shear, so there are no resonances as in the twice-odd case. However all the \( S[k] \) (except \( D \)) will still be formed in the same multi-step fashion, and once again this will influence their ‘in-situ’ families.

**Multi-step ‘in-situ’ families**

This analysis shows that the gender-change mutations in the twice-odd case are just one aspect of a broader issue in the evolution of the \( S[k] \). In general for \( N \) even, the \( S[k] \) are formed from star angle \( k'\phi \) where \( k' = N/2-k \), so \( D \) is the only tile which is formed in a ‘normal’ 1-step fashion and it is truly a ‘retrograde’ version of \( N \). The matching \( M \) tile will always be formed in a step-2 fashion and hence subject to a possible gender-change mutation – but even when \( M \) is not mutated, it is still formed in a step-2 fashion and the web evolution is recursive – so this step-2 origin will affect the local family structure of \( M \) for all even \( N \)-gons.

**Example 4.6** (The web of \( N = 22 \)). Compared with the vector plot above it is clear that \( W \) preserves the extended First Family of \( N = 22 \), including the imported First Family of \( N = 11 \). This family is 2-step but the local web of \( S[9] \) skips just one edge – and that is because of the gender change. Likewise \( S[8] \) has a step-3 family consisting of \( S[1], S[4], S[7] \) and \( S[10] \) and its local web will skip 2 edges in each iteration. Each magenta line represents an additional edge skipped, so the mutated \( S[3] \) will skip 7 edges and \( S[2] \) will skip 8 edges – which will always be \(-2 \mod <N/2>\). This means that \( S[2] \) will have a ‘retrograde’ ccw web that skips 2 edges and this will play a major part in the evolution of the \( 2^{nd} \) generation on the edges of \( N \). This is true for all even \( N \)-gons and the odd cases will be doubled.
**Example 4.7** (The web of N = 24) Since M = S[10] has the same gender as N, there is no First Family to import, and we have no information about the local geometry except that S[10] was formed in a step-2 fashion in the web, so the local family is also step-2 relative to N – consisting of the odd S[k]. The ‘in-situ’ family of S[9] is step-3 (on both sides), but it is complicated by the fact that the period of S[9] is just 3, so S[9] has an incomplete web – which we call a period-based mutation. These will be discussed in more detail below.

The digital-filter map discussed in the Appendix will work for step-k rotations, and we have been able to verify that using the maximal step-5 (24/4 -1) for N = 24 will reproduce the local geometry of S[10], but very little is known about the general case. It does appear that outer-billiards is just a step-1 version of a much broader class of mappings. For N = 60 there are 14 non-trivial step-k mappings (60/4 -1) and the maximal 14-step web appears to be identical to the local geometry of the S[28] M-tile of N = 60. See Appendix F of [H3].

**Period-based mutations of S[k] tiles**

For any composite N-gon, there will be ‘non-primitive’ S[k] with (k,N) > 1 and this raises the possibility of mutations which occur because the periods of these S[k] will be shorter than the ‘canonical’ period which is N. As illustrated in Example 2.5 with S[2] of N = 7, all the S[k] of a prime N-gon will have (center) period N. For a twice-prime the periods will alternate N and N/2 – but there is no issue with period-based mutations because the ‘base’ period is prime.

For N = 24 the ‘base’ period is 24 – but the only tiles with that period are the ‘primitive’ S[1], S[5], S[7] and S[11]. Of the non-primitive S[k] all are mutated except S[2] and S[10]. We do not have a definitive criteria for these mutations, but typically the M tiles (S[10] here) are not mutated. This may be due to their ‘redundant’ step-2 origin.

**Table 4.1** Outer-billiards periods of S[k] centers for N = 24

Whenever the $\tau$-period of an S[k] tile is reduced it may cause an incomplete local web to form. Therefore all such mutations are formed from extended edges of the ideal S[k] (in a manner similar to the gender-change mutations). Since the web is naturally recursive, the initial extended edge is simply rotated about the original center to yield an equilateral mutation.
**Example 4.8 (Period-based mutations of N = 24)** Of the S[k] with (k,N) > 1, S[2] and S[10] are the only tiles which are not mutated. Even though S[10] is not mutated its step-2 origin implies that the ‘in-situ’ family are just odd S[k] as seen here.

The mutated tiles are easy to construct from the underlying S[k]. For example the mutated S[8] has bottom edge which extends from the right-side star[3] of the underlying S[8] to the normal left-side star[1] vertex. This edge is then rotated in the web and merged with the extended top edge to form equilateral edges. The result is the weave of two regular hexagons at slightly different radii. Here are the steps to construct the mutated S[8]:

(i) Find the star[3] point: MidS8= {cS[8][[1]], -hN}; star[3] = MidS8+{Tan[3*Pi/24]*hS[8],0};
(ii) H1=RotateVertex[star[3], 6, cS[8]] (magenta); H2=RotateVertex[star[1],6, cS[8]] (blue)
(iii) MuS8 = Riffle[H1,H2] (black) (This weaves them as in a card shuffle.)

These mutations are consistent with the in-situ family issues observed earlier. For example S[9] is formed in a step-3 fashion so its local web will skip 2 edges.. From the earlier plot in Example 4.7, it is clear that the left side family of S[9] consists of S[1], a mutated S[4], S[7] and S[10], The right-side family consists of S[2], S[5], S[8] and N at S[11]. These are strange families.

**The general web**

These examples show that W does not always preserve the S[k] tiles of the First Family but Lemma 4.1 shows that the centers are preserved and it is an easy matter to construct the resulting mutated tiles and show that they are canonical - so in this sense the S[k] are preserved.

The limiting ‘tiles’ could be points - which must have non-periodic orbits, or possibly lines similar to the structures that appear for N = 11 on the right below. No one has ruled out the possibility of limiting regions with non-zero Lebesgue measure. This is a long-standing open question in the phase-space geometry of Hamiltonian systems. Any non-limiting tile must be convex with edges parallel to those of N, so it is easy to see that the D tiles are maximal among regular polygons – and in fact rings of these tiles must exist at all radial distances so the dynamics in any finite region must be bounded.

**Example 4.9** Some non-regular tiles in W_k (click to enlarge)
**Local webs of the S[k] – in-situ vs. in-vitro evolution**

Since the S[k] tiles of any regular N-gon appear to be preserved under W, their local evolution should be compatible with W and it may be possible to use this local evolution to help understand the limiting structure of W. Since these S[k] are always formed in a multi-step fashion in W, there are no ‘normal’ S[k] when it comes to evolution.

For our purposes the web W is the invariant ‘star-polygon’ web of Example 4.3, so it is always bounded by rings of D tiles. W can be generated by iterating any forward edge of N under a ‘normal’ clockwise τ - but when N is even, D is a reflection of N, so from D’s perspective W is a ‘right-side’ web which is generated counter-clockwise. This is just a conceptual distinction because W is the same in both cases, but if we apply this left-right distinction to an S[k] tile, the two local webs will be different and it may be useful to consider its ‘normal’ left-side local web (as if it were N) as well as its right-side web from the ccw D perspective. In terms of programming they are both iterated the same way under τ, but now they are different intervals.

We noted earlier that W evolves in a ‘shear and rotate’ fashion with constant shear sN and variable rotation angle that matches the local ‘star polygon angle’ θ. If \( \phi = 2\pi/N \) is the exterior angle of N, these star angles have the form \( \theta_k = k\phi \) for N even and \( \theta_k = \pi - k\phi \) for N odd as shown below for N = 14 and N = 11.

**Example 4.10** The ‘star polygon angles’ for N even and N odd

The smallest angle \( \theta_1 \) occurs at GenStar[N] and this will be the rotation angle for D, so when N is even, D will have rotation angle \( \phi \) to match N, and when N is odd it will have rotation angle \( \pi - \phi \) which is \( \phi/2 \), so D will be a 2N-gon. The subsequent S[k] will have increasing rotation angles. By the First Family Theorem these S[k] will be N-gons for N even and 2N-gons for N odd.

Therefore for N even, each S[k] will be formed with rotation angle that skips \(<N/2>-k\) edges and S[9] below for N = 22 will have a local web that begins by skipping one edge (relative to the underlying magenta N-gon). Here we show the first iteration of the ‘normal’ left-side webs.

**Example 4.11:** The first stage in the local webs of the S[k] of N = 22 showing skips from 1 to 9.
Since clockwise and ccw rotations have edge skips differing by $<N/2>$, the ccw web of each $S[k]$ will skip-k edges - to match its orbital rotation around N. This will yield valuable information about the local geometry of $W$.

If the intervals $H_k$ are taken to be disjoint and their union is one complete extended edge, then the local webs will also be disjoint and $W$ will be the disjoint union (coproduct) of the local webs. For $N$ even it is only necessary to consider the region to the right of $S[<N/2>-1]$.

**Example 4.12** The level 300 local webs of the $S[k]$ for $N = 22$

These four invariant regions to the right of $S[9]$ are the union of the 9 local webs from Example 4.11 above. Only $S[9]$ has congruent left and right-side local webs. The other $S[k]$ may have very different left and right-side dynamics which could cross normal ‘family’ boundaries. Therefore there is no obvious way to generate these invariant regions except the method used here – which is to simply generate the disjoint local webs and color them as they arise. For example the right-side local web of $S[5]$ is all that is needed to generate the blue region local to $N = 22$. This local invariance is one case that can be predicted, because it results from $S[5]$ and $S[6]$ sharing portions of an edge, so for $N$ twice-odd $S[<N/2>/2]$ should be the ‘shepherd’ $S[k]$. In general invariant regions occur on all scales and there are few predictive results.

The case of $N$ odd is similar but now the $S[k]$ are 2N-gons and the basic unit of rotation is doubled so the skips are also doubled starting with the maximal $S[<N/2>-1]$ at skip 2 (and retrograde N-2). Star[1] of N is now at retrograde skip-1, so the $S[k]$ will skip 2k-1 edges as illustrated below for $S[2]$ of $N = 17$. In particular $S[2]$ will always skip 5 edges.

**Example 4.13** The case of odd $N$ - showing the initial local web of $S[2]$ and $S[1]$ for $N = 17$

This 5-edge skip for $S[2]$ will be universal for $N$ odd just like the 2-skip is universal for $N$ even. We will explore the consequences of these facts below. There are conceptual and computational advantages to replacing the ‘awkward’ step-8 left-side web of $S[2]$ for $N = 22$ above with a simple right-side skip-2 web. The same applies to $N = 17$ where the right-side interval $H_0$ above combines the $S[2]$ and $S[1]$ webs and is an efficient way to generate the local web.
Example 4.14  The eight invariant regions of $N = 17$ showing the ‘shepherd’ at $S[8]$ of $D$.

For $N$-odd, the First Family includes even and odd cases so it contains two very different edge geometries at $D$ and at $N$. At $D$, $S[2]$ is known as $DS[2]$ and by the results above it will have a fairly well-behaved skip-2 local web that will include $DS[1]$ – which has the potential to be a 2nd generation $N = 17$. The 4k+1 conjecture below predicts that this process can be continued with generations of $D[k]$ and $M[k]$ tiles converging to $GenStar[17]$. The edge geometry of $N = 17$ is also dominated by the local web of $S[2]$ which contains $S[1]$, but these are $2N$-gon’s and $S[2]$ has a skip-5 geometry that is not so well-behaved. These two geometries will be studied below.

The 4k+1 Conjecture  (part (i) is not conjecture)

(i) For any regular $N$-gon with $N > 4$ Definition 3.3 describes a well-defined (ideal) sequence of $M[k]$ & $D[k]$ tiles converging to $GenStar[N]$ with $M[1] = DS[1]$ and $D[1] = DS[2]$ and for any positive integer $k$, $hM[k+1]/hM[k] = hD[k+1]/hD[k] = GenScale[N]$

(ii) When $N = 4k+1$ we conjecture that the $M[k]$ and $D[k]$ in part (i) exist under the outer-billiards map $\tau$.

(iii) When $N = 4k+1$ we also conjecture that the ratio of the $\tau$-periods of $cM[k]$, $cM[k-1]$ and $cD[k]$, $cD[k-1]$ approaches $N + 1$.

It appears that this conjecture is the recursive form of a more fundamental conjecture about the local web evolution of the $S[2]$ tiles for an arbitrary $N$-gon.

Definition: For any regular $N$-gon, the tiles on the edges of $N$ which are strongly conforming to $S[2]$ and exist in the limiting web $W$, will be called the ‘$DS[k]$ tiles of $S[2]$’ or simply $DS[k]$ when $S[2]$ is understood. These tiles make up the ‘actual’ First Family of $S[2]$ as opposed to the ideal First Family of $S[2]$ which is a scaled version of the First Family of $N$ (or $2N$ if $N$ is odd.)

Edge Conjecture. For an arbitrary regular $N$-gon, every potential $DS[k]$ tile on the edges of $N$ which satisfies the Rule of 4 for $N$-even or the Rule of 8 for $N$-odd, will be among those that exist in the web $W$. The Rule of 4 says that counting down from $S[1]$ at $DS[N/2-2]$, the $DS[k]$ will exist mod 4. The Rule of 8 says that counting down from $S[1]$ at $DS[N-4]$, the $DS[k]$ will exist mod 8. (Other $DS[k]$ may exist as secondary tiles.)

Every regular $N$-gon for $N$ even will have a similar Rule of 4 issue - with the possibility of three missing $DS[k]$ between existing $DS[k]$. $N = 22$ is typical of the $8k + 6$ case where $DS[1]$ will be among the survivors. Since $S[1]$ is always a survivor at $DS[N/2-2]$ it is easy to predict which $DS[k]$ will survive. The $8k + 2$ ($4k + 1$) case is the only one where $DS[3]$ is a guaranteed survivor and since this occurs adjacent to the edges of $S[2]$ , it allows for the possibility that the local web of $DS[3]$ will generate right and left-side $DS[2]$’s and the matching $DS[1]$’s to play the role of $D[2]$’s and $M[2]$’s for a 3rd generation on the edges of $S[2]$.

The Edge Conjecture can be applied recursively by promoting $S[2]$ to $N$ so $D[2]$ is the new $S[2]$. This recursion would be feasible if $D[2]$ has a local web evolution similar to $D[1]$ and there is evidence that the skip-2 web evolution of the $D[k]$ is inherited. This would imply part (ii) of the $4k+1$ conjecture and we will show here by a simple symmetry argument that the corresponding Rule of 4 would imply the $M[k]$ (or $D[k]$) $N +1$ temporal scaling of part (iii).

Example 4.16 The web evolution of $S[2]$ of $N = 34$. This is an $8k + 2$ case with $k = 4$.

Each $DS[3]$ ‘cluster’ shown here contains 2 $D[2]$’s, and there will always be $k$ clusters on the right side of $S[2]$, so the right-side count is $2k$ $D[2]$’s. Relative to the blue line of symmetry, the back side will also have $2k$ $D[2]$’s, with one cluster divided between the sides. This yields $4k + 2$ $D[2]$’s which is the $N/2 + 1$ temporal scaling predicted by the $4k + 1$ conjecture.
This predicted convergence at star[1] of S[2] is congruent to the ideal First Family convergence at GenStar from Definition 3.3, because the edges of N must have reflective symmetry and star[1] of N is a reflection of GenStar at D. Therefore this N/2+1 temporal scaling can be regarded as a N/2 scaling for D[k] itself along with the ‘+1’ which is the outlier D[k+1] at GenStar (or star[1] of D[k]). This D[k+1] becomes the foundation for the next generation.

The ‘worst’ case scenario for N even appears to be the 8k+4 case (with the exception of N = 12) where the chain of S[k] does not begin until DS[4], so N = 20 has no D[2] or M[2] tiles to form canonical generations on the edges of N. The extreme 8k + 6 and 8k cases are not much better because the former has isolated M[2]’s and the latter has isolated D[2]’s.

The web evolution of S[2] for N odd and the Rule of 8

All web evolution is based on the edges of N, so for the N even, the basic unit of rotation for S[2] is the same as N. Even though the local web of S[2] evolves by skipping edges, the unit of rotation is the same as N. This is no longer true when N is odd because S[2] and S[1] are now 2N-gon’s. This implies that the local S[k] webs will involve even-skips as shown above. Therefore the right-side local web of S[2] will now skip 5 edges and the Rule of 8 becomes the Rule of 8. (A related incompatibility issue is that in the First Family of N, S[2] how has an offset relative to N so that star[2] of S[2] is now the local GenStar. This means that the definition of ‘strongly conforming’ must be applied relative to star[2] instead of star[1], and the resulting DS[k] may be very different from the traditional First Family.)

As always the magenta web will generate S[1] and the Rule of 8 here is relative to this S[1] as DS[13] - so it just includes DS[5] as shown below.
Example 4.18 The extended web evolution of $S[2]$ for $N = 17$

This illustrates the $8k+1$ case where $DS[5]$ will always exist. The ‘boundary’ case is $8k+5$ where the smallest $DS[k]$ is $DS[1]$. For example $N = 21$ has $S[1]$ as $DS[N-4] = DS[17]$ so it includes $DS[9]$ and $DS[1]$. Since $S[2]$ is twice-odd this $DS[1]$ would normally be an $N$-gon acting as $M[2]$, but since the actual $S[2]$ family is based on star[2], $DS[1]$ will be a vertex based tile congruent to a $2N$-gon $D[2]$ and the entire family will be strongly conforming to star[2] and not star[1]. To see what these modified tiles look like, we will construct the $DS[k]$ for $N = 15$.

Example 4.19 The web evolution of $S[2]$ for $N = 15$  (the $8k+7$ case)

Table 4.2  Rule of 8 - surviving 2\textsuperscript{nd} generation tiles on the edge of N for N odd (To apply the Rule of 8, subtract 8 from previous DS[jj]. All existing DS[k] will be strongly conforming to star[2] of S[2].)

To summarize, the Edge Conjecture can be used to predict strongly conforming DS[k] tiles on the edges of N and when N is even the DS[k] are a subset of the known First Family of S[2], but when N is odd the DS[k] may no longer be members of the First Family of S[2].

Therefore it is now possible to make predictions about the geometry and dynamics on the edges of any regular N-gon and this may provide some insight into the overall evolution of W.

Below are examples of the 8 possible edge cases based on the Rule of 4 for N even and the Rule of 8 for N odd. In all cases we know that S[2] and S[1] are part of the First Family of N and it is no surprise that the local web of S[2] can generate the S[1] tile – but in the N-odd case, most of the resulting DS[k] tiles are not part of the normal First Family of S[2] – so the Rule of 8 seems to imply dynamics that are more complex than the N-even case.

Therefore all regular polygons belong to one of eight ‘dynamical’ classes under \( \tau \). These classes are based on the edge geometry of N, so when N is odd there will be competing classes on the edges of N and D and by convention we define the ‘2\textsuperscript{nd} generation’ of both N and D to be the edge geometry of D. These D’s are twice-odd so the only possibilities are 8k + 2 and 8k + 6 and this explains why the DS[1] = M[2] tile always exist in the 2\textsuperscript{nd} generation of odd N.

When N is odd, these 2\textsuperscript{nd} generations on the edges of D could be unrelated to the edge geometry of N where the DS[k] are relative to star[2] of S[2]. Technically these are odd DS[k], but their positions relative to S[2] are one-step removed, so the DS[1] in the 8k+5 family will play a role similar to a D[2]. Therefore N = 21 will have an isolated ‘DS[2]’ in a manner similar to N = 16. Both of these D[2]’s will generate local ‘3\textsuperscript{rd}-generations’ (with no M[2]), but only N = 16 seems capable of generating a 4\textsuperscript{th} generation with normal D[3] and M[3]. See Example 5.8.
Section 5  Examples of Singularity Sets

N = 5 and N = 8 are the only non-trivial regular cases where the singularity sets have been studied in detail. In [T] (1995) S. Tabachnikov derived the fractal dimension of W for N = 5 using ‘normalization’ methods and symbolic dynamics and in [S2] (2006) R. Schwartz used similar methods for N = 8. In [BC] (2011) Bedaride and Cassaigne reproduced Tabachnikov’s results in the context of ‘language’ analysis and showed that N = 5 and N = 10 had equivalent sequences. In [H3] we give an independent analysis of the temporal scaling of N = 5 based on difference equations and this will be reproduced here in the context of N = 10.

Example 5.1 The edge geometry of N = 10 - which is the first member of the 8k+2 family

Based on the Rule of Four, there will be k DS[3] ‘clusters’ on each side of S[2] and one cluster is divided by the line of symmetry to yield 4k+2 D[2]’s for a growth of N/2+1 as predicted by the 4k+1 conjecture. Since we have no proof of this conjecture, the predicted temporal scaling of 6 may be just a first approximation when applied to converging sequences of D[k] tiles at star[1] of N = 10 (or the equivalent convergence at star[1] of D[1] ).

The convergence shown here at star[1] of N = 10 appears to involve self-similar blue triangles which are anchored by D[k], so the geometric scaling of these triangles would be hD[k]/hD[k-1] = GenScale[5]. The predicted temporal scaling is 6 and (under the assumption of self-similarity) we show why this is correct - using difference equations relating the decagons and pentagons as in [H3]. These equations are shown in the table above. These two difference equations can be combined together to yield a second-order equation \( d_n = 5d_{n-1} + 6d_{n-2} \) which can be solved but it shows immediately that \( d_n/ d_{n-1} \) must approach 6.

Since the edges of any regular polygon have reflective symmetry relative to \( \tau \), there will always be a ‘3-dart’ configuration anchored by S[1] as shown below.

Example 5.2 Comparison of the edge geometry of the quadratic polygons N = 8, 10 and 12
These webs have just one non-trivial primitive geometric scale which is GenScale[N] (or GenScale[N/2] for N = 10). This is hD[k]/hD[k-1] = hM[k]/hM[k-1], so it is also the scale of the darts (or triangles) which are anchored by M[k] or D[k].

In each case the magenta ‘renormalization’ line shows how the initial dart (or triangle) is mapped to a self-similar version of itself under \( \tau^k \) for some k. As expected the N = 8 and N = 12 cases are closely related since their cyclotomic fields are generated by \( \{\sqrt{2}, i\} \) and \( \{\sqrt{3}, i\} \).

(i) For N = 8 (&12), the D[k] and M[k] are identical except for size. There are 3 darts in this invariant region and they are anchored by D[k]’s and each D[k] is surrounded by 3 M[k]’s - so the M[k]’s have temporal scaling of 9. (The M[2] count here is 8 plus 1 ‘outlier’ at star[1] of N.)

(ii) The temporal scaling of N = 10 is 6 as predicted by the 4k+1 conjecture and Example 5.1. Note that the ‘next-generation’ light-blue region shown here is composed of two overlapping ‘towers’ containing an M[k] and each M[k] is surrounded by 3 D[k+1]’s for a temporal scaling of 6 for the D[k]. Since these towers form a sequence converging to star[1] of M[1] this helps to explain why the D[k]’s overall should have this same scaling. This is a non-trivial fact and as explained earlier, the key issue is the relationship between the decagons and pentagons.

(iii) For N = 12, each dart is anchored by an S[4] and each S[4] is surrounded by 3 S[3]’s for a combined scaling of 9, and in the limit each S[3] will account for 3 M[k], so the M[k]’s scale by 27. This case is also not trivial and it is covered in more detail in Example 5.6.

Therefore the similarity (box-counting) dimension of the three webs should be:
(i) N = 5 & 10: \( \log[6]/\log[1/\text{GenScale}[5]] \approx 1.2411 \) where GenScale[5] = \( \tan[\pi/5]\tan[\pi/10] \)
(ii) N = 8: \( \log[9]/\log[1/\text{GenScale}[8]] \approx 1.2465 \) where GenScale[8] = \( \tan[\pi/8]^2 \)
(iii) N = 12: \( \log[27]/\log[1/\text{GenScale}[12]] \approx 1.2513 \) where GenScale[12] = \( \tan[\pi/12]^2 \)

For compact self-similar sets such as these, the similarity dimension will match the traditional Hausdorff fractal dimension. It is no surprise that these dimensions are increasing, but this applies only to the quadratic family. For the cubic family and beyond, the webs are probably multi-fractal – with a spectrum of dimensions. However it is likely that the maximal Hausdorff dimension will increase with the algebraic complexity of N, with limiting value of 2. See[LKV].

Below is a series of plots showing how the magenta web for N = 8 can be ‘smoothly’ mapped to the cyan web for N = 12, with N = 10 in between. These webs were generated by the digital-filter map of [H2] and the Appendix. This map creates webs which are clearly congruent to the outer-billiards map, but it allows for continuous variation of the angular parameter that defines N. That parameter is the same as the scaling field generator \( \lambda = 2\cos\theta \) which here increases from \( \sqrt{2} \) \( (2\cos[2\pi/8]) \) to \( \sqrt{3} \) \( (2\cos[2\pi/12]) \) with N = 10 in between at \( 2\cos[2\pi/10] = (\sqrt{5} + 1)/2 \).
Example 5.3 \((N = 7 \& N = 14)\). As with \(N = 5\) this web plot would be unchanged not matter which is at the origin (but the dynamics would differ). With \(N = 7\) at the origin, \(hM[1]/hN = \tan(\pi/7)\cdot\tan(\pi/14) = \text{GenScale}[7]\) and this is the scale of the 2nd generation at GenStar.

This 2nd generation at GenStar or \(\text{star}[1]\) of \(N= 14\) is clearly not self-similar to the 1st, but the even and odd generations appear to be self-similar and this dichotomy seems to be common for all \(N\)-gons with extended family structure at GenStar (including \(N = 5\) above where the periods are high and low). Most cases are similar to \(N = 13\) where the even and odd generations at GenStar are related in an imperfect fashion. This dichotomy is apparently driven by the fact that relative to \(N\) these even and odd generations require reflections. See Example 5.7 below.

\(N = 7\) and \(N = 9\) are ‘cubic’ polygons so they have a second non-trivial primitive scale along with \(\text{GenScale}[N]\). In both cases this competing scale is \(\text{scale}[2] = hS[1]/hS[2]\). Even though the local web of \(S[2]\) will always generate \(S[1]\), their families have little in common and \(\text{scale}[2]\) is non-commensurate with \(\text{GenScale}[7]\). This means that the geometry on the edges of \(N\) is very complex and in particular the limiting local dynamics at \(\text{star}[1]\) of \(N = 7\) is not predictable.

By contrast the 2nd generation dynamics on the edges of \(D\) or \(N = 14\) are more manageable since \(S[1]\) is now the penultimate ‘M’ tile of \(S[2]\). Therefore \(S[2]\) has the potential to play the role of a next generation \(D[1]\) with \(S[1]\) as the matching \(M[1]\). \(N = 14\) is a member of the \(8k+6\) family so the \(DS[1]\) tile of \(D[1]\) will exist as an \(M[2]\) but apparently it cannot generate \(D[2]\) without help from \(DS[3]\) (as in the \(8k+2\) cases). Here the required \(DS[3]\) is on the left side of \(D[2]\) and the early magenta web shows that it does share an edge with a virtual \(D[2]\) and this rotated edge will work for the real \(D[2]\). These ‘even’ generations are dominated by weakly conforming PM tiles. There is an orthogonal tile convergence at \(\text{star}[3]\) of \(D[1]\) with alternating PM and \(DS[3]\) tiles on the left and alternating virtual and real \(D[k]\) on the right.
Example 5.4 (N = 11 & N = 22) The two-elephant case from Example 1.2 takes place in the 2nd generation of N = 11 so these tiles exist on the edges of D – which is a reflection of N = 22. This is an 8k+6 family like N = 14 above so there is a DS[1] serving as an M[2], but it is not capable of generating D[2] without the help of a DS[3] and it appears that the weakly conforming Mx tiles that appear in the 2nd generation are the remnants of DS[3]’s which never formed.

The web plot below shows the predicted survival of M[2] and DS[5] – along with S[1] at DS[9]. This DS[5] played a role in the earlier construction of Sx and the other ‘elephant’ was Px which is only weakly conforming to D[1]. In [H6] we derive the parameters of Px along with Mx and Px. The difficult cases were Mx and Px and it was only possible to derive their parameters by doing exact calculations with the web of S[2].

These calculations for Mx are repeated in the Appendix to show that the toral digital-filter map and the complex-valued dual-center map give the same parameters. We will often use the dual-center map in these web calculations because it is trivial to implement. This map necessitates a change of origin so that in the plot above, star[1] of N is at the origin and the edge length is 1. This allows a natural juxtaposition of N and –N as shown in the insert below for N = 11. The symmetry between these two representations is the key to the simplicity of this map. (The only difference between these webs and the normal τ-webs is the number of iterations needed. The dual-center webs are simpler but need more iterations because they are based on both N and –N.)

Example 5.5 The edge geometry of N = 11 – which is in the 8k+3 family for N odd.

When N is odd, the 8k+1 and 8k+3 families have S[2]’s with no canonical DS[1],DS[2] or DS[3] tiles. For N = 11 the only canonical tile of S[2] is S[1] so most of the structure is due to the evolution of S[1] – which we know is retrograde skip-3. This is consistent with DS[4]’s which in turn generates M[2]’s - but no matching D[2]’s. There are also weakly conforming tiles that we call Gx’s. In [H6] we find the parameters of Gx and the elongated hexagons which we call Sk (see Example 4.15). Using Gx and one of the Sk as ‘elephants’ we also find the parameters of a small Sxx tile, but there is still no obvious sign of self-similarity or extended family structure.
Example 5.6 (N =12) For N twice-even the natural generation scaling is still through M[1] – which is identical to S[1] here. $hM[1]/hN = \tan(\pi/12)^2 = 7 - 4\sqrt{3} = \text{GenScale}[12]$. By contrast $hS[2]/hN = \tan(\pi/12)\tan(\pi/24) = 2/\sqrt{3} - 1$ is not an algebraic integer or a primitive scale.

There are period-based mutations in S[2] (period 6) and S[3] (period 4). Even though the period of S[4] is just 3, it is not mutated. This seems typical for first generation M-tiles, but the M[k] which form adjacent to D[k] will have missing S[1] and S[2] tiles. This seems unique to N = 12 and may be caused by the mutation of the matching D[k]. The first instance of this is D[1] below.

The S[2] period-based mutation is consistent the skip-2 nature of S[2] and indeed every S[k] can be regarded as a hidden ‘mutation’ since it is formed in a multi-step fashion. N = 12 is the first member of the 8k+4 family and it would be expected that the skip-2 nature of S[2] will have a dramatic effect on the resulting family of S[2]. The initial magenta web of S[2] just contains S[1] at DS[4] so it is fair to conclude that the resulting web shown here is based on S[1] as M[1]. Therefore the dynamics and geometry of N = 12 will be dominated by M[k] tiles – although the corresponding D[k] tiles do exist.

As indicated in Example 5.2, any $\tau$-web based on a single primitive scale should be eventually self-similar and that appears to be the case here. The three ‘darts’ above are anchored by S[4]’s and all the First Family tiles of M[1] scale by GenScale[12]. This determines the geometric scaling of the darts and assuming that these M[k] are dense, the only remaining issue is the ‘temporal’ scaling of the M[k]. The reasoning presented in Example 5.2 was that at each new generation the S[4] will scale by 3 and each S[4] is surrounded by 3 S[3]’s so the S[3]’s scale by
9. The non-trivial issue is to show that in the limit each $S[3]$ accounts for 3 $S[1]$'s – which are $M[k]$'s. The $M[2]$ count in the 2\textsuperscript{nd} generation above is 18 which is short of the predicted 27, but this is due to the mutated web of $M[1]$ which excludes as many as 10 $M[2]$'s.

Because of self-similarity, these mutations in the web of the $M[k]$ will persist in future generations – but they only exist in the $M[k]$ generated by $D[k]$ and it is clear that ‘most’ $M[k]$ are adjacent to the $S[3]$ since they are step-3 tiles of the $S[3]$. This can also be observed in the First Generation above.

In the 2\textsuperscript{nd} generation dart enlarged below, the only $M[2]$ that is generated by a $D[2]$ is at star[1] of N. The remaining 5 $M[2]$'s are generated as step-3 tiles of the $S[3][2]$ so they have normal webs which will contain $M[3]$'s at the step-1 positions. Therefore of the 23 ‘darts’ shown here only 3 are affected by the mutations – and this ratio will decrease with each new generation to yield a limiting count of 3 $M[k]$'s for each $S[3][k-1]$ and a limiting temporal scaling of 27 for the $M[k]$'s (and $D[k]$’s).

Another way to verify the temporal scaling for self-similar webs is to simply count the growth of the tiles using the $\tau$-periods. Here the $\tau$-periods of the $M[k]$ in the canonical invariant ‘star-region’ of Example 4.3 are 60, 942, 28292, 775356, 21055308,..with ratios of 15, 30, 27.41, 27.15. These are the combined periods of the $M[k]$ at GenStar and their reflections about $S[4]$. Even though the local web has perfect reflective symmetry with respect to $S[4]$, the dynamics are different and this combined count helps to minimize these differences. However the dynamics of any composite N-gon allows for ‘decomposition’ of expected orbits unto groups of orbits with smaller periods. This makes it difficult to match tile counts with periods, but for self-similar webs, the effect of these exceptions diminishes with each generation and in the limit the $\tau$-ratios will match the geometric ratios.

It is easy to find these $\tau$-periods because the $M[k]$'s scale by GenScale[12]. Setting $h_N = 1$

\[cM[k] = (1 - \text{GenScale[12]}^k) \cdot \text{GenStar} = \{-4215120(-1694157 + 978122\sqrt{3}), -4215120(-6322680 + 3650401\sqrt{3})\}.\]

The matching $M[12]$ at star[1] is a reflection of $M[12]$ about cS[4]. In both cases the periods are so high that these points will generate very accurate webs tiled by microscopic $M[12]$’s. In this GenStar or star[1] convergence the actual limit point does not have a well-defined orbit, but the astute reader may be able to do better and find a non-periodic interior point by tracing a sequence of $M[k]$ tiles that do not converge to an edge except in the limit. Such points are easy to find for $N = 5$ and $N = 8$ but they are more challenging here.
Example 5.7 (N = 13 & N = 26) These have algebraic order 6 along with N = 21, 28, 36 and 42. As predicted by the 4k+1 conjecture there appear to be sequences of M[k] and D[k] tiles converging to GenStar[13] which is also star[1] of D. Each of these M[k], D[k] pairs forms the basis for what we call generation k+1, so there should be an infinite sequence of generations as observed earlier in the quadratic cases. The M[1], D[1] tiles in that chain are shown below in the 2nd generation on the edge of N = 26 serving as a ‘right-side’ D tile of N = 13.

N = 26 is an 8k+2 polygon and therefore DS[3] exists and can construct matching D[2]’s and M[2]’s in clusters separated by 2 blank edges as in N = 34 and N = 10 earlier. There will be k of these clusters on both sides of the line of symmetry and a shared cluster, which yields 4k+2 D[2]’s = N/2+1. If this step-2 evolution continues for the new D[k] the temporal scaling of the D[k] should be 14, giving a local fractal dimension of Log[14]/Log[1/GenScale[13]] ≈ .7531. These limiting edge dimensions decrease with N with a minimum value of ½.

It is not difficult to find the parameters of weakly conforming tiles like Px. Py is not conforming to either D[1] or M[1] – but it is a ‘two-elephant’ case where Py shares star points with M[1] and a displaced S[2] of M[1]. See [H7] for a multi-generation derivation of Px and Py.

Below is the 3rd generation on the right side of D[1] but the left side of D[2]. This yields a ‘retrograde’ web relative to D[1] above, but it is still a classic 8k +2 case with canonical DS[3]’s and DS[7]’s. The reversed rotation entails a slight reduction of the resulting D[3]’s because the shared DS[3] has only one D[3]. This appears to be generic for 4k +1 cases so the relative D[k] periods alternate low/high starting with D[1]. For N = 13, the D[1], D[2], D[3], D[4] global τ-periods are 9*13, 119*13, 1673*13, 23415*13 with ratios 13.22, 14.06, 13.99.

The first few generations of N=13 are described in [H7]. It is no surprise that the 4th generation is closer to the 2nd with both Px’s and Py’s. There does not appear to be perfect self-similarity between generations but the local geometry of M[1] seems to survive on all generations so there are Py[k] for all k but Px[k] only for k even. It is expected that these canonical Rule of 4 DS[k] develop consistent local webs, and this would explain why the M[k] have similar dynamics.
**Example 5.8 (N = 16)**

N = 16 has ‘quartic’ complexity along N = 15, 20, 24, and 30. Both N = 16 and N = 24 are in the 8k family so the Rule of 4 implies that an isolated DS[2] will exist.

![Diagram](image1)

Even though M[2] is missing, the local web of D[2] contains a ‘normal’ M[3] and D[3] as well as matching S[3][3] and S[4][3] tiles as shown below. This makes the 3rd generation locally similar to the 1st generation. Since D[3] is clearly in the 8k dynamical family there is a well-defined 4th generation with M[4], D[4] and an S[4][4] – but no S[3][4] – so the 4th generation is only partially self-similar to the 2nd and 3rd. There is no doubt that this chain will continue and each generation may be locally unique with an even-odd dichotomy similar to N = 13.

![Diagram](image2)

The periods of the first 10 D[k] are: 8, 32, 456, 2464, 20872, 110368, 974664, 5165216, 45423368 and 240668192 which gives even and odd ratios of about 5.3 and 8.8.

N = 24 is also in the 8k family with an isolated D[2], but because of mutations, its local web is far from ‘normal’. There are no M[3]’s and only highly mutated D[3]’s which are quadrilaterals based on ideal DS[3]’s as shown below. It is possible for mutations to evolve in a self-similar manner as with N = 9 and N = 12, but there is no sign of that evolution here.

**Example 5.9** The 4th generation of N = 24.
Appendix. Exact Calculations using Symbolic Dynamics

In [H2] we describe mappings from physics, astronomy, circuit theory and quantum mechanics which have singularity sets $W$ which appear to be conjugate to the outer-billiards map. In most cases it is easy to see why these ‘webs’ are equivalent. These mappings are all piecewise isometries based on rational rotations – which are also known as affine piecewise rotations.

Starting with an initial partition of ‘phase’ space the individual mappings $T_i$ are usually bijective transformations so they map partitions to partitions. Therefore the main issue in describing the geometry of the combined map $T$ is understanding the evolution of these partitions. These partitions or ‘tiles’ lie in the complement of the singularity set $W$ and the natural way to find $W$ is to map the discontinuities under $T^{-1}$. For rational rotations $T^{-1}$ can be obtained by reversing the direction of rotation, so mappings like the outer-billiards map and digital-filter map are essentially their own inverses - so $W$ can obtained by mapping the extended edges of $N$ under $T$.

Example A1 Use the evolution of the ‘web’ $W$ to find the parameters of the $M_x$ tile of $N = 11$ with (i) the outer-billiards map, (ii) the digital-filter map and (iii) a complex-valued Goetz map.

Part (i): The outer-billiards map. In Example 5.3, we noted that the $M_x$ tile of $N = 11$ is a weakly conforming regular $N$-gon that occurs in the 2nd generation for $N = 11$ on the edges of $D$. Therefore $\text{star}[5]$ of $M_x$ is $\text{star}[1]$ of $D[1]$ as shown below. By the Two-Star Lemma, the parameters of $M_x$ can be determined by finding another star point of $M_x$. In this example we will find the $\text{star}[4]$ point of $M_x$ by tracing the web evolution of the interval $H_1$ - in the context of $N$ with radius 1. (By reflection, this evolution can equally be studied on the edges of $N = 22$.)

The interval $H_1$ lies on the horizontal base edge of $N = 11$ so there are 11 such intervals equivalent to $H_1$ under rotation, and the local $\tau$- web determined by $H_1$ includes the iteration of each of these rotated copies. Under $\tau$, these 11 regions map to each other and after 99 iterations of each interval, 8 segments land back at $D[1]$ as shown here.

The interval $H_2$ arises after just 13 iterations. Like all First Family vertices, $p_0$ is in $Q_{11}$ and we suspect that it maps to $p_1$ (as a one-sided limit) – and hence determines the offset of $p_2$. These vertices technically have no image under $\tau$, so we will find $p_1$ using the ‘surrogate’ orbit of a point that is close to $p_0$ and on the interval $H_2$. (Typically intervals like $H_2$ will get truncated under iteration, but by inspection it is clear that the inner portion of $H_2$ survives well beyond the few hundred iterations needed here.)
Here are the calculations using Mathematica:

(i) Since the image under $\tau$ of any edge is a parallel edge, the slope of H2 is known, so set $p0N$ to be a point on H2 within 8 decimal places of $p0$. \textbf{Orbit = NestList}[\tau, p0N, 200]

(ii) Since $\tau(p) = 2c_j - p$ for some vertex $c_j$ of $N = 11$, $\tau^k(p) = (-1)^k p + 2Q$ where Q is an alternating sum of vertices. Every $\tau$-orbit determines a sequence \{c_k\} of vertices and the matching indices are sufficient to find Q and determine the orbit. The study of these partition sequences is called ‘symbolic dynamics’ - as pioneered by George Birkhoff and Steven Smale. In this appendix we will call them S-sequences - and the Mathematica module IND will find them to any depth.

$S[p0N,150] = IND[p0N,150] = \{11,5,10,4,9,3,8,1,6,11,5,10,4,9,2,7,1,6,11,5,…\}$

Note that these indices initially advance by \{5,5,5,5,5,5,5,4\} (mod 11) because D has step sequence \{5\} and D[1] has (periodic) step sequence \{5,5,5,5,5,5,5,4\}. Here this sequence will eventually break down. In general no web point can have a periodic orbit because these points have no inverse. We will use these indices in pairs, using the ‘return’ map $\tau^2(p) = p + 2(c_k - c_j)$.

(iii) $P1 = PIM[p0N,75,1]$ will take these 150 indices in pairs and reconstruct the orbit – while $P3 = PIM[p0N,75,3]$ will construct a step-3 version of this orbit – which is called a ‘projection’ or algebraic graph as defined in [S2]. To get an exact orbit, simply use $p0$ instead of $p0N$.

$p1 = \tau^{150}(p0) = P1[[75]]$. $p1[[1]] = -6\cos(\frac{3\pi}{22}) - \cos(\frac{\pi}{11})\cos(\frac{\pi}{22}) + 4\sin(\frac{\pi}{22})\cos(\frac{\pi}{11}) + 8\sin(\frac{2\pi}{11})\cos(\frac{\pi}{11}) + \cos(\frac{\pi}{11})\tan(\frac{\pi}{11}) - \sec(\frac{\pi}{22})\sin(\frac{\pi}{11})\sin(\frac{5\pi}{22})\tan(\frac{5\pi}{11})$

(iv) Rotate by $6\pi/11$ about the center of D[1]: $p2 = RotationTransform[6\cdot\pi/11, cD[1]](p1)$

(v) As indicated earlier, the slope of the web interval determined by $p2$ must match an edge of N. Here it has same slope as the (right-side) star[4] edge of N – which we call slope4.

$x1 = p2[[1]], y1 = p2[[2]]; b = y1$-slope4*$x1$ so star[4][[1]] = (1 - b)/slope4

(vi) By the Two-Star Lemma $hMx = d/(Tan[5\pi/11] - Tan[4\pi/11])$ where d is the horizontal displacement of star[4] and star[5].

(vii) Of course the displacement d depends of hN but that dependence vanishes when hMx is divided by hN – which here is $\cos(\pi/11)$.

\textbf{AlgebraicNumberPolynomial[ToNumberField[hMx/hN,GenScale[11]], x]} =

\[1 - 23x - \frac{27x^2}{2} + \frac{x^4}{2}\]

Any other hN and matching hMx must yield this same ratio so this is a fundamental polynomial for Mx. Any ‘canonical’ tile with scaling in $S_N$ will have such a polynomial. See Example A2.
Part (ii) – The Digital Filter Map. The Df map is only compatible with the outer-billiards map when \( N \) is even, so it is necessary to work inside \( N = 22 \) (with \( hN = 1 \)). This is not a burden and actually simplifies the calculations. Except for scale, the First Family is unchanged from part (i) - except that \( S[9] \) is playing the part of \( N = 11 \), so we will show that \( hMx/hS[9] \) satisfies the polynomial above.

The Digital Filter map \( Df: [-1,1)^2 \to [-1,1)^2 \) is defined as

\[
Df(x,y) := \{ y, f(-x + ay) \}
\]

where \( f(v) = \text{Mod}[v+1,2]-1 \) models a sawtooth register.

For a given \( a \), \( Df \) is a piecewise isometry with three initial regions (‘atoms’) which can be labeled 1 (overflow), 0 (in bounds), or -1 (underflow).

Example: (\( N = 14 \)) With \( a = 2\cos(2\pi/14) \), the atoms are shown below with overflow at top. The two seperatices define the maximum extent of the linear center rotation, so they become extended edges of the bounding 14-gon. Note that the bounds of the 2-torus are also extended edges of the limiting 14-gon.

The equations for the three regions are:

\[
S[x,y] = \begin{cases} 
1 & \text{if } -x + ay \geq 1 \\
0 & \text{if } -1 \leq -x + ay < 1 \\
-1 & \text{if } -x + ay < -1 
\end{cases}
\]

If the \( S \)-sequence is known, the \( Df \) map can be written as \( Dfx[x_,y_,k_] := \{ y, -x + ay - 2S[[k]] \} \)

Using the original \( Df \) map (with approximate \( w \)), the singularity set \( W \) can be generated using the bounds of the torus or the two seperatices. These \( Df \) rotations are ‘elliptical’ rotations which can easily be rectified and the map that does this is called \( DfToTr \) with inverse \( TrToDf \). It is not surprising that the rectified web is identical to the outer-billiards web as shown below for \( N = 14 \).

Of course this is a redundant method of generating \( W \) and it is an open question to determine a minimal generation set. Even though these webs are computationally simple, their geometric evolution is far from simple and it is a challenge to find precise intervals that map to \( Mx \).
As a guide we will use part (i) above to construct the expected Mx tile inside N = 22 as shown below.

The closest connection between Mx and the First Family of D1 appears to be the (virtual) step-3 tile of D1 – which we call DS[3][2] or simply DS3. We will use DS3 to define an interval that maps to Mx. The green interval shown below is a rectified portion of an edge in W, and under Df this interval will map to the blue interval – when rectified. Therefore p0 maps to px (using Df) and p0 is exact. It only takes 136 iterations to accomplish this – but an exact calculation will be awkward with Df - so we will use surrogate orbits and Dfx instead.

Here are the calculations:

(i) Use \( p_1 = \text{TrToDf}[p_0] \) to generate an approximate Df orbit of length 140 using \( w = 2\cos(2\pi/22) \) to 30 decimal places. Orbit = NestList[Df, p1, 140]; S=S/@Orbit =\{1,0,0,0,0,0,0,0,0,-1,0,0,0,...\} (All the points at the foot of D are in overflow positions so they are displaced to the top right-side of N = 22 and then rotated until they underflow, and the underflow correction maps -1 to 1 because they are only one bit apart in 2’s complement.)

(ii) Generate an exact value of \( Df^{137}[p_1] \) using Dfx and exact \( w = 2\cos(2\pi/22) \). Set \( q=\text{Range}[140]; q[[1]]= p_1; \) For\([s=1, s<=140, s++, q[[s+1]]=\text{Simplify}[\text{Re}[\text{Dfx}[q[[s]],s]]]\); px (px unrectified) = q[[137]] \approx \{-6.679854552975, -0.9991754019926052\}

(iii) Set \( x_1 = px[[1]]; y_1 = px[[2]]; b = y_1-\text{slope4-}x_1 \) (where slope4 is the slope of right-side star[4] of N – as in part (i)). Therefore star[4][[1]] = (1-b)/slope4 =

\[
\frac{-13 - (-1)^{11} + 20(-1)^{211} + 14(-1)^{411} - 14(-1)^{611} - 20(-1)^{711} + (-1)^{811} + 13(-1)^{911}}{(1 + (-1)^{11})(1 + (-1)^{211})^4} - 2\text{Cot}\left[\frac{\pi}{11}\right]
\]
(iv) As in part (i), \( hMx = d/(\tan[5\pi/11] - \tan[4\pi/11]) \) where \( d \) is the horizontal displacement of star[4] and star[5].

(v) This displacement \( d \) is relative to \( hN \) so the ratio \( hMx/hN \) is the scaling field \( S_{11} \), but \( N \) is a 22-gon, so it makes more sense to use \( hMx/hS[9] \) where \( hS[9] = \tan[\pi/22]/\tan[\pi/11] \).

\[
\text{AlgebraicNumberPolynomial[ToNumberField[hMx/hS[9], GenScale[11]], x]} \]

\[1 - 23x - \frac{27x^2}{2} + \frac{x^4}{2}\]
as in part (i) above.

**Part (iii) A complex-valued Goetz Map**

Perhaps the simplest map that reproduces the outer-billiards web for a regular \( N \)-gon is a slight modification of the ‘dual center’ maps of Arek Goetz [Go]. These maps have the form 
\[
F[z] = \text{Exp}[-Iw] \cdot (z - I \cdot \text{Sign}[\text{Re}[z]])
\]
where \( w = 2\pi/N \) and the modified version as described in Section 8 of [H2], is 
\[
F[z] = \text{Exp}[-Iw] \cdot (z - \text{Sign}[\text{Im}[z]])
\]
It is called DKHOY.

The image on the left below was generated by iterating the x-axis interval \([-12, 0]\), 200 times under \( F \) with \( w = 2\pi/11 \) (to 30 decimal places). In the limit, the region above (or below) the x-axis will be a perfect reproduction of the web for \( N = 11 \) – with a side of 1 and star[1] at the origin. It is an easy matter to scale the First Family (and Mx) to use as guides to track the web development. On the right we show a portion of the ideal second generation in black - and the hypothetical Mx in cyan. Unlike the Df map, the webs tend to evolve is a predictable fashion from intervals on the x-axis - and this makes it easy to find intervals that will map to Mx. The chosen interval is shown in blue in the enlargement on the lower right, and the magenta interval is the negative of the image of this blue interval under \( F^{564} \).

Since the slope of this magenta line is known, all that is needed to find star[2] of Mx is px. Here are the calculations.

(i) The initial point is \( p0 = \text{StarD1}[3] = \)
\[
(\frac{5}{2} - \cot[\pi/22] \cdot \cot[\pi/11] + \tan[\pi/22] \cdot \tan[\pi/11] + \frac{1}{2} \cot[\pi/22] \cdot \cot[\pi/11] \cdot (1 - \tan[\pi/22] \cdot \tan[\pi/11] \cdot (2 + \tan[\pi/22] \cdot \tan[\pi/11] \cdot (1 - \cot[\pi/11]) + \frac{1}{2} \cot[\pi/11] \cdot (1 + \tan[\pi/22] \cdot \tan[\pi/11] \cdot (2 + \tan[\pi/22] \cdot \tan[\pi/11] \cdot (1 + \cot[\pi/11]) \cdot \cot[\pi/11]))))
\]
(ii) Using \( p0N = N[p0,30] \) (30 decimal place approximation to \( p0 \)), find the first 600 points in the (complex-valued) orbit: 
\[
\text{Orbit} = \text{NestList}[F,p0N,600]
\]

(iii) \( S[z_] := \text{Sign}[\text{Im}[z]] \); \( Sx = S[\text{Orbit}] = \{0,1,1,1,1,-1,-1,-1,-1,1,1,1,\ldots\} \)

(iv) Define a ‘literal’ version of \( F \) based on \( Sx \), namely 
\[
F[x_,k_] := \text{Exp}[-I*w](x - S[x[[k]]])
\]
(with an exact \( w \)) to obtain the exact orbit of \( p0 \) using the \( Sx \) sequence from the surrogate orbit. Store the orbit in the sequence \( q \):

\[
q = \text{Range}[600]; q[[1]] = p2[[1]]; \text{For}[s = 1, s <= 600, s++, q[[s+1]] = \text{Simplify}[F[x[[s]],s]]];
\]

**Note:** By modifying \( F \) to allow approximate calculations of the Sign function, it is feasible to do calculations like this directly with NestList. One possible modified function is \( F[z] = \text{Simplify}[\text{Exp}[-I\text{*w}](z - I\text{*IntegerPart}[\text{Sign}[N[\text{Re}[z]]]]]) \). This tricks Mathematica into regarding the Sign output as exact. Normally Mathematica attempts to evaluate Sign in an exact fashion and these expressions get so complex that typically it fails after a few hundred iterations.

(v) \( q[[564]] = \frac{6 - 8(-1)^{31} + 5(-1)^{21} - 2(-1)^{31} - (-1)^{31} + 3(-1)^{31} - (-1)^{31} + 5(-1)^{31} - 3(-1)^{31} + 4(-1)^{31}}{1 + 2(-1)^{31} - 3(-1)^{31} + 3(-1)^{31} - 2(-1)^{31} + (-1)^{31}} \)

The desired point is \( px = -q[[564]] \approx -10.415046959467414 + 0.01643324914196498\,i \)

(vi) \( x1 = \text{Re}[px]; y1 = \text{Im}[px]; \) The slope of \( \text{star}[2] \) of \( Mx \) is \( -\text{slope2} \) as defined using \( \text{star}[2] \) of \( N \), so \( b = y1 + \text{slope2}\times x1 \) and \( \text{star}[2][[1]] = b/\text{slope2} \approx -10.4075421460476045 \)

(vii) Using the Two-Star Lemma with opposite sides \( hMx = d/(\tan[2\pi/11] + \tan[5\pi/11]) \) where \( d = \text{star}[5][[1]] - \text{star}[2][[1]] \).

(viii) Since \( N \) has side 1, \( hN = \frac{1}{2}\cot[\frac{\pi}{11}] \). Use this to convert \( hMx \) to a scale in \( S_{11} \).

\[
\text{AlgebraicNumberPolynomial}[\text{ToNumberField}[hMx/hN,\text{GenScale}[11]],x] = 1 - 23x - \frac{27x^2}{2} + \frac{x^3}{2}
\]

Since the \( \text{star}[3]-\text{star}[4] \) interval of \( D1 \) generates \( Mx \), it can be regarded as a ‘mutated’ \( DS3[2] \). It is also true that \( Px \) is generated by the \( \text{star}[6]-\text{star}[7] \) interval so it is a mutated \( DS6[2] \). In fact \(-F^{292}[\text{star}[7]] \) is on an extended edge of \( Px \), and it yields \( hPx/hM = \frac{1}{4}[-1 + 25x + 5x^2 - x^3] \)

(\text{using surrogate orbits}). This is the same polynomial that arises in parts (i) and (ii) for \( Px \).

These three mappings generate a locally equivalent \( W \) in very different ways. It is possible that the outer-billiiards topology of \( W \) for a regular \( N \)-gon is ‘generic’ for such affine piecewise rotations based on \( N \). The approximate or ‘surrogate’ methods described here may be unavoidable for such mappings, because typically the matching \( S \) function is not computationally feasible - except by symbolic iteration or approximation. Since these \( S \) sequences largely define the dynamics, this is a fundamental issue.
We call the dual-center mapping DKHOY because it is the y-axis version of a ‘dissipative’
kicked Hamiltonian oscillator as discussed in [H2]. The zero-gravity version of kicked
Hamiltonian mappings has found many uses in orbital dynamics as well as quantum mechanics
but the full kicked harmonic oscillator with a natural frequency of oscillation is often desirable –
to model both classical and quantum diffusion - and this is what we are simulating here - with the
natural frequency determined by the N-gon. So these dual center maps are similar to Harper
Kicked Maps [H] – which are based on a stationary Schrodinger equation.

Because this dual-center DKHOY mapping is so efficient, it has the potential to uncover web
structure that might be impractical with the outer-billiards map or the digital-filter map. We will
be using it to publish a detailed ‘4K’ catalog of the edge geometry of regular polygons. For this
purpose the juxtaposition of N and –N is ideal and the natural +/- symmetry of W is augmented
by reflective symmetry about cN to yield almost 3 points or every one generated.

Below is an example from N = 14 where we iterate 1,000 points in the interval H = {-2,-1} at a
depth of 5,000. (The interval {-1,1} will generate N and –N in a period N orbit.) Here we crop
these 5 million web points and their negatives and reflections to the desired region. (Less than 1
minute to generate and 1 minute to crop on a modest computer.)

**Example A2** (The edge geometry of N = 14) \( F[z_] := \text{Exp}[-I*\text{w}]*\text{z-Sign}[\text{Im}[\text{z}]]; \)
\( \text{w} = \text{N}[2*\text{Pi}/14, 35]; (35 \text{ decimal places}); \text{H} = \text{Table}[x, \{x, -2, -1, .001\}]; \text{Web} = \text{Table}[\text{NestList}\[F, \text{H}[[k]], 5000], \{k, 1, \text{Length}[\text{H}]\}]; \text{RealWeb} = \{\text{Re}[#], \text{Im}[#]\} && \&/@\text{Web}; \)
\( \text{WebPoints} = \text{Crop}[[\text{Union}[\text{RealWeb}, -\text{RealWeb}, \text{Reflection}[\text{RealWeb}]]]]; (\text{about 450,000 points}) \)

Graphics[{\text{AbsolutePointSize}[1.0], \text{Point}[\text{WebPoints}]}]

The scaling fields \( S_7 \) and \( S_{14} \) are generated by \( x = \text{GenScale}[7] = \text{Tan}[\pi/7] \cdot \text{Tan}[\pi/14]. \) Inside \( N = 14, \) \( S[5] \) is the surrogate \( N = 7, \) so by convention all heptagons are scaled relative to \( S[5]. \) \( M[1] \)
(a.k.a.M1) is a 2\textsuperscript{nd} generation \( N = 7, \) but the edge dynamics are much simpler than \( N = 7 \)
because \( S[2] \) is missing. \( M[2] \) is the ‘matriarch’ of the 3\textsuperscript{rd} generation and has the same edge
geometry as \( N = 7. \) The PM tiles are only weakly conforming to D[1]. See [H8].

**Links**

(i) The author’s web site at DynamicsOfPolygons.org is devoted to the outer billiards map and related maps from the perspective of a non-professional.

(ii) A Mathematica notebook called FirstFamily.nb will generate the First Family and related star polygons for any regular polygon. It is also a full-fledged outer billiards notebook which works for all regular polygons. This notebook includes the Digital Filter map and the Dual Center map. The default height is 1 to make it compatible with the Digital Filter map. This full-fledged notebook is not necessary to implement the Digital Filter or Dual Center maps – but it is useful to have a copy of the matching First Family to be used as reference.

(iii) Outer Billiards notebooks for all convex polygons (radius 1 convention for regular cases). There are four cases: Nodd, NTwiceOdd, NTwiceEven and Nonregular.

(iv) For someone willing to download the free Mathematica CDF reader there are many ‘manipulates’ that are available at the Wolfram Demonstrations site - including an outer billiards manipulate of the author and two other manipulates based on the author’s results in [H2]. At the DynamicsOfPolygons site there are cdf manipulate at Manipulates – which can be downloaded. (The on-line versions have been phased out by most web browsers for security reasons.)
