(Dated: November 14, 2018)

Recent experiments on Majorana fermions in semiconductor nanowires [Albrecht et al., Nat. 531, 206 (2016)] revealed a surprisingly large electronic Landé $g$-factor, several times larger than the bulk value — contrary to the expectation that confinement reduces the $g$-factor. Here we assess the role of orbital contributions to the electron $g$-factor in nanowires and quantum dots. We show that an $\mathbf{L} \cdot \mathbf{S}$ coupling in higher subbands leads to an enhancement of the $g$-factor of an order of magnitude or more for small effective mass semiconductors. We validate our theoretical finding with simulations of InAs and InSb, showing that the effect persists even if cylindrical symmetry is broken. A huge anisotropy of the enhanced $g$-factors under magnetic field rotation allows for a straightforward experimental test of this theory.

Early electron spin resonance experiments in the 2D electron gas (2DEG) formed in AlGaAs/GaAs heterostructures found a reduced Landé $g$-factor of electrons [1], which was later theoretically explained to arise due to the electronic confinement [2–4]. It is by now well established that confinement in a nanostructure leads to a reduction in the $g$-factor [2–4] – the subband confinement increases the energy gap which is inversely proportional to $g^\prime - g_0$, where $g^\prime$ is the effective and $g_0$ the free electron $g$-factor [5, 7]. Surprisingly, experiments in InAs [8, 9] and InSb [10, 11] nanowires found $g$-factors surpassing the corresponding bulk $g$-factors by up to 40%.

Recently, this discrepancy has attracted interest due to the experimental discovery of a zero bias conductance peak in semiconductor nanowires proximity coupled to an s-wave superconductor [12–16], which is believed to be a signature of the Majorana bound state [17–19] having possible applications in topological quantum computation [20, 21]. The electron $g$-factor of the semiconductor nanowire determines the strength of magnetic field required to trigger the topological phase transition in these systems. It is desirable to keep the magnetic field low since it also suppresses superconductivity, and thus a large $g$-factor semiconductor is desired. Furthermore, Majorana proposals based on magnetic textures [22–24] and various spintronic devices [25] require large $g$-factors. Small band-gap semiconductors like InAs and InSb are therefore the materials of choice for Majorana nanowires, having large $g$-factors and strong spin-orbit coupling (SOC).

In a recent experiment with InAs nanowires $g$-factors [26] more than three times larger than the bulk $g$-factor ($g^\star_{\text{InAs}} = -14.9$ [5, 27]) were measured [15]. Moreover, it was found that the $g$-factor depends very strongly on the chemical potential $\mu$ tuned by the gate potential [28]. For low $\mu$ small $g$-factors where found which can be explained by the bulk $g$-factor of InAs. The anomalously large $g$-factors have been only detected at high chemical potential $\mu$.

In this work, we present a mechanism that can lead to very large $g$-factors in higher subbands of nanowires and similarly shaped nanostructures. With this we can explain both the large $g$-factors observed in Refs. 8–10, and 15, and the chemical potential dependence [28]. In particular, we find that the orbital angular momentum in the confined nanostructure plays a crucial role. The lowest conduction subband/state is characterized by no or only small orbital angular momentum. In this case the usual reasoning applies and confinement does lead to a reduction of the $g$-factor. Higher subbands/states, however, can have nonzero orbital angular momentum in an approximately cylindrical structure. Due to strong SOC in small band-gap semiconductors one finds an $\mathbf{L} \cdot \mathbf{S}$-type spin alignment if the orbital angular momentum $\mathbf{L}$ is nonzero. Kramers pairs of opposite orbital angular momentum form at $\mathbf{B} = 0$, and thus the $g$-factor obtains an additional contribution resulting from the coupling of the orbital angular momentum to the magnetic field. A similar orbital enhancement of the $g$-factor is known from the theory of the hydrogen atom [29] and has also been observed in carbon nanotubes [30, 31]. However, due to the small effective mass the $g$-factor enhancement can be orders of magnitude larger in the semiconducting structures investigated here.

**Cylindrical symmetry** — We start by considering cylindrical nanowires and estimate the maximally achievable $g$-factor for subbands as a function of their orbital angular momentum. Initially, we assume independent SU(2) spin rotation symmetry (no SOC) and time-reversal (TR) invariance without magnetic field. We then introduce magnetic field parallel to the wire, thus preserving the rotational invariance (both in real space and spin) around the axis of the wire ($z$ direction in the following).
As the wire is translationally invariant in the $z$ direction, and the conduction band minimum is at $k_z = 0$, we restrict to $k_z = 0$ in the following and investigate the wavefunction in the $xy$ plane only. As a consequence of separate real space and spin rotation symmetries, the states can be classified by their orbital angular momentum $L_z = 0, \pm h, \pm 2h$, etc. and spin $S_z = \pm \frac{1}{2}$ (for brevity we drop the $z$ subscript in the following and use the lower case letters for angular momentum in units of $\hbar$). The lowest subband is twofold spin degenerate ($|l| = 0, s = \pm \frac{1}{2}$), higher subbands with $l \neq 0$ being fourfold ($|l|, |l| + 1$).

In a simple quadratic band with an effective mass $m^*$, the momentum and electrical current are related as $J = \frac{e}{m^*} \mathbf{p}$. Using the orbital angular momentum $L = \mathbf{r} \times \mathbf{p}$ the orbital magnetic moment is expressible as

$$M_o = \frac{1}{2} \mathbf{r} \times \mathbf{J} = -\frac{e}{2m^*}L = -\frac{m_0}{m} \mu_B \mathbf{e}_z. \tag{1}$$

We see that the orbital magnetic moment is enhanced by the low effective mass of the bands. Because of the fourfold degeneracy, we cannot unambiguously calculate $g$-factors and thus next include spin-orbit coupling.

With SOC the orbital and spin angular momentum is no longer separately conserved, but the total angular momentum $f_z = l_z + s_z$ is still conserved and takes half-integer values. Without magnetic field the system is TR invariant. As angular momentum is odd under TR, the degenerate Kramers-pairs have opposite $f$. Turning on SOC splits the fourfold degeneracy of the $l \neq 0$ subbands into two degenerate pairs: $\pm(|l|, \pm \frac{1}{2})$ and $\pm(|l|, \pm \frac{3}{2})$ stay degenerate ($f = \pm(|l| + \frac{1}{2})$) and do so $\pm(|l|, \pm \frac{3}{2})$ ($f = \pm(|l| - \frac{1}{2})$), as shown in Fig. 1 (a). Even though the orbital and local angular momenta are no longer separately conserved their expectation values remain similar for realistic SOC strengths.

The magnetic field $\mathbf{B}$ couples to the total magnetic moment $\mathbf{M} = M_o - g^* \frac{e}{2m} \mathbf{S}$ [4]. Using Eq. (1), the Zeeman splitting of a Kramer’s pair $|\pm(|l|, \pm \frac{1}{2})$ and $|\mp(|l|, \mp \frac{1}{2})$ for a magnetic field in $z$-direction is given by $\Delta E_{\text{Zeeman}} = \mu_B (g^* \pm 2 \frac{e}{m} m^* |l|) \frac{\hbar}{2}$ and the resulting effective $g$-factor can be read off

$$g_f|l|\pm \frac{1}{2} = g^* \pm 2 \frac{m_0}{m} m^* |l|. \tag{2}$$

Below we will see from numerical simulation that this is a good approximation even in a less ideal case.

This result is analogous to the well known Landé $g$-factor of the Hydrogen atom when taking relativistic SOC into account: the splitting induced by weak external magnetic field has contributions from both the orbital and spin angular momentum [29]. This effect is amplified in semiconductor nanostructures because the small effective mass increases both the orbital magnetic moment and the bulk $g$-factor $g^*$.

**Wire simulations** — We next validate our theoretical findings with simulations of nanowires using an eight-band $k \cdot p$ model for zincblende semiconductors [5, 32, 33]. At first, we assume perfect cylindrical symmetry of a nanowire, grown in 001 direction, and employ the axial approximation [34–37]. In this case, the wavefunctions can be written as [38]

$$\psi(\rho, \phi, z) = \sum_n g_n(\rho, z) e^{i n \phi} |u_n\rangle, \tag{3}$$

where $|u_n\rangle$ are the basis states of the 8-band $k \cdot p$ Hamiltonian with local angular momentum $j_n$ [39]. Since the Hamiltonian conserves the total angular momentum $f$ one obtains the orbital part of each component as $l_n = f - j_n$. If we furthermore focus on an infinite wire in the $z$-direction the problem is reduced to a 1D boundary value problem in $\rho$ which we solve using the finite difference method [37].

Figure 1 (b) shows the subband edges of an InSb nanowire of 40 nm diameter. At $\mathbf{B} = 0$ one generically finds the lowest conduction subband to originate from the $|l| = 0$ state without SOC. At higher energy there are the $|l| = 1$ and $|l| = 2$ states and then another $|l| = 0$ state with a higher radial quantum number (not shown). This order of states is generic as long as the conduction band is approximately quadratic [40]. Figure 1 (c) zooms in on the $|l| = 1$ subbands. Due to SOC the $|f| = 2$ and $|f| = 1$ states are split at $\mathbf{B} = 0$ by $\Delta E_1 \approx 2$ meV. If a magnetic field $\mathbf{B} < B_{\text{crit}}$ (see Fig. 1 (c)) is turned on a splitting between states of opposite orbital angular momentum $l$ is observed and thus, enhanced $g$-factors according to Eq. (2). However, when the magnetic field is large, $\mathbf{B} > B_{\text{crit}}$, states of the same orbital angular momentum bundle together and their relative slope with
FIG. 2. (a) Diameter dependence of the SOC splitting $\Delta E_1$ and $\Delta E_2$ for InSb and InAs wires. (b) Diameter dependence of the critical magnetic field $B_{\text{crit}}$ defined in Fig. 1 (b). (c) Effective $g$-factors at infinitesimal magnetic field of the first five subbands of an InSb (InAs) wire: $l = 0$, $|f| = \frac{1}{2}$ (blue), $|l| = 1, |f| = \frac{1}{2}$ (green), $|l| = 1, |f| = \frac{3}{2}$ (red), $|l| = 2, |f| = \frac{1}{2}$ (cyan) and $|l| = 2, |f| = \frac{3}{2}$ (magenta). The dashed lines in the corresponding colors are the prediction of Eq. (2) where we substituted bulk values.

respect to $B$ corresponds to the normal $g$-factor without orbital contributions. Thus a splitting $\Delta E_1$ is a crucial ingredient for enhanced $g$-factors.

Figure 2 shows the dependence on the diameter of the nanowire. From the $\Delta E_1$ dependence it is evident that the wire cannot be made too thick to experimentally observe the effect with a detectable energy scale, e.g., to distinguish the split energy levels using Coulomb oscillations [41]. Figures 2 (c) and (d) show that at large wire diameters Eq. (2) is reproduced perfectly by numerics, but for small diameters the $g$-factor enhancement is reduced by the confinement. Thus, the optimal diameter range where enhancement of the $g$-factor is strong and at the same time $\Delta E_1$ and $B_{\text{crit}}$ are large enough is in between 10 and 100 nm. We see that the $g$-factors of higher subbands can be very large — enhancements of an order of magnitude compared to the bulk $g$-factor are possible.

The splitting $\Delta E_1$ is generic if SOC is present, since in a typical semiconductor wire with SOC there is no symmetry that would protect the degeneracy between states of different total angular momentum. The conduction band of zincblende semiconductors has a purely $s$-orbital character at the $\Gamma$-point of the Brillouin zone (BZ), which is insensitive to SOC. Thus, also the conduction subbands of a zincblende nanowire are mostly derived from $s$-orbitals. Any nonzero splitting $\Delta E_1$ results from $p$-like hole contributions to the conduction band due to confinement. This explains why the splitting in the conduction band is so small compared to the split-off energy of the valence bands $\Delta$, which is 0.81 eV for InSb and 0.38 eV for InAs [5].

Since $\Delta E_1$ results from the scattering of states at the surface of the wire the boundary conditions impact the numerical value, and even the sign, of $\Delta E_1$ [37]. Abrupt boundaries can be problematic in $k \cdot p$ simulations [42], therefore, we use tight-binding (TB) simulations to check the robustness of our results. The effective tight-binding Hamiltonian is generated from the first-principles $s$ and $p$-like Wannier functions [43], calculated using the Vienna ab initio simulation package (VASP) [44–47] with the projector augmented-wave method [48, 49], a cut-off energy of 300 eV, a $8 \times 8 \times 8$ Monkhorst-Pack mesh and using the HSE06 hybrid functional [50–52]. Furthermore, the TB model includes the Dresselhaus term which was neglected for the zincblende $k \cdot p$ simulations since its effect is found to be very small [37]. In Fig. 3 (a) we show the magnetic field dependence of the $|l|=1$ subbands in a hexagonal InSb wire. The $g$-factors of $-59$ and $+40$ and $B_{\text{crit}} \approx 0.2$ Tesla agree qualitatively with the $k \cdot p$-results.

While in zincblende wires boundary effects are dominating, in wurtzite wires the situation is different: There, the conduction band has a mixed $s$ and $p$-character. Thus, wurtzite wires have an intrinsic splitting independent of confinement [53]. Using a $k \cdot p$-model for wurtzite semiconductors [54], we find a nearly size-independent $\Delta E_1$ of order 1 meV for [0001] grown wurtzite InAs wires for experimentally used diameters of 40 to 160 nm [55], see Fig. 3 (b). At very large wire diameters $> 200$ nm the confinement induced subband splitting becomes smaller than $\Delta E_1$, leading to a reduction of $\Delta E_1$, and at very small diameters $< 20$ nm the cubic Dresselhaus term dominates over the linear Rashba term, causing a sign change in $\Delta E_1$ [37, 56].

Symmetry breaking — We now consider the effects of broken cylindrical symmetry and solve the full 2D cross section of hexagonal zincblende wires, grown in the 111 direction, using a 2D discretization of the $k \cdot p$-model [37, 57]. We allow for symmetry breaking by electric field and off-axis magnetic field, see Fig. 4 (a) for the definitions of the relevant directions. In experimental situations, the symmetry is generally broken by electric fields, e.g., due to the backgate for tuning the electron density in the
wire [8, 10, 15, 28]. We find that, especially in higher subbands, the enhanced g-factors are quite robust to an external electric field.

In Fig. 4 (b-d) we simulate a hexagonal InSb wire, of 40 nm diameter, in a perpendicular external electric field $\mathcal{E}$. The point group of the wire at $\mathcal{E} = 0$ is $C_{3v}$ and crossings between states of different angular momentum are protected, as illustrated in Figure 4 (c). At nonzero $\mathcal{E}$ the different angular momentum eigenstates hybridize, which reduces their orbital angular momentum expectation value. However, as shown in Figs. 4 (b) and (d), the orbital contribution to the g-factor remains very significant until very large fields are applied. Bands with larger values of $|l|$ have larger splitting $\Delta E_l$ and, therefore, the orbital contribution to their g-factors is more robust and can remain significantly larger than the bulk g-factor until large electric fields, e.g. see the cyan and magenta lines corresponding to $|l| = 2$ in Fig. 4 (b).

The electron g-factor anisotropy in the magnetic field of 2DEGs is well established [3, 5, 58, 59]. In our case of orbitally enhanced g-factors in nanowires we expect an even stronger anisotropy. Indeed, the electron spins in subbands with $l \neq 0$ feel a very strong orbital magnetic field that aligns them (anti-)parallel to the wire axis. Therefore, a perpendicular magnetic field first needs to overcome this orbital effect to create a Zeeman splitting of the states [30, 31].

This is illustrated in Fig. 4 (e), where we simulate a hexagonal InSb wire of 40 nm diameter in a magnetic field of 0.2 Tesla. We show there the g-factor as a function of the angle $\alpha$ between the magnetic field and the nanowire axis. While the g-factor of the lowest $l = 0$ subband is unaffected by the direction of $\mathbf{B}$, the g-factor for bands with $l \neq 0$ almost vanishes for perpendicular magnetic field. This strong anisotropy of the electron g-factor can be used in experiments to prove the important role of orbital angular momentum in nanowires.

In a Majorana wire circular symmetry breaking by gate potentials and band bending is mandatory to create a Rashba effect in the wire [18, 19, 60]. The results shown above suggest that even in such an environment orbital effects still dominate the g-factors of certain subbands in wires. This is illustrated in Fig. 5 (a) and (b), where we simulate an InAs wire proximity coupled to an Al superconductor (see the Supplemental Material [37] for the details of the simulation). When the chemical potential is tuned to the $|l| = 1$ and $|l| = 2$ subbands, the g-factors, extracted from the slope of the Majorana state forming Andreev bound state, are 23 and 43 [61], respectively. These g-factors are significantly larger than the bulk g-factor of InAs, thus reproducing the experimental result of Ref. 15.

Conclusions and Outlook — In summary, we have provided a theory for the previously unexplained large g-factors observed in nanowires. Our findings help to better understand and optimize Majorana experiments. Similar results apply to quantum dots. For cylindrical quantum dots we find that orbital g-factor enhancements are still significant if the length of the dot is much shorter than its diameter, see the Supplemental Material 37 for more details. Due to the observed robustness of the effect, it also applies in irregularly shaped quantum dots and can explain g-factor fluctuations there.

I. SOLVING CYLINDRICAL NANOSTRUCTURES IN THE AXIAL APPROXIMATION

A. Numeric simulations employing the axial approximation

The cylindrical symmetry of a quantum wire allows for a considerable reduction in the computational effort of simulating the wire. To make use of this we furthermore assume that the zincblende structure itself has cylindrical symmetry by employing the so-called axial approximation [1]. In this approximation the $\mathbf{k} \cdot \mathbf{p}$-Hamiltonian has continuous rotational symmetry about the principal axis of the crystal. In this section we consider wires consisting of a zincblende semiconductor grown in the 001 direction and wurtzite semiconductor in the 0001.

In its simplest form the axial approximation amounts to equalling the two Luttinger-Kohn parameters $\gamma_2 = \gamma_3$. We choose to set $\gamma_2 = \gamma_3$ only in the terms of the Kane Hamiltonian [2] that would otherwise break the cylindrical symmetry. For the exact definition of the Hamiltonian see Tab. V in Ref. 3. The $\mathbf{k} \cdot \mathbf{p}$-parameters of InAs and InSb are taken from Ref. 4. Throughout the paper, we avoid spurious solutions by renormalizing the bare electron mass to $m_0 = 5$ [5, 6].

Within the axial approximation, the wave-function can be written as [7]

$$\psi(\rho, \phi, z) = \sum_n g_n(\rho, z) e^{il_nz} u_n, \quad (S1)$$

where $|u_n\rangle$ are the basis states for the 8-band $\mathbf{k} \cdot \mathbf{p}$ Hamiltonian $|j_{\text{tot}}, j_z\rangle$: $|u_1\rangle = |\frac{1}{2}, \frac{1}{2}\rangle, |u_2\rangle = |\frac{1}{2}, -\frac{1}{2}\rangle, |u_3\rangle = |\frac{3}{2}, \frac{3}{2}\rangle, |u_4\rangle = |\frac{3}{2}, -\frac{3}{2}\rangle, |u_5\rangle = |\frac{3}{2}, -\frac{1}{2}\rangle, |u_6\rangle = |\frac{3}{2}, \frac{1}{2}\rangle, |u_7\rangle = |\frac{1}{2}, \frac{1}{2}\rangle, |u_8\rangle = |\frac{1}{2}, -\frac{1}{2}\rangle. \quad (S2)$

The states $|u_1\rangle$ and $|u_2\rangle$ derive from $s$-orbitals, whereas the remaining basis states are derived from $p$-orbitals. Since the Hamiltonian is block-diagonal in the total angular momentum $j_z$, one obtains the orbital part of each component $l_{zn} = l_z - j_{zn}$.

The Hamiltonian is transformed into polar coordinates $(x, y, z) \to (\rho, \phi, z)$

$$H_{ij}^{\text{Polar}}(\rho, \phi, z) = e^{-i(f_{i-j_z})} H_{ij}^{\text{Cartesian}}(x, y, z) e^{i(f_{i-j_z})}, \quad (S3)$$

where the $\phi$-dependence of $H_{ij}^{\text{Polar}}$ drops out due to the axial approximation. The momenta $k_x$ and $k_y$ are transformed by

$$k_x = -i \frac{\partial}{\partial x} = -i (\cos \phi \frac{\partial}{\partial \rho} - \sin \phi \frac{\partial}{\partial \phi}) = \cos \phi k_\rho - \frac{\sin \phi}{\rho} k_\phi,$$

$$k_y = -i \frac{\partial}{\partial y} = -i (\sin \phi \frac{\partial}{\partial \rho} + \cos \phi \frac{\partial}{\partial \phi}) = \sin \phi k_\rho + \frac{\cos \phi}{\rho} k_\phi. \quad (S4)$$

* winklerg@ethz.ch
Below we write all the terms that appear in the Hamiltonian and need to be transformed (note that \( k_\rho \) and \( k_\phi \) do not commute when the magnetic field is turned on)

\[
k_+ = k_x + i k_y = e^{i\phi}(k_\rho + \frac{i}{\rho}k_\phi), \quad (S5)
\]
\[
k_- = k_x - i k_y = e^{-i\phi}(k_\rho - \frac{i}{\rho}k_\phi), \quad (S6)
\]
\[
(k_+)^2 = e^{2i\phi}[k_\rho^2 + \frac{i}{\rho}k_\rho + \frac{1}{\rho^2}(k_\rho k_\phi + k_\phi k_\rho)] + \frac{1}{\rho^2}(-2k_\phi - k_\phi^2)], \quad (S7)
\]
\[
(k_-)^2 = e^{-2i\phi}[k_\rho^2 + \frac{i}{\rho}k_\rho - \frac{i}{\rho}(k_\rho k_\phi + k_\phi k_\rho)] + \frac{1}{\rho^2}(2k_\phi - k_\phi^2)], \quad (S8)
\]
\[
k^2_\rho + k^2_\phi = k^2_\rho - \frac{i}{\rho}k_\rho + \frac{1}{\rho^2}k^2_\phi. \quad (S9)
\]

According to Eq. (S1), in the final matrix elements \( H_{ij} \), one needs to replace each occurrence of \( k_\phi \) by \( l_{zn} = f_z - j_{zn} \).

For a uniform magnetic field \( B \) in the \( z \) direction the vector potential may be taken as

\[
A_z = A_\rho = 0, \quad A_\phi = \frac{1}{2}B\rho, \quad (S10)
\]

which can be included in the simulation by substituting

\[
k_\phi \rightarrow k_\phi - \frac{\pi}{2\phi_0}B\rho, \quad (S11)
\]

where \( \phi_0 \) is the magnetic flux quantum.

We solve the system of coupled differential equations for the eigenmodes by rewriting it first to a generalized eigenvalue problem

\[
H\psi_n = E_n C\psi_n, \quad (S12)
\]

where \( H \) is the Hamiltonian with substituted discretized expressions for the differential operators. The indices \( i, j \) of \( H_{ij} \) run over both the basis states Eq. (S2) and the discretized radial positions \( \rho \).

We have to consider boundary conditions of both Dirichlet type \( v_{ni} = 0 \) and Neumann type \( v_{ni} - v_{n(i+1)} = 0 \). If \( i \) corresponds to a position with \( \rho = W \), with \( W \) being the radius of the wire, the Dirichlet condition is taken. If \( i \) corresponds to \( \rho = 0 \) the Dirichlet condition is taken for \( l_z \neq 0 \) and the Neumann condition for \( l_z = 0 \). Thus, the matrix \( C_{ij} \), which encodes the boundary conditions, has only diagonal elements which are 1 if \( i \) corresponds to an interior site of the wire and 0 if \( i \) is either at \( \rho = 0 \) or \( \rho = W \).

### B. Analytic estimates for the spin-orbit splitting

We calculate the spin-orbit interaction (SOI) splitting \( \delta E \) of the subbands perturbatively in the rotational invariant case with \( \gamma_2 = \gamma_3 \) in a circular wire. We use the continuum Hamiltonian in cylindrical coordinates. Starting from the exact solution in the \( \gamma_1 = \gamma_2 = \gamma_3 = 0 \) case [8] we find a splitting that lowers the energy of subbands with parallel angular momentum using the minimal boundary amplitude condition. This splitting scales as \( W^{-4} \) for thick wires and as \( \Delta \) for small \( \Delta \).

#### 1. Exact solution of a special case

The real-space continuum problem can be exactly solved for the electron-like wave functions when \( \gamma_1 = \gamma_2 = \gamma_3 = 0 \). Following Ref. 8 we express the hole-like components in terms of the electron-like ones from the Schrödinger equation, and substitute it back to the electron component equation to get the Helmholtz-equation

\[
\left\{ \left[ \frac{P^2}{3} \left( \frac{2}{E + E_0} + \frac{1}{E + E_0 + \Delta} \right) + \frac{\gamma_0}{2m_0} \right] \nabla^2 + E \right\} \psi_{e\sigma}(r) = 0 \quad (S13)
\]
where \( \nabla^2 \) is the Laplacian, \( E \) is the (unknown) energy of the state and \( \psi_{e\sigma}(r) \) is the wave function amplitude in the electron-like bands (the equations are identical for the two spin sectors). The full wave-function, including the hole-like components can be written as

\[
\psi_{\uparrow}(r) = \begin{pmatrix} 1 & 0 & -\frac{k_z}{\sqrt{E_0 + E}} & \frac{k_z}{\sqrt{E_0 + E}} \end{pmatrix} \psi_{e\uparrow}(r)
\]

\[
\psi_{\downarrow}(r) = \begin{pmatrix} 0 & 1 & 0 & -\frac{k_z}{\sqrt{E_0 + E}} \end{pmatrix} \psi_{e\downarrow}(r)
\]

where for a cylindrical wire the momenta can be written in cylindrical coordinates as in Eq. (S4). The hole-like components of the real space wave-function are obtained by acting with the differential operators on the electron-like wave-function on the right.

As the equation is invariant under rotations around the \( z \) axis and translations along the \( z \) axis, the wave-function can be separated as \( \psi_{e\sigma}(\rho, \phi, z) = R_{\sigma}(\rho)e^{il\phi}e^{ik_zz} \), substituting this we get the Bessel equation for the radial part

\[
\frac{d^2}{d\rho^2} + \frac{1}{\rho} \frac{d}{d\rho} - \frac{l^2}{\rho^2} + \chi^2 = 0
\]

with

\[
\chi^2 = -k_z^2 + E \left[ \frac{P^2}{3} \left( \frac{2}{E + E_0} + \frac{1}{E + E_0 + \Delta} \right) + \frac{7}{2m_0} \right]
\]

where \( \chi \) is the radial wavenumber and is determined by the boundary conditions. The solutions can be written in terms of Bessel functions \( R_{\sigma}(\rho) = J_l(\chi \rho) \). Setting \( k_z = 0 \), the full wave function can be written as

\[
\psi_{\uparrow}(\rho, \phi) = \begin{pmatrix} 1 & 0 & e^{il\phi}P(l + k_\rho) \frac{k_\rho}{\sqrt{E_0 + E'}} & e^{il\phi}P(l + k_\rho) \sqrt{E_0 + E'} \end{pmatrix} R_{\uparrow}(\rho)
\]

\[
\psi_{\downarrow}(\rho, \phi) = \begin{pmatrix} 0 & 1 & e^{-il\phi}P(l + k_\rho) \frac{k_\rho}{\sqrt{E_0 + E'}} & e^{-il\phi}P(l + k_\rho) \frac{k_\rho}{\sqrt{E_0 + E'}} \end{pmatrix} R_{\downarrow}(\rho)
\]

where we used that the action on our ansatz amounts to the replacement of \( k_\rho \) with \( l \). The different hole-like Bloch states have different internal angular momentum, but the total angular momentum of each component is the same, this is manifest in the extra orbital phase factors in the expression.

The hole-like contribution is proportional to the radial derivative of the wave function. As the Bessel-functions cannot have both vanishing magnitude and derivative at finite \( \rho \), it is not possible to demand vanishing of all components of the wave function at the boundary. In the large wire (large \( W \) and small \( \chi \)) limit the hole-like amplitude is suppressed, so demanding the electron-like component to vanish is approximately a good boundary condition.

### 2. Minimal boundary amplitude boundary condition

We assume that the system is infinite, but the states are confined by a large potential \( V \) at the boundary. Assuming \( V \) is much larger than any of the energy scales in the problem, then the wave function decays exponentially outside as

\[
\psi(W) \approx e^{-(\rho - W)\sqrt{2m_0/V}}
\]

where \( W \) is the radius of the wire where the potential step is. The expectation value of the potential energy goes as \( \sqrt{\frac{k^2}{2m_0}V}\psi(W)^2 \), so in the large \( V \) limit the wave function amplitude is minimized, and the states get shifted up as \( \sqrt{V} \).

We express the magnitude squared of the wave function on the boundary using our previous expression.

\[
|\psi_{e\sigma}(W, \phi)|^2 = R^2 \left( 1 + \frac{l^2(2a + b)}{3W^2} + \sigma lR^2 \frac{2(a - b)}{3W^2} + (R')^2 \frac{(2a + b)}{3W^2} \right)
\]

where \( \sigma = \pm 1 \) stands for up and down spin,

\[
a = \frac{P^2}{(E_0 + E)^2},
\]

\[
b = \frac{P^2}{(E_0 + E + \Delta)^2}
\]
are constants with length squared dimension and we introduced the dimensionless quantity \( \chi' = \chi W \), such that
\[
R = J_1(\chi W) = J_1(\chi') \quad \text{and} \quad R' = W \frac{dJ_1}{d\chi}(\chi W) = \chi' J_1'(\chi').
\]
It can be seen that in the \( W^2 \gg a, b \) limit (for InSb \( b < a \approx 10\text{nm}^2 \)) the total amplitude can be minimized by minimizing the amplitude in the electron bands. This happens when \( \chi' = z_{lp} \), the \( p^{th} \) root of \( J_1 \).

For finite \( W \) we expand around this solution. To get a tractable approximation we can treat \( R \) and \( R' \) as independent variables and express \( R \) that minimizes the amplitude in terms of \( R' \):
\[
R = -\sigma l R' \frac{(a-b)}{3W^2 + (2a+b)t^2}.
\]  
(S24)

The right hand side does not depend on \( \gamma_0 \) and is linear in \( \Delta \) for small values and \( E \) can be set to zero for approximate calculations if the subband energy is much smaller than the bandgap, \( E \ll E_0 \). We expand both sides to first order in \( \delta \chi' = \chi' - z_{lp} \) and use the identity\[9] \( J_1'(z_{lp}) + z_{lp} J_1''(z_{lp}) = 0 \) to get
\[
\delta \chi' = -\sigma l z_{lp} \frac{a-b}{3W^2 + (2a+b)t^2}.
\]  
(S25)

Such a change in \( \chi' \) effectively renormalizes the radius of the wire and results in a splitting between states with different total angular momentum. From Eq. (S17) the energy \( E \) of a state in the small \( \chi \) (large \( W \), small \( l \) and \( p \) and small \( E \)) limit is approximately
\[
E_{lp} = \frac{z_{lp}^2 P^2}{3W^2} \frac{3E_0 + 2\Delta}{E_0(E_0 + \Delta)},
\]  
(S26)

where we set \( \chi = z_{lp}/W \) ignoring SO corrections. Note that this approximation does not depend on \( \gamma_0 \). Substituting \( \chi' \) with \( \chi' + \delta \chi' \) from (S25) and expanding to linear order the energy change induced by SOI is
\[
\delta E_{lp\sigma} = -\sigma l \frac{2E_{lp}(a-b)}{3W^2 + (2a+b)t^2}.
\]  
(S27)

In the large \( W \) limit the subband splitting is (dotted lines in Fig. S1)
\[
E_{lp\uparrow} - E_{lp\downarrow} = -l \frac{4z_{lp}^2 P^4 \Delta(\Delta + 2E_0)(2\Delta + 3E_0)}{9W^2 E_0^3(\Delta + E_0)^3},
\]  
(S28)

which for the lowest \( l = 1 \) subband gives
\[
E_{11\uparrow} - E_{11\downarrow} \approx -\frac{1}{W^4} 687 \text{ eV nm}^4
\]  
(S29)
where in the last approximation we used the renormalized parameters for InSb [5, 6], note that $W$ is the radius of the wire.

In the above calculation we used the linearized expression for $E$ and set $E = 0$ in $a$ and $b$. A more precise result can be obtained for thin wires by numerically solving the third order Eq. (S17) for $E$ with $\chi' = z_{lp}$ (no SOI), substituting it in Eq. (S25) and calculating the energy at the modified $\chi'$ by again using Eq. (S17).

C. Numerical results for wires with soft boundary conditions

All results shown in the main text refer to the hard boundary condition case, where the wave functions is set to zero at the boundary of the wire. Here we instead apply a step potential, which is set to zero inside the wire and 0.2 eV outside of the wire. This mimics the minimal amplitude boundary condition referred to above.

Most results, like the $g$-factors and the magnitude of $\Delta E_l$, are very similar with soft and hard boundary conditions. The most striking difference is that, for soft boundary conditions, and zero magnetic field, the Kramers pair $|\pm|l|, \pm \frac{1}{2} \rangle$ is higher in energy than the Kramers pair $|\pm|l|, \mp \frac{1}{2} \rangle$. Thus $\Delta E_l$ has a negative sign in the soft boundary case.

In Fig. S1 we show the SOI splitting for wires with soft boundary conditions. Apart from the sign, the asymptotic behavior is identical. Especially, the $W^{-4}$ dependence for large $W$, as in Eq. (S28), is present in both the soft and hard boundary case. Generally, the agreement of the numerics with the analytic approximation Eq. (S28) is quite good.

D. Numerical results for wurtzite wires

Here we consider InAs wurtzite wires in the 0001 growth direction, as they have been used in Majorana experiments [10]. The main difference in the conduction band of a wurtzite-type semiconductor to a zincblende one is the linear Rashba-like spin-splitting in directions orthogonal to the 0001 wurtzite direction [11]. Therefore, the SOI splitting has a contribution originating from this linear spin splitting. Apart from the origin of the SOI splitting, the mechanism for the enhancement of $g$-factors in wurtzite wires is equivalent to zincblende wires.
We describe the conduction band of wurtzite InAs by a Rashba model

\[ H = -\frac{\hbar^2}{2} \left( \frac{k_x^2 + k_y^2}{m_\perp} + \frac{k_z^2}{m_\parallel} \right) + \alpha (\sigma_x k_y - \sigma_y k_x). \]  

(S30)

using \( m_\perp = 0.0416 \, m_e \) and \( m_\parallel = 0.0370 \, m_e \) [12] and \( \alpha = 0.03 \, \text{eV nm} \) [13]. We solve this model in an infinite wire geometry using cylindrical coordinates as described above. In Fig. S2 (a) we show the SOI splittings \( \Delta E_1 \) and \( \Delta E_2 \) as a function of wire diameter. For wire diameters smaller than 100 nm it is approximately constant. For small wire diameters the SOI splitting is approximately given by [14]

\[ \Delta E_l = E(l + \frac{1}{2}) - E(l - \frac{1}{2}) = -l \frac{2m^*\alpha^2}{\hbar^2}, \]  

(S31)

which is in good agreement with our numerical solution. Note that the sign is opposite from the zincblende hard boundary case. For large wire diameters (around 100 nm) the subband splitting becomes of similar size as the SOI splitting leading to a reduction of the SOI splitting. This is also visible in the rescaled energies shown in Fig. S2 (b).

While the Rashba model can explain the origin of the SOI splitting in wurtzite wires it neglects several other aspects like the nonparabolicity of bands and the cubic Dresselhaus splitting. Therefore, we solve the 8-band \( \mathbf{k} \cdot \mathbf{p} \)-model for wurtzite InAs introduced in Ref. 13 in cylindrical coordinates. Note, that the model is already axially symmetric and no further simplification is needed as in the zincblende case. The results are shown in Fig. S2 (c) and (d). For small wire diameter the cubic in \( k \) Dresselhaus spin splitting dominates over the linear in \( k \) Rashba splitting and causes an SOI splitting that is different in sign. At large wire diameter the results are very similar to the Rashba model.

E. Quantum dots

The same reasoning as for wires leads to enhanced \( g \)-factors in quantum dots with (approximate) cylindrical symmetry. Cylindrically symmetric quantum dots are simulated in the axial approximation. Due to the additional confinement in \( z \)-direction a 2D boundary value problem needs to be solved now.

In Fig. S3 we investigate the length dependence of the \( g \)-factor in a short cylindrical InSb wire of 40 nm diameter. The \( g \)-factors of higher subbands stay larger than the bulk \( g \)-factor even when the wire length is already much shorter than the wire diameter. The kinks in the \( g \)-factors result from level crossings with \( z \)-confinement induced subbands. Therefore, besides wires, the enhanced \( g \)-factors could be observed in gate-defined quantum dots embedded in a 2DEG, either of circular or approximately square shape (the square case is treated below).
FIG. S4. Tight-binding simulation of a hexagonal InSb wire, grown in the 111 direction, with 20.1 nm diameter. (a) The $g$-factor of the lowest five Kramers pairs in the conduction states as a function of $B$. (b) Energy levels of the lowest $|l|=1$ states as a function of $B$.

II. TIGHT-BINDING SIMULATIONS

The $k \cdot p$ approximation is only guaranteed to work for long wavelengths and the zincblende $k \cdot p$ model used in our simulations neglects the Dresselhaus term, which results from inversion symmetry breaking. For comparison, we also simulate semiconductor wires in zincblende structure using highly accurate first-principles derived tight-binding models. In the tight-binding framework the states are described correctly in the whole Brillouin zone of the lattice, thus, abrupt changes like a hard boundary pose no problem.

For the first-principles calculations we used the Vienna ab initio simulation package (VASP) [15, 16] with the projector augmented-wave method, a cut-off energy of 300 eV and using the HSE06 hybrid functional [17–19]. The BZ integration was facilitated with an $8 \times 8 \times 8$ Monkhorst-Pack mesh. The effective tight-binding Hamiltonian is generated from the first-principles Wannier functions [20], by projecting the first-principles wave-function on the s and p-like orbitals of In, As and Sb. The magnetic field is added via Peierls substitution to the Hamiltonian [21].

In Fig. S4 we show results for a InSb wire grown in the 111 direction and with 20.1 nm diameter. The measured $g$-factors and the critical magnetic field $B_{\text{crit}}$ of about 0.2 Tesla agree qualitatively with the $k \cdot p$-results presented in the main text. We also find that for the $l \neq 0$ states the Kramers pair with negative $g$-factor, corresponding to $|\pm|l|, \mp \frac{1}{2}\rangle$, is lower in energy than the one with positive $g$-factor, which corresponds to $|\pm|l|, \pm \frac{1}{2}\rangle$. Thus, the tight-binding approach gives the same sign of $\Delta E_l$ as the hard wall case in $k \cdot p$, justifying our choice of boundary conditions in the main text.

III. $k \cdot p$ SIMULATIONS WITH BROKEN CYLINDRICAL SYMMETRY

A. Hexagonal wires

In the main text we consider hexagonal wires grown in the 111 direction of a zincblende semiconductor. Again we take the $k \cdot p$-parameters from Ref. 4. The 8-band Kane model, this time without the axial approximation, is taken from Ref. 4 and is discretized on a simple cubic lattice. Apart from the Majorana simulations we use a lattice constant of 0.5 nm for the discretization. The wire is built and infinitely extended in the 111 direction. Magnetic and electric fields are added to the lattice Hamiltonian [21]. Note that the simple cubic discretization conserves all symmetries of the cubic zincblende lattice, thus also conserving all symmetries of the wire. Sparse diagonalization is finally used to solve for the eigenenergies and eigenstates of the wire. In Fig. S5 we show results for a hexagonal InSb wire of 40 nm diameter.

In previous 8-band zincblende $k \cdot p$ simulations we neglected the Dresselhaus term. While we implicitly checked that the Dresselhaus term does not introduce significant changes via the tight-binding calculation, it is convenient to have a direct comparison of 8-band $k \cdot p$ results with and without Dresselhaus term. The Dresselhaus term is added to the 8-band $k \cdot p$ Hamiltonian using the definitions and parameters of Ref. 4. In principle, the Dresselhaus term
FIG. S5. Hexagonal InSb wire with 40 nm diameter with perpendicular electric field. (a) (b) Energy levels of the first ten states as a function of $B$ at an electric field of $E = 0$ meV/nm ($E = 3$ meV/nm). In the $E = 0$ case the colors mark different angular momenta. (c) (d) Norm squared wave functions of the first five conduction levels at $k = 0$ and $B = 0$ at an electric field of $E = 0$ meV/nm ($E = 3$ meV/nm).

FIG. S6. Diameter dependence of the SOI splitting $\Delta E_1$ and $\Delta E_2$ for hexagonal InSb and InAs wires ($B = 0$ and $E = 0$). Results with and without Dresselhaus term are compared.

should affect the SOI splitting $\Delta E_l$, like it is the case in wurtzite wires. However, for InAs and InSb it is too small in magnitude to have a significant effect, see Fig. S6.

B. Rectangular wires

In the main text we focused on hexagonal and cylindrical wires, here we consider now rectangular wires. The parameters of the simulation are identical to the hexagonal case apart from the the growth direction which is now 001.

For a simple quadratic band with effective mass $m^*$ the energy levels at $k = 0$ of a rectangular wire with dimensions $L_x$ and $L_y$ are given by

$$E_{n_x, n_y} = \frac{\hbar^2}{2m^*} \left[ \left( \frac{n_x \pi}{L_x} \right)^2 + \left( \frac{n_y \pi}{L_y} \right)^2 \right],$$  \hspace{1cm} (S32)
FIG. S7. Results for rectangular InSb wires with fixed crossection of $40 \times 40 = 1600\, \text{nm}^2$ and variable ratio of height to width ($L_x/L_y$). (a) ((b)) Energy levels ($g$-factors) of the first four conduction Kramers pairs as a function $L_x/L_y$. (c) ((d)) Norm squared wave functions of the first four conduction states at $L_x/L_y = 1$ ($L_x/L_y = 1.1$). The color code for the Kramers pairs is the same in (a), (b), (c) and (d).

with the quantum numbers $n_x$ and $n_y$ taking on nonzero positive integer values. The corresponding wavefunctions are given by

$$
\psi_{n_x,n_y}(x,y,z) = \frac{1}{\sqrt{N_{n_x,n_y}}} \sin\left(\frac{n_x \pi}{L_x} x\right) \sin\left(\frac{n_y \pi}{L_y} y\right) e^{ikz},
$$

where $N(n_x,n_y)$ is a normalization factor.

In the case $L_x = L_y$ the lowest energy level is $E_{0,0}$ and the first excited level is two-fold degenerate $E_{1,2} = E_{2,1}$. With SOI the two-fold degeneracy is lifted into two separate states with $f_z = \frac{1}{2}$ and $f_z = -\frac{1}{2}$ with SOI splitting $\Delta E_1$. Note that due to the $C_4$ symmetry of the wire the angular momenta $f_z = \{-\frac{3}{2}, -\frac{1}{2}, \frac{1}{2}, \frac{3}{2}\}$ are still in different symmetry sectors. Therefore, we can still talk of the $l \approx 1$ subbands as in the cylindrical case and also the enhanced $g$-factors are found. This is illustrated in Fig. S7 where a rectangular InSb wire is simulated. For $L_x = L_y$ we find $\Delta E_1$ and the $g$-factor for the $l \approx 1$ bands similar to the cylindrical and hexagonal case. The wavefunctions of the second and third state shown in Fig. S7 (c) are clearly angular momentum eigenstates.

Upon deformation of the quadratic wire the geometry splitting of the second and third state soon surpasses the SOI splitting $\Delta E_1$ and $g$-factors decline rapidly, see Fig. S7 (a) and (b). In the simple quadratic band model the geometry splitting is given by

$$
E_{n_x,n_y} - E_{n_y,n_x} = \frac{\hbar^2 \pi^2}{2m^*} \left( \frac{1}{L_x^2} - \frac{1}{L_y^2} \right) (n_x^2 - n_y^2),
$$

which is also found in good approximation in our more sophisticated 8-band $k \cdot p$ calculation. If $L_x$ and $L_y$ differ enough the geometry splitting exceeds the SOI splitting and the wavefunctions are no more angular momentum eigenstates, see Fig. S7 (d).

C. Efficient Majorana wire simulations

The realization of Majorana states requires a proximity induced superconducting pairing potential in the wire [22, 23]. For the superconducting calculations we transform the zincblende $k \cdot p$ Hamiltonian in the Bogoliubov de Gennes (BdG) basis and double the Hilbert space via adding the hole degrees of freedom. Then, we add an $s$-wave pairing term $\Delta$ to the off-diagonal block of the Hamiltonian [24]

$$
H_{\text{BdG}}(k_z) = \begin{pmatrix}
H(k_z) & \hat{\Delta} \\
\hat{\Delta}^\dagger & -H^*(-k_z)
\end{pmatrix},
$$

(S35)
The $s$-wave pairing $\hat{\Delta}$ is assumed to be local and is kept constant throughout the wire. Furthermore, we restrict it to the conduction band $s$-like orbitals (the $|u_1\rangle$ and $|u_2\rangle$ basis states), which dominate near the Fermi level. It is then of the form

$$\hat{\Delta} = \Delta \sum_{i} \left( c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger + \text{h.c.} \right),$$

where $c$ and $c^\dagger$ are annihilation and creation operators and with $i$ running over all sites and the $s$-like $|u_1\rangle = i \uparrow$ and $|u_2\rangle = i \downarrow$ basis states.

Differential conductivity measurements in semiconductor nanowires in contact to a superconductor are an important probe of possible Majorana states [10, 25–28]. Simulating a realistic infinite wire is already computationally demanding, however, simulating a finite 3D wire long enough to host protected Majorana modes by exact diagonalization would be a hopeless endeavor using current computer hardware. Using the clever Sancho-Rubio scheme [29, 30] it is possible to significantly lessen the computational strain to something which is tractable on modern supercomputers. With the Sancho-Rubio scheme one can simulate the boundary and bulk Greens function of a wire in an iterative fashion, doubling the effective wire length in each iteration [31].

We begin by writing the 1D Hamiltonian in a form that has only nearest neighbor interactions and is translationally invariant inside the wire

$$H_{\text{wire}} = \begin{pmatrix} \epsilon & \alpha & 0 & \cdots \\ \beta & \epsilon & \alpha & 0 & \cdots \\ & \beta & \epsilon & \alpha & 0 & \cdots \\ & & \ddots & \ddots & \ddots & \ddots \end{pmatrix},$$

where $\beta = \alpha^\dagger$. Longer range interactions can be incorporated by artificially increasing the size of the unit cell such that the effective interactions become nearest neighbor again. Now one can make use of Dyson’s identity to write the Green’s function $G_{n=2}^{-1}$ at the left site for a chain of length $2$

$$G_{n=2}^{-1} = \omega - (\epsilon + \alpha (\omega - \epsilon)^{-1} \beta),$$

where $\omega$ is the energy and $\epsilon_i$ is an effective Hamiltonian for the left surface site. Equivalently, one can attach two sites to the left and to the right to obtain the effective bulk Hamiltonian in the middle of a chain of three sites

$$\epsilon_1 = \epsilon_0 + \alpha (\omega - \epsilon)^{-1} \beta + \beta (\omega - \epsilon)^{-1} \alpha.$$  

It can be shown that the new effective interactions $\alpha_1$ and $\beta_1$ for the effective Hamiltonians $\epsilon_1$ and $\epsilon_i^\dagger$ are given by [30]

$$\alpha_1 = \alpha (\omega - \epsilon)^{-1} \alpha,$$
$$\beta_1 = \beta (\omega - \epsilon)^{-1} \beta.$$  

Thus the effective Hamiltonian for a system of length $2^l a$, with $a$ being the lattice constant of the chain, can be obtained by iterating the following set of equations

$$\alpha_l = \alpha_{l-1} (\omega - \epsilon_{l-1})^{-1} \alpha_{l-1},$$
$$\beta_l = \beta_{l-1} (\omega - \epsilon_{l-1})^{-1} \beta_{l-1},$$
$$\epsilon_l = \epsilon_{l-1} + \alpha_{l-1} (\omega - \epsilon_{l-1})^{-1} \beta_{l-1} + \beta_{l-1} (\omega - \epsilon_{l-1})^{-1} \alpha_{l-1},$$
$$\epsilon_i^\dagger = \epsilon_i^\dagger (\omega - \epsilon_{l-1})^{-1} \beta_{l-1}.$$  

The bulk and surface Green’s function are given by $G_{\delta} = (\omega - \epsilon_1)^{-1}$ and $G_{\epsilon} = (\omega - \epsilon)$. In practice a small imaginary part is added to $\omega$ to broaden the energy levels for better visibility.

From the diagonal part of the Greens function we obtain the local density of states (LDOS) at the boundary of the wire, which is closely related to the differential conductivity [32]. Due to the increased computational effort a coarser discretization with a lattice constant of 2.5 nm is used in these simulations.
IV. COMPUTER CODES

We provide the computer code for our k · p simulations as supplementary files. All numerical simulations use the Python 3 programming language [33]. Demonstrations of the code are given in form of Jupyter notebooks [34]. The provided environment.yml file can be used to create a virtual environment suitable for executing the scripts [35]. Some simulations use the kwant package [36].

- A demonstration of the simulations of the cylindrical zincblende wire with hard and soft boundaries, and also of the finite wire, using the axial approximation is given in axialapproximation.ipynb.
- A demonstration of the Rashba model is given in Rashba_model_cylindrical.ipynb (and Rashba_model_dresselhaus.ipynb with added Dresselhaus term) and a demonstration of the InAs wurtzite wire in wurtzite_wire.ipynb.
- A demonstration of the hexagonal zincblende wire is given in hexagonal_wire.ipynb and of the rectangular wire in rectangular_wire.ipynb.
- The superconducting Hamiltonian is demonstrated in superconducting_wire.ipynb. Due to the computational complexity it is recommended to run the 3d Majorana wire simulations on a computing cluster. We provide the python script calculate_LDOS.py and sample submit scripts to generate the data for Fig. 5 of the main text.
