ABSTRACT

We use a three-dimensional magnetohydrodynamic simulation of the solar wind to calculate cosmic ray diffusion coefficients throughout the inner heliosphere (2 R⊙ – 3 AU). The simulation resolves large-scale solar wind flow, which is coupled to small-scale fluctuations through a turbulence model. Simulation results specify background solar wind fields and turbulence parameters, which are used to compute diffusion coefficients and study their behavior in the inner heliosphere. The parallel mean free path is evaluated using quasi-linear theory, while the perpendicular mean free path is determined by non-linear guiding center theory with the random ballistic interpretation. Several runs examine varying turbulent energy and different solar source dipole tilts. We find that for most of the inner heliosphere, the radial mean free path (mfp) is dominated by diffusion parallel to the mean magnetic field; the parallel mfp remains at least an order of magnitude larger than the perpendicular mfp, except in the heliospheric current sheet, where the perpendicular mfp may be a few times larger than the parallel mfp; in the ecliptic region, the perpendicular mfp may influence the radial mfp at heliocentric distances larger than 1.5 AU; our estimations of the parallel mfp in the ecliptic region at 1 AU agree well with the Palmer “consensus” range of 0.08 – 0.3 AU; solar activity increases perpendicular diffusion and reduces parallel diffusion; the parallel mfp mostly varies with rigidity (P) as P⁻³, and the perpendicular mfp is weakly dependent on P; the mfps are weakly influenced by the choice of long wavelength power spectra.

Keywords: Solar wind — diffusion — turbulence — cosmic rays — solar energetic particles — simulation

1. INTRODUCTION

The interaction of energetic particles with the solar wind is a topic of wide interest in space physics and astrophysics. Several varieties of charged particles populate the heliosphere, including energetic particles originating at the sun (solar energetic particles, or SEPs) and galactic cosmic rays (GCRs) that enter the heliosphere uniformly and nearly isotropically from the outside (Kunow et al. 1991). These cosmic rays (CRs) are strongly guided and scattered by the solar wind and the turbulent fluctuations that transport with it (Parker 1956, 1964; Jokipii 1966). As such, the study of the origin and transport of cosmic rays is an important problem in heliospheric physics, with implications ranging from space weather and exploration to fundamental space plasma physics (Jokipii 1971; Fisk 1979; Kunow et al. 1991). The effects of these energetic particles on the health of astronauts (Parker 2005) and the well-being of electronic components in spacecraft (Tylka et al. 1997) are an immediate concern. In addition, the accuracy with which we can understand CR propagation also provides a testbed for energetic particle transport in numerous space and astrophysical applications (Kulsrud & Pearce 1969; Drège 2003). The solar wind provides us with an opportunity to observe, at close range, the behavior of energetic particles in random, turbulent magnetic fields (Bruno & Carbone 2013). Such fields are ubiquitous in astrophysical systems (Candia & Roulet 2004), and the insights we glean from studies of CRs in the heliosphere can potentially find application elsewhere in the universe. Finally, observations of cosmic rays can also serve as probes into solar activity and solar wind structure, as CR variations are seen to be correlated with solar and geomagnetic activity (Snyder et al. 1963).

Theories of the modulation of cosmic rays in the heliosphere attempt to explain the observed temporal and spatial variation in their spectra (Fisk 1979; Potgieter 2013), and for that purpose, require a knowledge of the cosmic ray diffusion tensor. In fact, one of the key challenges in solving the Parker CR transport equation (Parker 1965) is the inadequate knowledge of the spatial, temporal, and rigidity dependence of the components of the diffusion tensor. In turn, the specification of this tensor through the heliosphere requires an understanding of two topics. First, a theoretical understanding of the diffusion process itself is needed, which would lead to predictions of the structure of the diffusion tensor itself. Equally important is the knowledge of the large scale flows and electromagnetic field in the plasma, and the distribution of background solar wind turbulence in which the particles are scattered. The present approach permits three dimensional, and (in principle) time-varying calculation of all three of these properties (diffusion tensor, large scale flow, large scale electromagnetic field) to be computed in a single model.

The formal structure of the diffusion tensor involves diagonal components corresponding to diffusion parallel and perpendicular to the interplanetary magnetic field (IMF), as well as off-diagonal components describing perpendicular drifts (e.g., Moraal 1976; Minnie et al. 2007).
While quasi-linear theory [Jokipii 1966] extended to include time-dependent and non-linear corrections [Goldstein 1976; Bieber et al. 1994; Droge 2003] provides a relatively good accounting of parallel diffusion, theories of perpendicular diffusion have faced the challenge of accounting for non-linear effects such as transfer of particles across field lines, backscatter from parallel diffusion, and field-line random walk [Jokipii 1966; Giacalone & Jokipii 1999]. The non-linear guiding center (NLGC) theory [Matthaeus et al. 2003; see also Shalchi 2009] accounts for the above, and is further improved by the random ballistic interpretation of Ruffolo et al. [2012a]. In the current work we focus on the parallel and perpendicular diffusion coefficients; the drift motion could be a topic for future work.

Since turbulent fluctuations are responsible for scattering CRs, the diffusion theories mentioned above typically involve turbulence parameters such as the energy of the random magnetic fluctuations and correlation scales. In the solar wind, low-frequency turbulence evolves via a non-linear cascade, while also being transported and processed by the large-scale radially expanding solar wind. At all but the smallest scales, these processes are well described by magnetohydrodynamic (MHD) models [Marsh & Tu 1989a; Zhou & Matthaeus 1999]. Over the years, turbulence models have incorporated simplifying assumptions relevant to the solar wind, yielding increased tractability of the governing equations [Zank et al. 1996; Matthaeus et al. 1999b].

The increased sophistication of the models and improvements in computational power have led to numerical simulations yielding good agreement with Voyager, Ulysses, Helios, and WIND observations [Breech et al. 2008; Usmanov et al. 2011]. These turbulence models have also been used to study the propagation of coronal mass ejections [Wiesengarten et al. 2015]. Extensions to the Breech et al. [2008] model have been developed [Oughton et al. 2011; Zank et al. 2012; 2017], and applied to the inhomogeneous solar wind [Shota et al. 2017].

Our strategy for evaluating the CR diffusion coefficients through the inner heliosphere consists of two steps: first, specification of the relevant turbulence parameters based on a global solar wind model, and second, evaluation of the CR diffusion coefficients using the specified heliographic distribution of turbulence. For the first step, we deduce turbulence parameters from a global, three-dimensional (3-D) MHD simulation of the solar wind [Usmanov et al. 2014].

The spatial resolution that can be realistically achieved in such simulations cannot resolve the small-scale fluctuations that cause scattering of CRs. For instance, the spatial resolution of our simulation, at 1 AU, can be estimated as roughly 0.03 AU. However, the mean free path, at 1 AU, for scattering perpendicular to the mean magnetic field has been estimated to be as low as 0.001 AU [Zhang et al. 2009; Pei et al. 2010], and the correlation scale of the turbulence has been estimated to be around 0.007 AU [Matthaeus et al. 2005; Bruno & Carbonne 2013]. This is where our turbulence model for the “sub-resolution” physics comes in. Our simulation explicitly resolves the large-scale, mean solar wind bulk flow, which is coupled to small-scale inhomogeneities by means of an MHD-Reynolds-averaged Navier-Stokes (RANS; see, e.g., McComb 1990) model for the random fluctuations. The simulation has been well-tested, and gives reasonable agreement with many spacecraft observations of large-scale solar wind fields, turbulence parameters (energy, cross helicity and correlation scale), as well as the temperature, for varying heliocentric distance, and where feasible, varying helio-latitudinal [Usmanov et al. 2011; 2012; 2016]. In recent “applied” work, the simulation has been used to study the collisional age of the solar wind plasma [Chhiber et al. 2016], and we view the present work as a continuation of such application-oriented studies.

Once the turbulence parameters are specified through the model heliosphere, for the second step of our calculation, we use, as a starting point, fairly standard, well-tested formalisms for parallel and perpendicular diffusion coefficients - quasi-linear theory [Jokipii 1966; Bieber et al. 1995; Zank et al. 1998] to compute the parallel component of the diffusion tensor, and the random ballistic decorrelation (RBD) interpretation of NLGC theory [Matthaeus et al. 2003; Ruffolo et al. 2012a] for perpendicular diffusion.

Previous studies of the heliographic dependence of the CR diffusion coefficients include work based on both WKB models for Alfvén waves [Völk et al. 1974; Möller & Voelk 1979], and models for strong turbulence [Breech et al. 1995; Zank et al. 1998; Pei et al. 2010]. The present work builds on these studies, but also makes some significant departures, motivated and enabled by recent advances in diffusion theory and sophistication of solar wind simulations. The major points of departure from previous work are listed below:

1. We use a fully 3-D global simulation of the solar wind that provides us with a reliable and self-consistent model heliosphere. Previous work has used one-dimensional (1-D) radial evolution models with spherical symmetry, with shear-driving effects included through a model [Zank et al. 1998; Pei et al. 2010]. Thus, while examining latitudinal dependence of the diffusion tensor, these studies implicitly assume that they are far from regions with significant latitudinal gradients. In contrast, three dimensionality improves the physical authenticity of the simulation by explicitly including shear-driving effects on the flow across latitudes, and leads to improved data-visualization through two-dimensional (2-D) contour plots. A similar 3-D approach has been recently used in Guo & Florinski [2016] to study the propagation of GCRs from 0.3 AU to the termination shock.

2. The computation of the CR diffusion tensor requires specification of the background solar wind speed, and the underlying large-scale heliospheric magnetic field. Previous work [Bieber et al. 1995; Zank et al. 1998; Pei et al. 2010] used a radially constant solar wind speed with some latitudinal variation, and a Parker-spiral type magnetic field model. However, the use of a prescribed model for the background fields has been found inadequate [Reinecke et al. 1997a,b], and instead we use the large-scale, resolved flow from our MHD-RANS simulation. This provides a complete specification of the background large-scale fields, with spatial variation that has been found to agree well with observations [Usmanov et al. 2014].

3. We examine the diffusion coefficients at radial distances between 2 $R_\odot$ and 3 AU, where $R_\odot$ denotes a solar radius. We are not aware of any other similar study
that has probed regions close to the sun, which are of prime interest for SEP propagation, space weather, and for upcoming spacecraft missions, including Solar Probe Plus. Resolving this entire domain (2 \(R_\odot\) – 3 AU) in one simulation is a challenge, as modeling approximations that are appropriate very close to the sun may not be valid at larger heliocentric distances. Furthermore, the timescales associated with the different domains are disparate (Hundhausen 1972; Tu & Marsch 1995; Bruno & Carbone 2013). We use an approach where the computational domain is split into three regions: inner (1 – 20 \(R_\odot\)), intermediate (20 – 45 \(R_\odot\)), and outer (45 \(R_\odot\) – 3 AU). The inner and intermediate regions employ a WKB Alfven wave model, and the outer region solves a full turbulence transport model, with the inner boundary conditions for each region being provided by the preceding one (Usmanov et al. 2014).

4. A magnetic dipole with its tilt (relative to the solar rotation axis) varying through the solar activity cycle is a fast and rough approximation for the solar magnetic field (Babcock 1961). We examine the effect of changing the tilt of the source solar dipole by using simulations with a dipole untilted with respect to the solar rotation axis, and a dipole with 30° tilt, in contrast to previous work employing axisymmetric solar wind parameters (Zank et al. 1998; Pei et al. 2010). The tilt of the solar dipole and the warping of the heliospheric current sheet (Smith 2001) indicate high levels of solar activity (Heber & Potgieter 2006), which is a factor of interest since CR intensity is anticorrelated to solar activity levels (Moraal 1976; Jokipii & Thomas 1981), though these processes take place over a wider region than considered in the present work (\(r < 3\) AU).

We shall also examine the radial diffusion coefficient \(\kappa_{rr} \equiv \kappa_\parallel \cos^2 \Psi + \kappa_\perp \sin^2 \Psi\), (2) which is of particular relevance to models of solar modulation of CRs. Here, \(\Psi\) is the “winding” angle between the IMF and the radial direction. Following previous work, we define mean free paths, \(\lambda_{\parallel,\perp}\), that are equivalent to the diffusion tensor through

\[
\lambda_{\parallel,\perp} = 3\kappa_{\parallel,\perp}/v, \tag{3}
\]

where \(v\) is the particle speed.

We note that in the present work we use the large-scale flow from our simulation to specify \(B\) and \(\Psi\) as spatially varying fields through the 3-D heliosphere. This is in contrast to previous studies (Bieber et al. 1995; Zank et al. 1998; Pei et al. 2010), where \(B\) and \(\Psi\) were specified through a Parker-type model and a radially constant solar wind speed (to compute \(\Psi\)). However, the features of the IMF have a major influence on CR transport, and a Parker-type field is an oversimplification, particularly at high heliolatitudes (See Heber & Potgieter 2006 for an overview of suggested modifications to the Parker field). Moreover, the use of a-priori prescribed background fields in modulation studies has been held responsible for restricting the diffusion tensor to values that preclude agreement of models with observations (Reinecke et al. 1997a, b), and the present work makes a significant improvement in this regard.

2.1. Parallel mean free path

In determining the parallel mean free path (mfp), the turbulence “geometry”, i.e., the distribution of energy over parallel and perpendicular wavevectors, is a controlling factor. Observations (Bieber et al. 1994) show that

\[
\kappa_{ij} = \kappa_\perp \delta_{ij} + \frac{B_i B_j}{B^2}(\kappa_\parallel - \kappa_\perp) + \epsilon_{ijk}\kappa_A B_k B_j, \tag{1}
\]

where \(B\) is the mean IMF, \(\delta_{ij}\) is the Kronecker delta, and \(\epsilon_{ijk}\) is the Levi-Civita symbol. This work presents calculations of \(\kappa_\parallel \) and \(\kappa_\perp\), which are the diagonal components of the diffusion tensor parallel and perpendicular, respectively, to the mean IMF.

The present work does not calculate \(\kappa_A\), which can describe particle drifts under the influence of large-scale gradients and curvature in the IMF. Our results are directly relevant to the outward propagation of SEPs, for which \(\kappa_\parallel\) and \(\kappa_\perp\) are needed to describe how the SEP distribution spreads in the parallel and perpendicular directions, whereas over the short time scale of the SEP outflow the drifts may mainly shift the lateral distribution over a small angle. The lateral distribution of particle injection is often unknown, and the effects of drifts are often neglected, though Marsh et al. (2013) argue that they should be considered. Both diffusion and drifts are considered to be important to the modulation of GCR with the solar cycle and the small gradients in GCR density (Moraal 1976; Jokipii & Thomas 1981), though these processes take place over a larger region than considered in the present work (\(r < 3\) AU).

The CR diffusion tensor, \(\kappa_{ij}\), describes the scattering of CRs by random fluctuations in the IMF. It may be expressed as (Parker 1965; Jokipii & Parker 1970)

\[
\kappa_{ij} = \kappa_\perp \delta_{ij} + \frac{B_i B_j}{B^2}(\kappa_\parallel - \kappa_\perp) + \epsilon_{ijk}\kappa_A B_k B_j, \tag{1}
\]

where \(B\) is the mean IMF, \(\delta_{ij}\) is the Kronecker delta, and \(\epsilon_{ijk}\) is the Levi-Civita symbol. This work presents calculations of \(\kappa_\parallel\) and \(\kappa_\perp\), which are the diagonal components of the diffusion tensor parallel and perpendicular, respectively, to the mean IMF.

The present work does not calculate \(\kappa_A\), which can describe particle drifts under the influence of large-scale gradients and curvature in the IMF. Our results are directly relevant to the outward propagation of SEPs, for which \(\kappa_\parallel\) and \(\kappa_\perp\) are needed to describe how the SEP distribution spreads in the parallel and perpendicular directions, whereas over the short time scale of the SEP outflow the drifts may mainly shift the lateral distribution over a small angle. The lateral distribution of particle injection is often unknown, and the effects of drifts are often neglected, though Marsh et al. (2013) argue that they should be considered. Both diffusion and drifts are considered to be important to the modulation of GCR with the solar cycle and the small gradients in GCR density (Moraal 1976; Jokipii & Thomas 1981), though these processes take place over a larger region than considered in the present work (\(r < 3\) AU).

We shall also examine the radial diffusion coefficient

\[
\kappa_{rr} \equiv \kappa_\parallel \cos^2 \Psi + \kappa_\perp \sin^2 \Psi, \tag{2}
\]

which is of particular relevance to models of solar modulation of CRs. Here, \(\Psi\) is the “winding” angle between the IMF and the radial direction. Following previous work, we define mean free paths, \(\lambda_{\parallel,\perp}\), that are equivalent to the diffusion tensor through

\[
\lambda_{\parallel,\perp} = 3\kappa_{\parallel,\perp}/v, \tag{3}
\]

where \(v\) is the particle speed.

We note that in the present work we use the large-scale flow from our simulation to specify \(B\) and \(\Psi\) as spatially varying fields through the 3-D heliosphere. This is in contrast to previous studies (Bieber et al. 1995; Zank et al. 1998; Pei et al. 2010), where \(B\) and \(\Psi\) were specified through a Parker-type model and a radially constant solar wind speed (to compute \(\Psi\)). However, the features of the IMF have a major influence on CR transport, and a Parker-type field is an oversimplification, particularly at high heliolatitudes (See Heber & Potgieter 2006 for an overview of suggested modifications to the Parker field). Moreover, the use of a-priori prescribed background fields in modulation studies has been held responsible for restricting the diffusion tensor to values that preclude agreement of models with observations (Reinecke et al. 1997a, b), and the present work makes a significant improvement in this regard.

2.1. Parallel mean free path

In determining the parallel mean free path (mfp), the turbulence “geometry”, i.e., the distribution of energy over parallel and perpendicular wavevectors, is a controlling factor. Observations (Bieber et al. 1994) show that
a pure “slab” model of heliospheric turbulence (Jokipii 1966) underestimates the parallel mfp. In the slab model, the magnetic fluctuations are polarized perpendicular to the mean field and their wave-vectors are parallel to the mean field. Bieber et al. (1994) find that a composite model with a dominant 2-D part (fluctuations and their wave-vectors both perpendicular to the mean field) and a minor slab part provides a better approximate parameterization of the turbulence and an improved description of the observed mean free paths. Furthermore, theoretical studies and observations (Matthaeus et al. 1990; Zank & Matthaeus 1992, 1993; Bieber et al. 1996; Ghosh & Goldstein 1997) suggest that around 80% of magnetic fluctuation energy resides in the slab component, with the rest in the slab component.

In the following, we take the z-component along the mean field. Considering parallel diffusion first, we note that in quasilinear theory the 2-D fluctuations are effectively invisible to CRs resonating with the turbulence, and the scattering by slab fluctuations (assumed to be axisymmetric) is described by the parallel mfp (Zank et al. 1998)

\[
\lambda_\parallel = 6.2742 \frac{B_{5/3}}{\langle b_z^2 \rangle} \left( \frac{L}{c} \right)^{1/3} \lambda_s^{2/3} \times \left[ 1 + \frac{7A}{(1/3 + q)(q + 7/3)} \right], \tag{4}
\]

where

\[
A = (1 + s^2)^{5/6} - 1, \tag{5}
\]

\[
q = \frac{5s^2/3}{1 + s^2 - (1 + s^2)^{1/6}}, \tag{6}
\]

\[
s = 0.746834 \frac{R_L}{\lambda_s}, \tag{7}
\]

and a model 1-D Kolmogorov spectrum is assumed, with a power spectrum of the form \( P(k) \propto (1 + k_\parallel \lambda_s)^{-5/6} \). Here \( c \) is the speed of light, \( R_L = P/Bc \) the particle Larmor radius, \( \langle b_z^2 \rangle \) the variance of the slab geometry fluctuation, \( P \equiv \bar{p}/Ze \) the particle rigidity (\( \bar{p} \) and \( Ze \) are the particle momentum and charge, respectively), \( k_\parallel \) is the wave vector parallel to the mean field, and \( \lambda_s \) the correlation length for slab turbulence. Equation (4) is valid at rigidities ranging from 10 MV to 10 GV (Zank et al. 1998). At larger heliocentric distances, the fractional term in braces becomes significant due to high rigidity particles resonating with fluctuations in the energy containing range instead of the inertial range. This is discussed further below in the context of rigidity dependence of the mfps (Section 4.4).

2.2. Perpendicular mean free path

Perpendicular diffusion is often not considered as important as parallel diffusion in energetic particle studies, because it is usually inferred that \( \lambda_\perp << \lambda_\parallel \) (Palmer 1982). However, Dwyer et al. (1997) found that for strong particle enhancements related to corotating interaction regions, \( \lambda_\perp/\lambda_\parallel \) rose to \( \sim 1 \) in the fast solar wind stream arriving after the stream interface. Using data from the Ulysses spacecraft during the SEP event of 2000 Jul 14, Zhang et al. (2003) inferred \( \lambda_\perp/\lambda_\parallel \approx 0.25 \). Our 3-D model inner heliosphere provides an opportunity to examine the domains where perpendicular diffusion can be comparable with parallel diffusion.

Quasi-linear theory (Jokipii 1966) provides a physically appealing description of perpendicular diffusion in terms of the diffusive spread of magnetic field lines, with the gyrocenters of charged particles following the field lines. Other approaches have considered the relationship between \( \kappa_\perp \) and \( \kappa_\parallel \) (Axford 1965; Gleeson 1969), and applied the Taylor-Green-Kubo formulation (BAM, Bieber & Matthaeus 1997) to the problem. However, the field line random walk (FLRW) approach (Jokipii 1966) overestimates the strength of the diffusion, while BAM predicts diffusion that is weaker than that observed in numerical experiments (Giacalone & Jokipii 1999; Mace et al. 2000). The NLGC theory (Matthaeus et al. 2003) accounts for both the random walk of the field lines and the influence of parallel scattering, and shows good agreement with both observations (Bieber et al. 2004) and simulations, with the NLGC results bracketed by the FLRW and BAM results (Matthaeus et al. 2003).

Recent work (Ruffolo et al. 2012a) has reinterpreted NLGC by replacing the diffusion of gyrocenter trajectories with a random ballistic decorrelation (RBD), where the guiding center motion is approximated as ballistic (i.e., with constant velocity) between scattering events. The RBD-modified theory agrees with numerical simulations over a wider range of fluctuation amplitudes than the original NLGC, specifically for fluctuations comparable in size to the large-scale field. This makes it particularly suited for application to the solar wind (Belcher et al. 1969; Marsch 1991). Other improvements to NLGC have also been developed (see, e.g., Shalchi 2009).

The phenomenon of “backtracking” due to parallel scattering causes a particle to reverse its motion along the field line, thus retracing its steps over a certain timespan. This leads to a negative \( v_x \)-correlation (\( v_x \) being a component of the particle’s velocity perpendicular to the mean field), which results in a reduction in the running perpendicular diffusion coefficient. With this backtracking correction, RBD yields the following perpendicular diffusion coefficient (Ruffolo et al. 2012b).

\[
\kappa_\perp = \frac{a^2 v^2}{6B^2} \sqrt{\frac{\pi}{2}} \int_0^\infty \frac{S_2(k_\perp)Erfc(\alpha)2\pi k_\perp dk_\perp}{k_\perp \sqrt{\langle \dot{b}_z^2 \rangle}}, \tag{8}
\]

where \( a^2 = 1/3 \), \( v \) is the particle speed, \( \dot{v}_x \) the \( x \)-component of the guiding center velocity, \( S_2 \) is the 2-D axisymmetric turbulent fluctuation spectrum, Erfc is the complementary error function, and \( k_\perp \) is the component of the wave-vector perpendicular to the mean magnetic field. We also have

\[
\alpha = \frac{v^2}{3\kappa_\parallel \sqrt{2\langle \dot{b}_z^2 \rangle}}, \tag{9}
\]

and

\[
\langle \dot{b}_z^2 \rangle = \frac{a^2 (\dot{v}_x^2)}{6B^2}, \tag{10}
\]

where \( b^2 \) is the combined variance of the 2-D and slab magnetic fluctuations: \( b^2 = \langle b_z^2 \rangle + \langle b_z^2 \rangle \). Note that in Equation (8), the slab turbulence spectrum does not appear. This is because we follow the suggestion by Shalchi...
that the direct contribution of the slab component to perpendicular transport is subdiffusive, and therefore the slab term should not contribute to Equation (8). This hypothesis has been supported by simulations (Ruffolo et al. 2012a,b), and accordingly, has been adopted in the present work as well. Slab fluctuations can, however, still influence \( \kappa_{\perp} \) through \( \kappa_{||} \), which appears in Equation (9) for \( \alpha \) and \( \langle v_{z}^{2} \rangle \).

The 2-D power spectrum may be expressed as a power law (Matthaeus et al. 2007)

\[
S_{2}(k_{\perp} \leq 1/\lambda_{2}) = C_{2}(b_{2}^{2})C_{1}(\lambda_{2}k_{\perp})^{p}, \tag{11}
\]

\[
S_{2}(k_{\perp} > 1/\lambda_{2}) = C_{2}(b_{2}^{2})\lambda_{2}^{-2}(\lambda_{2}k_{\perp})^{-\nu - 1}, \tag{12}
\]

where \( \lambda_{2} \) is the 2-D correlation scale, \( C_{2} \) is a normalization constant, \( \langle b_{2}^{2} \rangle \) is the variance of the 2-D turbulent fluctuations, and \( p \) is a power index that takes on integral values that correspond to different power spectra. We assume a Kolmogorov spectrum in the inertial range by taking \( \nu = 5/3 \). From the requirement that \( \langle b_{2}^{2} \rangle = 2\pi \int_{0}^{\infty} S_{2}(k)k^{p} dk \), we get

\[
C_{2} = \frac{(\nu - 1)(p + 2)}{2\pi(p + \nu + 1)}, \tag{13}
\]

Note that the inertial range \( (k_{\perp} > 1/\lambda_{2}) \) behavior is described by a conventional power law, and \( p \) only determines the long-wavelength properties of the spectrum. The spectral behavior of interplanetary magnetic fluctuations at long wavelengths is not well determined from single point measurements (Matthaeus et al. 2016), and there are ambiguities surrounding the question of whether the observed structures are spatial or temporal in origin. The observations of “1/f” noise at low frequencies also complicate matters (Matthaeus & Goldstein 1989). All values of \( p \geq -1 \) yield power spectra that give rise to a finite energy, but these spectra may be differentiated based on the characteristic length scales associated with them. In addition to the standard correlation scale (Batchelor 1953), there is a distinct scale, called the ultrascale, which is of importance in applications of 2-D turbulence (Matthaeus et al. 2007) and references therein. The ultrascale is so named because it is generally larger than the correlation scale, and it may be interpreted as a typical size of an “island” of 2-D turbulence (Matthaeus et al. 1999a) and as the perpendicular coherence length of the FLRW (Ruffolo et al. 2004).

We consider the following cases (Matthaeus et al. 2007): \( p = -1 \) (infinite correlation scale and an infinite ultrascale), \( p = 0 \) (finite correlation scale but an infinite ultrascale), and \( p \geq 1 \) (finite ultrascale and finite correlation scale). The case \( p = 2 \) is of special interest since it corresponds to homogeneous turbulence. Each of the above possibilities is realizable as each yields a finite energy. However, unlike the correlation scale, the values taken by the ultrascale in space and astrophysical plasmas are not well known, and there is a paucity of established methods to measure it (see Matthaeus et al. 2007 for a proposed technique). Therefore, it is of interest to examine the dependence of the diffusion coefficients on \( p \). If there is a marked differentiation between the mfps computed for different cases, then observations of the mfps may be used to infer constraints on the ultrascales prevailing in the heliospheric plasma.

To finally obtain an expression for the perpendicular mean free path, we use Equations (11) and (12) in Equation (8) and set \( \nu = 5/3 \) to get

\[
\lambda_{\perp} = \mathcal{F}_{1} \left[ \frac{\lambda_{2}^{-2/3}}{5\mathcal{F}_{2}^{5/3}/\sqrt{\pi}} \left[ 3\sqrt{\pi} \mathcal{F}_{2}^{5/3} \lambda_{2}^{5/3} \text{Erf} (\mathcal{F}_{2} \lambda_{2}) + \Gamma \left( \frac{1}{3} \right) - 3\Gamma \left( \frac{4}{3}, \mathcal{F}_{2}^{2} \lambda_{2}^{2} \right) \right] \right],
\]

\[
+ \frac{\delta_{p,-1}}{p} \left[ \mathcal{F}_{2} \lambda_{2}^{2} \mathcal{F}_{2}^{2} \left( \frac{1}{2} \mathcal{F}_{2}^{2} \lambda_{2}^{2} - 3\mathcal{F}_{2}^{2} \lambda_{2}^{2} \right) \right] - 0.981755 - \log(\mathcal{F}_{2} \lambda_{2})
\]

\[
- \mathcal{F}_{2} \lambda_{2}^{2} E_{2}^{2} \mathcal{F}_{2}^{2} \lambda_{2}^{2} \right), \tag{14}
\]

where

\[
\mathcal{F}_{1} = \sqrt{\pi^{3} C_{2}} \frac{\nu \langle b_{2}^{2} \rangle a_{z}^{2}}{B^{2} \sqrt{2\langle v_{z}^{2} \rangle}}, \tag{15}
\]

and

\[
\mathcal{F}_{2} = \frac{v}{\lambda_{||} \sqrt{2\langle v_{z}^{2} \rangle}}. \tag{16}
\]

In Equation (14), \( \text{Erf} \) is the error function, \( \Gamma \) is the gamma function, \( \mathcal{F}_{2} \) is a hypergeometric function, \( E_{2}^{2} \) is the generalized exponential integral function, and the Kronecker delta function is used as a switch between the four values of \( p \). \( C_{2} \) depends on the value of \( p \), as can be seen from Equation (13). Note that in the corresponding NLGC result (Pei et al. 2010), an implicit method is required to obtain \( \lambda_{\perp} \), in contrast to the RBD result, which is an explicit solution for \( \lambda_{\perp} \).

3. SOLAR WIND MODEL

Equations (4) and (14) require specification of the large-scale IMF, and the magnetic fluctuation energies and correlation lengths for both slab and 2-D turbulence. For this purpose, we use a Reynolds-averaged Navier-Stokes approach, based on the Reynolds decomposition (e.g., McComb 1990) of a physical field, \( \tilde{a} \), into a mean and a fluctuating component:

\[
\tilde{a} = a + a', \tag{17}
\]

where \( a = \langle \tilde{a} \rangle \) is an ensemble average, associated with the large scales of motion, and \( a' \) is a fluctuating component, here assumed to be small scale. By construction, \( \langle a' \rangle = 0 \). Application of this decomposition to the MHD equations, along with a series of approximations appropriate to the solar wind, leads us to a set of mean-flow equations that are coupled to the small-scale fluctuations via another set of equations for the statistical descriptors of turbulence. For the details of the procedure for handling the fluctuations, we refer the reader to Breech et al (2008).

In this study, we use the solar wind model described in detail by Usmanov et al. (2014). It is a global, fully three-dimensional magnetohydrodynamic model that accounts
for the effects of fluctuations in heating and acceleration of the solar wind flow. The computational domain, which in the present study extends from the coronal base to 3 AU, is split into three regions: inner \((1 - 20 R_\odot)\), intermediate \((20 - 45 R_\odot)\), and outer \((45 R_\odot - 3 AU)\). In the inner region, steady-state solutions of one-fluid, polytropic \((\gamma = 1.08)\) solar wind equations with WKB Alfvén waves are obtained by time relaxation starting from an initial state composed of a Parker-type flow in a dipole magnetic field \((\text{Usmanov et al. } 2000, \text{Usmanov \& Goldstein } 2003)\). Two-fluid steady-state equations for protons and electrons with Hollweg’s electron heat flux and WKB Alfvén waves are solved in the intermediate region by forward integration along the radius \(r\) \((\text{Pizzo } 1978, 1982, \text{Usmanov } 1993)\). The boundary conditions for the intermediate region are extracted from the inner region solution. In the outer region, we solve three-fluid (thermal protons, electrons, and pickup protons) Reynolds averaged solar wind equations simultaneously with transport equations for turbulence energy, cross helicity and correlation length. Steady-state solutions in the outer region are obtained by time relaxation, using an eddy-viscosity approximation for the Reynolds stress tensor and turbulent electric field, with boundary conditions provided by solutions in the intermediate region \((\text{Usmanov et al. } 2014)\). The use of steady-state simulations is justified here since ambient solar wind conditions change on time scales long compared to the time energetic particles spend in the inner heliosphere.

In our calculations, we have used the same input parameters at the coronal base as in \((\text{Usmanov et al. } 2014)\): the driving amplitude of Alfvén waves is set to \(35 \text{ km s}^{-1}\), the initial density is \(4.0 \times 10^6 \text{ cm}^{-3}\), and the initial plasma temperature is \(1 \times 10^6 \text{ K}\). The magnetic field magnitude is assigned as the field strength of the source magnetic dipole on the poles. This parameter is set to \(16 \text{ G}\) to match the magnitude of the heliospheric magnetic field observed by Ulysses. The computations are carried out on a composite spherical grid \((\text{Usmanov } 1996, \text{Usmanov et al. } 2012)\) using the Central Weighted Essentially Non-Oscillatory (CWENO) spatially third-order reconstruction algorithm \((\text{Kurganov \& Levy } 2000)\). The spatial CWENO discretization is combined with the Strong Stability-Preserving Runge-Kutta scheme of \((\text{ Gottlieb et al. } 2001)\) for time integration and the method of \((\text{Powell } 1994)\) for maintaining the \(\nabla \cdot \mathbf{B} = 0\) condition.

For our purposes here, we extract from the outer region simulation \((45 R_\odot - 3 \text{ AU})\) the mean magnetic field, \(\mathbf{B}\), the fluctuation energy, \(Z^2\) (defined below), and the correlation length for the turbulence, \(\lambda\). Here,

\[
Z^2 = (\langle v'^2 \rangle + b'^2) = (\langle v'^2 \rangle + b'^2), \tag{18}
\]

is twice the turbulent energy per unit mass, defined in terms of the velocity and magnetic field fluctuations, \(v'\) and \(B'\), respectively. The amplitude of magnetic fluctuations has been normalized to Alfvén units using \(b' = B'/(4\pi \rho)^{-1/2}\), where \(\rho\) is the mass density. To extend our calculation closer to the sun, we use data from the inner \((1 - 20 R_\odot)\) and intermediate \((20 - 45 R_\odot)\) regions, where the simulation does not have a turbulence model for \(Z^2\) and \(\lambda\). We then use the WKB Alfvén wave energy density \((\text{Usmanov et al. } 2000)\), \(\mathcal{E}\), as a proxy for the turbulent fluctuation energy via \(Z^2 = 2\mathcal{E}/\rho\). To get an approximation for the correlation scale in these regions, we use the hypothesis from \((\text{Hollweg } 1986)\) that the correlation length varies as the distance between magnetic field lines, which in turn depends on the field strength \((\text{Spruit } 1981)\), so that \(\lambda \propto B^{-1/2}\). We set the constant of proportionality such that \(\lambda\) at the boundaries of the intermediate and outer regions matches. We are currently working on refinements of the model that will modify the region in which turbulence modeling is included, so that this region will extend closer to the sun.

To proceed with the calculation of the mfps, some assumptions must be made in order to relate the correlation scale of our turbulence model \((\lambda)\) to the slab and 2-D correlation scales in Equations \((1+)\) and \((14),\) respectively. First, we note that the turbulent fluctuations in our model are primarily transverse to the mean magnetic field \((\text{Breech et al. } 2008)\), and thus identify the correlation scale of 2-D turbulence to be equal to the correlation scale of our turbulence model, so that \(\lambda_s = \lambda\). Observational studies \((\text{Osman \& Horbury } 2007, \text{Weygard et al. } 2009, 2011)\) indicate that the slab correlation scale is about a factor of two larger than the 2-D correlation scale, and accordingly, we assume \(\lambda_s = 2\lambda\). In our approximate treatment, we assume in effect that the magnetic and velocity correlation functions are structurally similar \((\text{Zank et al. } 1996)\), so that the magnetic correlation length is found to be equal to the single correlation scale that we follow dynamically. In the inner heliosphere where the cross helicity is large, it becomes advantageous to employ a two correlation length theory \((\text{Matthaeus et al. } 1994, \text{Wan et al. } 2012, \text{Zank et al. } 2012, 2017)\), as has been implemented, e.g., by \((\text{Adhikari et al. } 2015)\).

To approximate the energy in slab and 2-D magnetic fluctuations, we first convert \(Z^2\) to \(B^2\) using Equation \((18)\),

\[
\langle B^2 \rangle = \frac{Z^2}{r_A + 1} 4\pi \rho, \tag{19}
\]

where \(r_A = \langle \langle v'^2 \rangle / \langle b'^2 \rangle \rangle\) is the Alfvén ratio. An accurate dynamical model for \(r_A\) is desirable, but must include complications such as non-local effects \((\text{e.g., Grappin et al. } 1983, \text{Matthaeus et al. } 1994, \text{Hossain et al. } 1995)\). At present we maintain a simpler approach, and take \(r_A\) to have a value of 1 in the inner and intermediate regions \((1 - 45 R_\odot)\), and a value of 1/2 for heliocentric distances larger than 45 \(R_\odot\). These values are motivated by spacecraft observations \((\text{Tu \& Marsch } 1995)\), but we recognize that attempts have been made to treat \(r_A\) dynamically \((\text{Grappin et al. } 1983, \text{Marsch \& Tu } 1989, \text{Tu \& Marsch } 1990, \text{Matthaeus et al. } 1994, \text{Yokoyama \& Hamser } 2001, \text{Zank et al. } 2012)\). See especially the comparison with observations by \((\text{Adhikari et al. } 2015)\) and \((\text{Zank et al. } 2017)\.

Next, recalling the assumption that the magnetic fluctuations have a dominant 2-D component with a small slab contribution, and following observations \((\text{Matthaeus et al. } 1990, \text{Bieber et al. } 1994)\) that find the ratio of the 2-D and slab energies to be \(80\%\) to \(20\%\), we use

\[
\frac{\langle b'^2 \rangle}{\langle B^2 \rangle} = 0.25 \tag{20}
\]

to compute the slab and 2-D fluctuation energies from Equation \((19)\) and \(\langle b'^2 \rangle + \langle b'^2 \rangle = \langle B^2 \rangle\). In recent work
by [Hunana & Zank (2010)] and [Zank et al. (2017)], refinements to this simplified perspective on the breakdown of the slab and 2-D fluctuation energies are discussed. In particular, [Zank et al. (2017)] solve separate equations for the slab and 2-D energies with a simplified IMF and background solar wind flow. They find that the evolution of the two components is markedly different in the outer heliosphere (beyond \( \sim 3 \) AU), where driving by pickup ions leads to an increase in the slab component’s energy, while the energy of the 2-D component continues to decrease with heliocentric distance. Their results show, however, that the radial evolution of slab and 2-D energies is not too dissimilar below 3 AU. Similar results are presented by [Oughton et al. (2011)] using their two-component model. Therefore, for the purposes of our present work, where we focus on the inner heliosphere, our simple decomposition of \( \langle B^2 \rangle \) into slab and 2-D components, using the constant ratio expressed in Equation (20), seems appropriate. Studies of CR diffusion in the outer heliosphere would undoubtedly benefit from using a two-component turbulence transport model. A detailed assessment of different transport equations for turbulence is beyond the scope of this work.

4. RESULTS

4.1. Solar wind model results

We begin our presentation of the results with a discussion of the core fields from the simulation - \( B, \lambda \), and \( Z^2 \) - which are the ingredients that go into our calculation of the diffusion coefficients. Figure 1 shows the radial evolution of the turbulence energy and the turbulence correlation scale from our model with simulation and with an untilted dipole source. The data are for a 7° heliolatitude, which we take to be the broadly-defined ecliptic region. Also shown are observational results from Voyager 2, Helios, and the National Space Science Data Center (NSSDC) Omnitape dataset, indicating a reasonable agreement with the simulation results. The observational data for \( Z^2 \) and \( \lambda \) are from [Zank et al. (1996)] and [Smith et al. (2001)], respectively. Note that the observations are for various times in the solar cycle, and are shown here for general context only. The dashed vertical lines in Figure 1 represent the boundaries of the different simulation regions, with red marking the inner-intermediate region boundary at 21 AU, and blue marking the intermediate-outer region boundary at 45 AU, respectively. The solid lines are from our simulations. The different symbols represent different methods of calculation. The dashed vertical lines represent the boundaries of the different simulation regions, with red marking the inner-intermediate region boundary at 20 AU, and blue marking the intermediate-outer region boundary at 45 AU, respectively. Note that the observations are for various times in the solar cycle, and are shown here for general context only.

4.2. Radial evolution of mean free paths

In Figure 2, we show the radial evolution of the parallel, perpendicular, and radial mfps (black, red, and blue lines, respectively) in the ecliptic region (Figure 3a) and near the solar rotation axis (86° heliolatitude, Figure 3b), for an untilted source dipole. Also shown is the ratio of the perpendicular mfp to the parallel mfp (green lines). The solid, dotted, dashed, and dash-dotted lines correspond to \( p = -1, 0, 1, \) and 2, respectively, and the mfps are computed for protons with rigidity equal to 445 MV, corresponding to a kinetic energy of 100 MeV. Here we would like to remind the reader that our turbulence parameters \( (Z^2, \lambda) \) in the region \( 1 - 45 \) AU are not from the turbulence model, but are calculated using the approximations detailed in Section 3. As such, these results represent a preliminary attempt at mapping the diffusion length-scales in a region that will soon be investigated by upcoming spacecraft missions such as Solar Probe Plus.

Near the ecliptic plane (Figure 3a), as one moves outward from the solar surface, the increasing strength of the turbulence energy (see Figure 1) leads to a sharp decrease in \( \lambda \) in the region \( 2 - 5 \) AU, with the rapidly decreasing IMF reinforcing this behaviour. In this re-
region, $\lambda_\| \propto r^{-3.46}$, and there is a corresponding increase in $\lambda_\perp (\propto r^{-3.55}$ for $p = -1$ and $\propto r^{4.34}$ for $p = 2$). Since the IMF has a significant meridional component here, the large winding angle ($\Psi$) between the radial direction and the IMF leads to $\lambda_\perp$ having an influence on the radial mfp (see Equation 2), with $\lambda_{rr} \propto r^{-1.97}$. From $0.03 - 3$ AU, $\lambda_\|$ mostly increases as $r^{0.82}$, and $\lambda_\perp$ as $r^{0.79}$. From 0.1 to 3 AU, $\Psi$ is once again large because of the increased azimuthal component of the IMF, and $\lambda_\perp$ reduces the radial mfp, with $\lambda_{rr} \propto r^{0.53}$. Observational studies for $r < 3$ AU have found $\lambda_{rr} \propto r^b$ with $b$ ranging from $0.4 - 0.7$ (Beeck et al. 1987). Note that the radial mfp depends on the value of $p$ (through $\lambda_{rr}$), but the $\lambda_{rr}$ curves for different $p$ coincide.

Moving on to the radial evolution of the mfps in the polar region, Figure 3 shows that the radial mfp is completely dominated by $\lambda_\|$. This is because the IMF is near radial at the poles, with a very small winding angle. At the poles, $\lambda_{rr} \propto r^{-1.1}$ until 0.1 AU, after which it remains nearly constant, with identical behavior exhibited by $\lambda_\perp$. From $2 R_\odot$ to 0.2 AU, $\lambda_\| \propto r^{2.10}$ for $p = -1$ and $\lambda_\| \propto r^{2.34}$ for $p = 2$. From 0.2 - 3 AU, $\lambda_\| \propto r^{0.78}$ for $p = -1$ and $\lambda_\| \propto r^{0.69}$ for $p = 2$.

Figure 4 shows the effect of a source dipole with a $30^\circ$ tilt when one encounters the heliospheric current sheet (HCS) at around 1 AU: $\lambda_\| \propto r^{0.82}$ as $r$ goes through a sudden dip of almost two orders of magnitude, while $\lambda_\perp$ has a corresponding increase of around an order of magnitude. (The radius where the HCS crosses our chosen heliolatitude of $7^\circ$ depends on our choice of the azimuthal angle for which we plot results as a function of radius.) The vanishing mean magnetic field and non-vanishing turbulence amplitude at the HCS explain this behaviour, which will be further illustrated in the next subsection discussing the 2-D variation of the mfps in the meridional plane. We note from Figures 3 and 4 that the ratio $\lambda_\perp/\lambda_\|$ stays between 0.1 and 0.01 for most of the inner heliosphere, but it exceeds unity at the HCS. Keeping in mind that the current sheet is a singular region in our simulation, in its vicinity the fields do possess physically realizable values. Therefore we may stress the fact that similarly large values of $\lambda_\perp/\lambda_\|$ have been observed (Dwyer et al. 1997; Zhang et al. 2003). We will come across these domains of significant perpendicular diffusion once again in the meridional plane contours in Section 4.5, below.

In the results presented so far the choice of the long wavelength spectral index $p$ does not significantly alter the mfps, with $\lambda_\perp$ for $p = -1$ generally not more than a factor of two larger than $\lambda_\perp$ for $p = 2$. Referring to the discussion in Section 2.2, this result indicates a rather weak dependence of the mfps on the ultrascalar (via different $p$ values). The exception appears very close to the solar surface ($2 R_\odot$) in Figure 5, where the perpendicular mean free path for the $p = -1$ case is several times larger than that for the $p = 2$ case. This behaviour may be probed further in simulations with improved coronal turbulence models that are more reliable at such small heliocentric distances. In the following results, unless specified otherwise, we will choose $p = 2$, which corresponds to homogeneous turbulence.

In Figure 5 we examine the effect of varying the turbulence energy amplitude at the inner boundary ($45 R_\odot$) of the outer region of the simulation, again for 100 MeV protons. Such variation may arise due to solar activity. The solid lines represent a standard $Z^2$ specified at the inner boundary, and dashed and dotted lines represent simulations performed with double and half of this standard value specified at the inner boundary, respectively. In the ecliptic region ($7^\circ$ heliolatitude), Figure 5 indicates, as expected, that an increasing turbulence level leads to a decrease in $\lambda_\perp$ (and consequently $\lambda_{rr}$). The stronger turbulence increases $\lambda_\perp$ in proportion to $Z$, and therefore increases the extent to which particles may diffusively penetrate the heliosphere. Comparing Figures 5a and 5b, it is interesting to note that in the

**Figure 2.** Contour plots of the heliospheric magnetic field ($B$), the turbulence correlation scale ($\lambda$), and the turbulence energy ($Z^2$) in the meridional plane for an uniltled solar dipole. The figures on the left cover $2 - 45 R_\odot$, and the ones on the right cover $0.21 - 3$ AU ($45 - 645 R_\odot$).

elliptic region, varying turbulence at the inner boundary leads to an effect on \( \lambda_\parallel \) that becomes less pronounced with radial distance. This is not the case in the polar regions with fast wind, however, where the turbulence is less “aged” compared with low latitudes (Matthaeus et al. 1998). Stream interactions near the elliptic plane reduce the turbulence at a faster rate compared to the rate in the polar regions far from such shearing interactions.

We end this subsection by comparing our solutions in the elliptic plane with “consensus” constraints on observations (Palmer 1982; Bieber et al. 1994). Based on information compiled from several sources, the Palmer consensus finds that for particles in the rigidity range 0.5–5000 MV, \( \lambda_\parallel = 0.08 – 0.3 \) AU. We note here that the values for the mfps obtained by fitting observational data may depend on the model used. Reames (1999) reviews some such results and suggests a higher parallel mfp of \( \sim 1 \) AU. Our \( \lambda_\parallel \) for a 100 MeV proton at 1 AU varies from 0.29 – 0.40 AU, and fits the consensus range well. Our solutions are smaller than the values from Breech et al. (2008) and Pei et al. (2010), which we list in Table 1 along with our results. Here, cases 1, 2, and 3 refer to standard, doubled, and halved turbulence levels, as described above. Note that unlike our calculation of \( \lambda_\parallel \), the calculations from Breech et al. (2008) and Pei et al. (2010) depend on the value of \( p \).

Our improved agreement with the Palmer consensus range may be attributed to two improvements in modeling: (1) Here \( B \) is a spatially varying field computed dynamically from a self-consistent 3-D model, in contrast to the Parker-type model used in Breech et al. (2008) and Pei et al. (2010); (2) The effect of shear interactions is computed self-consistently in our turbulence model (Usmanov et al. 2014), unlike in Breech et al. (2008) and Pei et al. (2010), where a shear-driving parameter is employed.

4.3. Latitudinal evolution of mean free paths

Figure 3 shows the variation of mfps with latitude at different heliocentric distances for an untilted solar dipole. We see from Figure 3a that, in general, \( \lambda_\parallel \) (solid lines) increases by almost an order of magnitude as one leaves the solar equatorial plane and moves to higher latitudes, and assumes a near constant value as one approaches the polar regions. The opposite behaviour is seen for \( \lambda_\perp \) (dashed lines), which decreases on moving away from the equatorial plane. This is a combined result of the increase in the IMF strength and the correlation scale of the turbulence (\( \lambda \)) while moving away from the solar equatorial plane (i.e., away from the HCS), and the increase in the turbulence energy due to shear-interactions between slow and fast solar winds. We note that very close to the sun (4 \( R_\odot \), black line), \( \lambda_\parallel \) first decreases with latitude as one leaves the equatorial plane, then increases at higher latitudes, to values larger even than those seen at larger heliocentric distances. This behavior is because of the IMF increasing monotonically with latitude, close to the sun. At larger distances, the IMF plateaus with increasing latitude, and from 1 AU onwards it decreases in the polar regions (see Figure 2). Thus, particles experience less scattering in polar regions close to the sun. This also explains the latitudinal variation of \( \lambda_\parallel \) at 4 \( R_\odot \).

Figure 4 shows the increase in \( \lambda_\perp \) as one moves towards the polar regions, and illustrates once again the fact that while \( \lambda_\perp \) is affected by \( \lambda_\parallel \), very close to the sun at low latitudes, near the polar regions it follows the trend set by \( \lambda_\parallel \). Figure 4 shows that the ratio of \( \lambda_\perp \) to \( \lambda_\parallel \) decreases as one leaves the solar equatorial plane (i.e., away from the HCS), with the perpendicular mfp staying 1-2 orders of magnitude below the parallel mfp.
Figure 4. Radial dependence of the parallel (black), perpendicular (red), and radial (blue) mfps near the ecliptic plane (7° heliolatitude), with a solar dipole having a 30° tilt. For our particular choice of azimuthal angle (26°), an HCS crossing occurs at 0.8 AU. Also shown is $\lambda_{r}/\lambda_{l}$ (green). The solid lines are for $p = 0$, the dashed lines for $p = 1$, and the dash-dotted lines for $p = 2$. Proton rigidity is 445 MV (100 MeV kinetic energy).

except very close to the sun ($4 R_\odot$, black line) where it becomes 3 orders of magnitude smaller because of the low turbulence levels in that region. We will examine the latitudinal dependence of the mfps once again in meridional plane figures in Section 4.5, below.

4.4. Rigidity dependence of mfps

In Figure 7 we plot the rigidity ($P$) dependence of mfps for protons at different radial distances in the ecliptic and polar regions. Below 1 AU, $\lambda_\parallel \propto P^{0.33}$ for all rigidities considered here ($10 - 10^4$ MV). Above 1 AU there is a steepening of the slope for rigidities larger than $10^3$ MV. As noted in Section 2.1, this is due to high energy particles resonating with turbulent fluctuations in the energy containing range instead of the inertial range. As the IMF ($B$) decreases with heliocentric distance, a high rigidity particle’s Larmor radius ($R_L = P/Bc$) may become resonant with the correlation scale of the turbulence ($\lambda_\parallel$). When $R_L/\lambda_\parallel >> 1$, the expression in brackets in Equation (4) scales with rigidity as $P^{5/3}$, and we have $\lambda_\parallel \propto P^2$ instead of $\lambda_\parallel \propto P^{1/2}$. Indeed, for rigidities $\sim 10^4$ MV we find that $\lambda_\parallel \propto P^{1.2}$ at 1 AU and $\lambda_\parallel \propto P^{1.8}$ at 3 AU (See also the discussion on the effect of pickup ion driven turbulence on high-rigidity particles in the outer heliosphere in Zank et al. 1998). Our results agree well with the observations shown in Bieber et al. (1994), with power indices ranging from 0.2 to 0.56 for a number of solar events where rigidity ranges from 10 to $10^3$ MV. Our results also agree with the theoretical and numerical findings in Bieber et al. (1994) and Pei et al. (2010).

In general, $\lambda_\parallel$ shows lower variation with rigidity. In the polar regions $\lambda_\bot$ stays nearly constant with rigidity. This behavior is consistent with the finding of Bieber et al. (2004) that NLGC predicts a very weak rigidity dependence, and they note that this is supported by observations for rigidities between $10^2 - 10^4$ MV. Note that the rigidity profiles of $\lambda_\parallel$ and $\lambda_\bot$ that we derive from simulation results and diffusion theories are quite different from some that have been employed in the literature to model solar modulation of Galactic cosmic rays (e.g., see Figure 12 of Vos & Potgieter 2015).

4.5. Meridional plane contours

In this section, we describe the variation of $\lambda_\parallel$, $\lambda_\bot$, $\lambda_{rr}$, and $\lambda_{r}/\lambda_{l}$ in meridional planes for 100 MeV protons, complementing results of the previous sections. Figure 8 shows results from a simulation with a source magnetic dipole that is untilted with respect to the solar rotation axis. It is clear that at the HCS, with its vanishing magnetic field, perpendicular diffusion is comparable to parallel diffusion in most of the inner heliosphere, with $\lambda_\bot$ and $\lambda_{rr}$ both around 0.01 AU. In the broader ecliptic plane, however, $\lambda_\parallel$ remains 1-2 orders of magnitude above $\lambda_\bot$, varying from 0.01 to almost 1 AU within a radial distance of $10 R_\odot$ to 3 AU, while $\lambda_\bot$ increases from $\sim 0.0001$ to 0.01 AU. As noted in the 1-D plots, very close to the sun $\lambda_\parallel$ experiences a dramatic increase to

Figure 5. Radial dependence of the parallel (black), perpendicular (red), and radial (blue) mfps (a) near the ecliptic plane (7° heliolatitude) and (b) in the polar region (86°), for varying turbulence amplitudes, with $p = 2$. The dashed and dotted lines represent simulations with the turbulence energy ($Z^2$) at the inner boundary of the outer region ($45 R_\odot$) doubled and halved, respectively, relative to a standard level. See text for more details. Note that the curves for $\lambda_\parallel$ and $\lambda_{rr}$ coincide in (b).
Cosmic Ray Diffusion coefficients from 3-D SW simulation

Figure 6. The top panel (a) shows the latitudinal dependence of parallel (solid lines) and perpendicular (dashed lines) mfps. The middle (b) and bottom (c) panels show the latitudinal variation of $\lambda_{\|}$ and $\lambda_\perp / \lambda_{\parallel}$, respectively. All panels are for an untilted solar dipole and $p = 2$. Black, blue, green, and red lines represent radial distances of 0.02, 0.2, 1, and 3 AU (4, 45, 215, and 645 $R_\odot$), respectively. Proton rigidity is 445 MV (100 MeV kinetic energy).

Figure 7. Rigidity dependence of $\lambda_\parallel$ (solid line) and $\lambda_\perp$ (dashed line), (a) near the ecliptic plane (7° heliolatitude), and (b) in the polar regions (86° heliolatitude), for an untilted solar dipole and $p = 2$. Black, blue, green, and red lines represent radial distances of 0.02, 0.2, 1, and 3 AU (4, 45, 215, and 645 $R_\odot$), respectively. a value of 1 AU due to the weak turbulence and strong magnetic field prevailing there.

We also see that at radial distances of 1.5 – 3 AU, $\lambda_\|/\lambda_\parallel$ is a few times larger at lower latitudes, compared to values in polar regions. This is because the IMF decreases and the turbulence energy increases with latitude at these radial distances, leading to a reduction in parallel diffusion in the polar regions, and a corresponding increase in perpendicular diffusion. This can also be seen in Figure 8h showing contours of $\lambda_\perp / \lambda_{\parallel}$, which increases by nearly one order of magnitude from low latitudes to the poles. The radial mfp increases uniformly with heliocentric distance at lower latitudes, but is dominated by $\lambda_{\parallel}$ in polar regions, because of the small winding angle between the IMF and the radial direction here. This leads to $\lambda_{rr}$ acquiring a nearly constant value of around 0.2 AU in polar regions beyond 2 AU.

Figure 9 shows contour plots for mfps in the meridional plane at azimuthal angle equal to 26°, for a simulation with a source magnetic dipole that is tilted by 30° with respect to the solar rotation axis. In this case, solar rotation produces an asymmetrical magnetic field structure, which has a striking effect on the diffusion pa-
rparameters, with the displacement of the current sheet from the ecliptic plane modifying their distribution at low latitudes. Note that the blob-like structures in Figures 8 and 9 arise due to grid points coinciding with the HCS. The rapid decrease in the magnitude of the IMF near the HCS leads to the formation of the blob contours around grid points where B vanishes. This effect is not seen in Figure 8 for the untilted dipole case, where the HCS lies at 0° heliolatitude, where no grid points are present, by construction.

As noted previously in Section 4.2, observations indicate that the ratio $\lambda_\perp/\lambda_\parallel$ may approach, and even exceed unity. In our simulation, this happens in the HCS. The basic features described above for the untilted dipole are still present in this case, but are now organized with respect to the tilted HCS. During periods when solar activity levels are high, the warped current sheet is spread out across a larger portion of the heliosphere (Figure 9) compared with the low activity case (untitled dipole, Figure 8), and the HCS is thus more likely to influence CRs.

5. CONCLUSIONS AND DISCUSSION

We have presented a detailed analysis of the diffusion coefficients for cosmic ray transport in the inner heliosphere. The purpose is to use a well-tested, fully 3-D global simulation of the solar wind, with turbulence modeling, to obtain the heliospheric distribution of the large-scale heliospheric magnetic field, the energy in the turbulent fluctuations, and the correlation scale of the turbulence. This distribution has been coupled with a quasi-linear theory for parallel diffusion, and the recent random ballistic decorrelation interpretation of the non-linear guiding center theory for perpendicular diffusion. The present work extends previous studies on the heliospheric diffusion of cosmic rays by Bieber et al. (1993), Zank et al. (1998), and Pei et al. (2010), but has a stronger focus on the inner heliosphere, with the inner boundary of our simulations at $1 R_\odot$. Recent complementary work (Guo & Florinski 2016) carries out similar computations of diffusion coefficients for the outer heliosphere.

We find that at the heliospheric current sheet $\lambda_\perp$ can be greater than $\lambda_\parallel$, but usually $\lambda_\parallel$ is 1-2 orders of magnitude larger through most of the inner heliosphere. Very close to the sun ($2 R_\odot$), the strong IMF leads to a large value of $\lambda_\parallel$ ($\sim 0.5$ AU), which initially decreases for several solar radii before increasing with radial distance at low to intermediate latitudes, and becomes nearly constant at the polar regions. $\lambda_\perp$ increases with heliocentric distance throughout the inner heliosphere, and is larger in the polar regions compared to low latitudes. $\lambda_\perp$ is dominated by $\lambda_\parallel$ through most of the inner heliosphere. However, $\lambda_\perp$ does affect $\lambda_\perp$ in parts of the near-ecliptic region. Our estimations of $\lambda_\parallel$ near the ecliptic plane at 1 AU show good agreement with the Palmer consensus range of 0.08 – 0.3 AU.

At heliocentric distances below 1 AU, we find that the parallel mfp varies with rigidity as $P^{-0.33}$ for all rigidities considered here ($10 - 10^4$ MV). Above 1 AU, highly energetic particles begin to resonate with turbulent fluctuations in the energy containing scales, and the rigidity dependence of $\lambda_\parallel$ steepens. The perpendicular mfp is weakly dependent on rigidity. Our results on the rigidity dependence of mfps are consistent with observations.

The mfps are found to be weakly dependent on the type of power spectrum used to represent the large scale fluctuations. This suggests that any attempts to use spacecraft observations of mfps to infer constraints on the ultrascale would be challenging. The effects of solar activity (via a tilted solar dipole and variations of turbulence levels) are also studied, with increased activity leading to stronger perpendicular diffusion and weaker parallel diffusion.

The model we have adopted for turbulence transport has been thoroughly studied and tested (Breech et al. 2008). More elaborate models, with more transport equations (and more free parameters) are available (Zank et al. 2012). In particular, these models include extensions such as dynamically variable residual energy, separate transport equations for slab and 2-D fluctuations, and as many as three distinct dynamically evolving correlation lengths (Oughton et al. 2011; Zank et al. 2017). For the present we forgo the associated additional complication and rely on the present model’s ability to account very well for a variety of observations (Usmanov et al. 2011, 2012, 2014).

We also remark that the turbulent fluctuations we follow dynamically are the quasi-two dimensional fluctuations that we assume are energetically dominant. A variety of studies (Matthaeus et al. 1990; Zank & Matthaeus 1993; Bieber et al. 1994, 1996) are consistent with dominance by quasi-2D turbulence in solar wind turbulence. In the present approach we assumed that the quasi-slab component of the fluctuations, which represent perhaps 20% of the total fluctuation energy, are a constant fraction of the turbulence energy. Useful extensions have been presented by Oughton et al. (2011); Zank et al. (2017) that adopt somewhat different approaches with the common goal of independently transporting both 2-D and slab-like fluctuations. As noted above, these models find that the radial evolution of 2-D and slab fluctuation energies is not too dissimilar in the inner heliosphere, and therefore our decomposition of the total turbulence energy into slab and 2-D components using a constant ratio appears reasonable. These models also show that in the outer heliosphere (above 3-4 AU), the energy in the slab fluctuations increases with heliocentric distance due to driving by pickup ions, while the 2-D fluctuation energy continues to decrease. As such, studies of CR diffusion in the outer heliosphere would undoubtedly benefit from using a two-component turbulence transport model.

Such models have been implemented (Wiengarten et al. 2016; Shiota et al. 2017), with many differences relative to the present model. For example, the Shiota et al. (2017) model has a more elaborate transport formalism, as described above, but neglects the impact of turbulence on the background flow and relies on ad-hoc shear terms instead of fully coupling to the large-scale solar wind solutions. In contrast, we employ a dynamic eddy-viscosity model (Usmanov et al. 2014) to achieve this coupling. Clearly no model at present is a complete treatment, and there are advantages and trade-offs in various approaches. We hope to advance our own model with additional refinements in the near future.

We anticipate that 3-D calculations of the CR diffusion coefficients in the way we have demonstrated here, employing large scale solar wind solutions with turbulence transport and turbulence modeling, will become in-
creasingly important for realistic energetic particle transport calculations in the future. We also note that related types of diffusion coefficients, such as drag or self-diffusion, may be similarly estimated using adaptations of the above approach, as described briefly in the Appendix. Studies of phenomena such as shock-ensembles and super-events \cite{Mueller-Melin1986, Kunow1991}, where several shocks merge to influence energetic particle transport at widely separated locations, would benefit enormously from such 3-D studies in model heliospheres. Our findings of domains where $\lambda_\perp/\lambda_\parallel \geq 1$ may be used to further study the effects of significant perpendicular diffusion, which has been seen to reduce the SEP flux and make it more uniform \cite{Zhang2009}. Additional development at the MHD level will be needed to utilize this kind of tool for explaining observed SEP events associated with transient phenomena such as flares, CMEs and interplanetary shocks \cite{Ruifolot2006, Droeget2016, Aguera2016}. In the present paper we have not undertaken specific calculations employing the diffusion coefficients we obtained using a global model; this is deferred to future work. We anticipate that this approach will be useful in understanding Solar Probe Plus observations of energetic particles near the Sun.

As we have now demonstrated that such an approach can provide detailed three dimensional information concerning both MHD transport and particle mean free paths, it becomes clear that what will be needed are improved methods for driving this kind of model with more sophisticated and detailed solar observations. Meanwhile, we are continuing to improve our MHD modeling by building a coronal module that includes a full turbulence transport model, and by further developing the eddy viscosity approach \cite{Usmanov2014}. Future work could also investigate the influence of drifts on CR modulation. To facilitate use of the present data from this model for particle transport calculations of relevance to the current generation energetic particle and Space Weather studies, we are uploading as Supplementary Material the 3-D grids of the diffusion coefficients that were described here.

6. APPENDIX

Here we present an estimation of a general turbulent diffusion coefficient that is based on Taylor’s formulation of the problem \cite{Taylor1922}. The diffusion coefficient for the passive transport of any quantity in a turbulent neutral fluid may be approximated by \cite{Choudhuri1998}

$$D_T \approx \frac{1}{3} \langle v^2 \rangle \tau_{\text{cor}},$$

(21)

where $\langle v^2 \rangle$ is the mean square turbulent velocity and $\tau_{\text{cor}}$ is the correlation time of the turbulence. By assuming $\langle v^2 \rangle \sim Z^2$, and defining the turbulence correlation length $\lambda \sim Z \tau_{\text{cor}}$, we rewrite the above equation as

$$D_T \propto Z \lambda.$$  

(22)

Note that any standard diffusion coefficient, drag coefficient, eddy viscosity, or other similar quantity can be expressed in a form similar to Equation (22), i.e., as a product of a characteristic velocity and a length scale (see, for example, Tennekes & Lumley \cite{1972}).

In Figure 10 we show contour plots for $D_T$ in the meridional plane, computed from a simulation with a solar dipole that is untitled with respect to the solar rotation axis. We may interpret $D_T$ as a turbulent drag coefficient, which is of relevance to the propagation of CMEs in the solar wind. At high heliolatitudes, the drag coefficient increases from the solar surface to 0.5 AU, and then gradually decreases. Notably, at heliocentric distances smaller than 0.5 AU, $D_T$ increases by an order of magnitude in moving from the ecliptic to polar regions. This implies that a CME would be “channelled” to lower latitudes as it propagates through the inner heliosphere. Applications involving these more general approximations to diffusion processes may also be enabled by the approach described in the present paper.

This research is partially supported by NASA grant NNX14A163G (Heliophysics Grand Challenges Research), NASA IWS grants NNX15AB88G and NNX13AR42G, and the Solar Probe Plus mission through the ISOIS project and SWRI subcontract D9031L, and the Thailand Research Fund (grant RTA5980003). The authors would like to thank the anonymous Referee for their thorough reading of the manuscript and useful suggestions for its improvement.
