On the equivalence between multiclass processor sharing and random order scheduling policies

ABSTRACT
Consider a single server system serving a multiclass population. Some popular scheduling policies for such system are the discriminatory processor sharing (DPS), discriminatory random order service (DROS) and GPS and weighted fair queueing (WFQ). In this paper, we propose two classes of policies, namely MPS (multiclass processor sharing) and MROS (multiclass random order service), that generalize the four policies mentioned above. For the special case when the multiclass population arrive according to Poisson processes and have independent and exponential service requirement with parameter \( \mu \), we show that the tail of the sojourn time distribution for a customer is a constant multiple of the tail of the waiting time distribution of a customer in a system with the MPS policy. This result implies that for a class \( i \) customer, the tail of the sojourn time distribution in a system with the GPS (PS) scheduling policy is a constant multiple of the tail of the waiting time distribution in a system with the DROS (respectively WFQ) policy.

1. INTRODUCTION
Consider a single server system with multiclass customers. Some commonly used scheduling policies in such multiclass system are DPS, DROS, GPS and WFQ. A quick overview of these policies is as follows. Policies like GPS and DPS are variants of the processor sharing policy where the server can serve multiple customers from the system simultaneously. In case of GPS, a separate queue is maintained for each customer class and the total service capacity of the server is shared among customers of the different classes in proportion to predefined weights \( p_i \). The GPS scheduling policy is often considered as a generalization of the head-of-line processor sharing policy (HOLPS) as described in [8] [10] [17]. (Refer [18] [19] for details about HOLPS). As a generalization of HOLPS, GPS maintains a FIFO scheduling policy within the queue of each class and only the head-of-line customers of different classes are allowed to share the processor. The share of the server for a head-of-line Class \( i \) customer is proportional to the weight \( p_i \) and is independent of the number of other customers in the queue. The service rate received by the customer is precisely given by \( \sum_{j=1}^{N} p_j \phi_j \) where \( \phi_j = 1 \) if the queue has at least one class \( j \) customer and \( \phi_j = 0 \) otherwise. Refer Parekh and Gallager [13], Zhang et al. [14] for an early analysis of the model.

In case of DPS, the total service capacity is shared among all the customers present in the system and not just among the head-of-line customers of different classes. The share of the server for a customer of a class is not only in proportion to the class weight, but also depends on the number of multiclass customers present in the queue. In particular, a Class \( i \) customer in the system is served at a rate of \( \frac{p_i}{\sum_{j=1}^{N} p_j n_j} \) where \( n_j \) denotes the number of Class \( j \) customers in the system. The DPS system was first introduced by Kleinrock [7] and subsequently analyzed by several authors [8] [15] [10] [9] [11]. See [4] for a survey of various results on DPS.

The DROS and WFQ scheduling policies are also characterized by an associated weight for each customer class. However these policies are not a variant of the processor sharing policies and hence their respective server can only serve one customer at a time. The DROS and WFQ policies differ in their exact rule for choosing the next customer. In the DROS policy, the probability of choosing a customer for service depends on the weights and the number of customers of the different classes in the queue. A Class \( i \) customer is thus chosen with a probability of \( \frac{p_i}{\sum_{j=1}^{N} p_j n_j} \) where \( n_j \) denotes the number of Class \( j \) customers waiting in the system for service. DROS policy is also known as relative priority policy and was first introduced by Haviv and van der Wal [9]. For more analysis of this policy we refer to [9] [12]. In the WFQ policy, a separate queue for each class is maintained and the next customer is chosen randomly from among the head-of-line customers of different classes. As in case of the GPS scheduling policy, a FIFO scheduling policy is used within each queue for a class. WFQ can be seen as a packetised version of GPS and the probability of choosing a head-of-line Class \( i \) customer for service is given by \( \frac{p_i}{\sum_{j=1}^{N} p_j \phi_j} \) where \( \phi_j \) is as defined earlier. Refer Demers [16] for the detailed analysis of the WFQ policy.

It is interesting to note that for a Class \( i \) customer, the service rate received in DFS and the probability of being chosen next for service in case of DROS is given by \( \frac{p_i}{\sum_{j=1}^{N} p_j n_j} \). Similarly, the service rate received in GPS and the probability of being chosen next for service in case of WFQ is \( \frac{p_i}{\sum_{j=1}^{N} p_j \phi_j} \).

This similarity in the scheduling rules motivates us to compare the tail of the waiting time and sojourn time distributions of the multiclass customers with these scheduling policies. Assuming identically distributed service requirements for all customers, we will show that the tail of the
waiting time distribution of a Class $i$ customer in a system with DROS (WFQ) scheduling policy is $\rho$ times the tail of the sojourn time distribution of any Class $i$ customer with FPS (resp. GPS) scheduling policy. This is a generalization of [4], where the equivalence has been established between single-class processor sharing and random order service discipline.

**Organization:** In the next section, we introduce a generalized notion of multiclass processor sharing (MPS) and random order service (MROS) policies. The FPS, GPS, DROS and WFQ policies will turn out to be special cases of MPS and MROS. In Section 3, we show that the tail of the sojourn time distribution of a Class $i$ customer with MPS scheduling is equivalent to the tail of the waiting time distribution of a Class $i$ customer with MROS policy. As a special case, this proves the mentioned equivalences among the four multiclass scheduling policies.

**Notation:** We use $N$ to denote the total number of customer classes in the system. Let $\lambda_i$ denote the arrival rate for a Class $i$ customer, $i = 1 \ldots N$. Let $\lambda = (\lambda_1, \ldots, \lambda_N)$ and $\rho = (\rho_1, \ldots, \rho_N)$. Further, let $p_i$ denote a weight parameter associated with a Class $i$ customer.

**Assumptions:** We assume that the service requirement of each customer is independent and exponentially distributed with rate $\mu$. Thus the service requirements are independent of their class. We also assume that customers from different classes arrive according to independent Poisson processes. For the purpose of stability, we assume that $\Lambda < \mu$.

**2. GENERALIZED MULTICLASS SCHEDULING POLICIES**

In this section, we will describe two multiclass scheduling policies that are a generalization of policies such as FPS, DROS, GPS and WFQ. The two policies are based on the processor sharing and random order service mechanism and will be labeled as MPS and MROS respectively.

The MPS scheduling policy is a multiclass processor sharing policy where the server can serve multiple customers simultaneously. A separate queue for each customer class is maintained and a FIFO scheduling policy is used within each queue of a class. The MPS scheduling policy is parameterized by a vector $\alpha = (\alpha_1, \ldots, \alpha_N)$ that characterizes the maximum permissible number of customers of each class that can be served simultaneously with other customers.

We shall henceforth use the notation $\text{MPS}(\alpha)$ when we talk about an MPS policy with parameter $\alpha$. Let $n_i$ denote the instantaneous number of Class $i$ customers in the queue and $\bar{n} := (n_1, \ldots, n_N)$ denotes the corresponding state in the MPS system. Let $\beta_i(\bar{n})$ denote the number of Class $i$ customers under service when the state of the MPS system is $\bar{n}$. Then, clearly $\beta_i(\bar{n}) = \min(n_i, \alpha_i)$. In other words, if $n_i \leq \alpha_i$, then all the Class $i$ customers present in the queue are being served simultaneously for $i = 1, \ldots, N$. However if $n_i > \alpha_i$, then only the first $\alpha_i$ customers of Class $i$ in its queue are served simultaneously. It should be noted that due to the FIFO policy within each queue of a class, only the first $\beta_i(\bar{n})$ customers in the queue are served at any time. To lighten some of the notation, we shall drop the dependence on $\bar{n}$ and use only $\beta_i$ when the context is clear. For an $\text{MPS}(\alpha)$ scheduling policy in state $\bar{n}$, the service rate received by a particular Class $i$ customer which is in service is given by $\frac{p_i}{\sum_{j=1}^{N} p_j \beta_j}$. When $\alpha_i = \infty$, for $i = 1 \ldots N$, the corresponding scheduling policy will be denoted by $\text{MPS}(\infty)$. In this case, $\beta_i = \min(n_i, \alpha_i) = n_i$ and therefore $\text{MPS}(\infty)$ corresponds to the FPS scheduling policy. Similarly if $\bar{c} = (1, \ldots, 1)$, then $\text{MPS}(\bar{c})$ corresponds to the GPS scheduling policy where only the head-of-line customers of each class can be served.

In a similar manner, we can define the $\text{MROS}(\alpha)$ scheduling policy where $\alpha = (\alpha_1, \ldots, \alpha_N)$ denotes the vector of multiclass customers from which the subsequent customer is chosen for service. As in case of the MPS policy, note that a separate FIFO queue for each customer class is also maintained for the MROS system. At any given time, the first $\beta_i = \min(n_i, \alpha_i)$ customers are candidates for being chosen for service while the remaining $n_i - \beta_i$ customers have to wait for their turn. Note that the state $\bar{n}$ for an $\text{MROS}(\alpha)$ scheduling policy denotes the vector of waiting multiclass customers present in the system. In the $\text{MROS}(\alpha)$ system, a Class $i$ customer within the first $\beta_i$ customers in its queue will be chosen next for service with probability $\frac{p_i}{\sum_{j=1}^{N} p_j \beta_j}$.

As in case of the MPS scheduling, $\text{MROS}(\infty)$ corresponds to the DROS policy whereas $\text{MROS}(\bar{c})$ corresponds to the WFQ policy.

**Remark 1.** A policy closely related to the FPS discipline is the limited processor sharing (LPS) policy. LPS is a single class processor sharing policy parametrized by an integer $c$ where $c$ denotes the maximum number of customers that can be served simultaneously. Here $c = \infty$ corresponds to the processor sharing policy while $c = 1$ corresponds to FCFS policy. LPS can also be viewed as a special case of the FPS policy when there is a single service class for the arriving customers. See [2, 20] more more details about the LPS-c policy.

Having introduced the generalized multiclass scheduling policies, we shall now establish an equivalence relation between the tail of the sojourn time distribution of a Class $i$ customer in MPS system with the tail of the waiting time distribution of a Class $i$ customer in MROS system.

**3. COMPARING THE SOJOURN AND WAITING TIME DISTRIBUTIONS IN MPS AND MROS**

The analysis in this section is inspired from that in [4] where a similar result is established for the case of a single class of population. For a given state of $\bar{n} = (n_1, \ldots, n_N)$, define $n := \sum_{i=1}^{N} n_i$. Let random variable $S_i(\bar{n}, \bar{n})$ denote the conditional sojourn time experienced by an arriving Class $i$ customer that sees the $\text{MPS}(\bar{\alpha})$ system in state $\bar{n}$. The corresponding unconditional random variable will be denoted by $S_i(\bar{\alpha})$. We shall occasionally use the notation $\text{MPS}(\bar{\alpha})$ to denote the $\text{MPS}(\bar{\alpha})$ system with $n$ customers. Along similar lines, let the random variable $W_i(\bar{n}, \bar{n})$ denote waiting time (time until chosen for service) experienced by an arriving Class $i$ customer that sees the $\text{MROS}(\bar{\alpha})$ system in state $\bar{n}$, i.e., it sees a vector of $n$ waiting customers in the system. This system will be often denoted as $\text{MROS}(\bar{n}, \bar{n})$ and the unconditional random variable will be denoted by $W_i(\bar{\alpha})$. Let $P$ and $P'$ denote the probability distribution of the random variables $S_i(\bar{n}, \bar{n})$ and $W_i(\bar{n}, \bar{n})$ respectively.
Now let random vectors \( N^{\text{MPS}} \) (resp. \( N^{\text{MROS}} \)) denote the vector of multiclass customers present in the system in steady state (resp. waiting in the system in steady state in MROS). The subscript 1 in \( N^{\text{MROS}} \) is used to indicate a busy server. Since the arrival process is Poisson, the unconditional probabilities are given by the following

\[
P(S_i(\hat{n}) > t) = \sum_{\hat{n}} P(N^{\text{MPS}} = \hat{n}) P(S_i(\hat{n}, n) > t).
\]

Similarly, we have

\[
P(W_i(\hat{n}) > t) = \sum_{\hat{n}} P(N^{\text{MROS}} = \hat{n}) P(W_i(\hat{n}, n) > t).
\]

Now if \( P(N_1^{\text{MROS}} = \hat{n}) = \rho P(N^{\text{MPS}} = \hat{n}) \) is true, then from Eq. (4), the statement of the theorem follows and this would complete the proof. In the following lemma, we shall prove that indeed \( P(N_1^{\text{MROS}} = \hat{n}) = \rho P(N^{\text{MPS}} = \hat{n}) \).

**Lemma 1.** \( P(N_1^{\text{MROS}} = \hat{n}) = \rho P(N^{\text{MPS}} = \hat{n}) \) for \( \hat{n} \) such that \( |\hat{n}| \geq 0 \).

**Proof.** We first simplify the notations as follows. Let \( \pi(\hat{n}) := P(N^{\text{MPS}} = \hat{n}) \) and \( \pi_1(\hat{n}) := P(N_1^{\text{MROS}} = \hat{n}) \). Let \( \pi(0, 0) \) denote the probability that the MROS system has no customers and is idle. The statement of the lemma now requires us to prove that \( \pi(1, \hat{n}) = \rho \pi(\hat{n}) \). To prove this result, consider the balance equation for the MROS system where \( \pi \) shall denote the stationary invariant distribution for the system. The assumption \( \Lambda < \mu \) implies that the underlying Markov process is ergodic and hence the stationary distribution \( \pi \) is unique. For \( \hat{n} \) such that \( |\hat{n}| \geq 0 \), the global balance equations for the MPS(\( \hat{n} \)) system are

\[
(\Lambda + \sum_{i=1}^{N} \left( \frac{\beta_i(\hat{n}) p_i}{\sum_{j=1}^{N} p_j \beta_j(\hat{n})} \right) \mu \mathbb{1}_{(|\hat{n}| > 0)} \pi(\hat{n}) 
= \sum_{i=1}^{N} \lambda_i \mathbb{1}_{(n_i > 0)} \pi(\hat{n} - e_i) 
+ \sum_{i=1}^{N} \left( \frac{\beta_i(\hat{n} + e_i) p_i}{\sum_{j=1}^{N} p_j \beta_j(\hat{n} + e_i)} \right) \mu \pi(\hat{n} + e_i).
\]

Now since

\[
\sum_{i=1}^{N} \frac{\beta_i(\hat{n}) p_i}{\sum_{j=1}^{N} p_j \beta_j(\hat{n})} = 1,
\]

the balance equations can be written as

\[
(\Lambda + \mu \mathbb{1}_{(|\hat{n}| > 0)} \pi(\hat{n}) = \sum_{i=1}^{N} \lambda_i \mathbb{1}_{(n_i > 0)} \pi(\hat{n} - e_i) 
+ \sum_{i=1}^{N} \left( \frac{\beta_i(\hat{n} + e_i) p_i}{\sum_{j=1}^{N} p_j \beta_j(\hat{n} + e_i)} \right) \mu \pi(\hat{n} + e_i).
\]

Similarly, the global balance equations for the MROS(\( \hat{n} \)) system are as follows for \( \hat{n} \) such that \( |\hat{n}| \geq 0 \).
\[(\Lambda + \mu I_{(|\hat{n}| > 0)} ) \hat{\pi}(1, \bar{n}) = \sum_{i=1}^{N} \lambda_i I_{(n_i > 0)} \hat{\pi}(1, \bar{n} - e_i) + \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n} + e_i) p_i}{\sum_{j=1}^{N} p_j \beta_j(\bar{n} + e_i)} \right) \mu \hat{\pi}(1, \bar{n} + e_i) \quad (6)\]

Additionally, the idle system should satisfy
\[\Lambda \hat{\pi}(0, \bar{0}) = \mu \hat{\pi}(1, \bar{0}) \quad (7)\]

where \(\hat{\pi}(0, \bar{0}) = 1 - \rho\) is the probability that the system is empty. Now, again, the assumption \(\Lambda < \mu\) implies that the underlying Markov process is ergodic and hence the stationary distribution \(\hat{\pi}\) is also unique. Therefore to prove the lemma, it is sufficient to check if the global balance equations for the MROS system given by Eq. (6) are satisfied when \(\hat{\pi}(1, \bar{n}) = \rho \pi(\bar{n})\).

Now from Eq. (6) and assuming that \(\hat{\pi}(1, \bar{n}) = \rho \pi(\bar{n})\), we have
\[\Lambda \hat{\pi}(0, \bar{0}) - \mu \hat{\pi}(1, \bar{0}) = \Lambda \hat{\pi}(0, \bar{0}) - \mu \rho \pi(\bar{0}) = \mu (\rho \hat{\pi}(0, \bar{0}) - \rho \pi(\bar{0})) = \mu (\rho \hat{\pi}(0, \bar{0}) - \rho (1 - \rho)) = 0. \quad (8)\]

The last equality follows from Eq. (8) after dividing throughout by \(\rho\). Similarly,
\[\Lambda \hat{\pi}(0, \bar{0}) - \mu \hat{\pi}(1, \bar{0}) = \Lambda \hat{\pi}(0, \bar{0}) - \mu \rho \pi(\bar{0}) = \mu (\rho \hat{\pi}(0, \bar{0}) - \rho \pi(\bar{0})) = \mu (\rho \hat{\pi}(0, \bar{0}) - \rho (1 - \rho)) = 0. \quad (8)\]

Here the third equality is from the fact that \(\pi(\bar{0}) = (1 - \rho)\) is the probability that the MPS(\(\bar{n}\)) system is empty. Clearly, substituting \(\hat{\pi}(1, \bar{n}) = \rho \pi(\bar{n})\), satisfies the balance equations for the MROS system. Since \(\hat{\pi}\) is the unique invariant distribution, the statement of the lemma follows.

We now have the following corollary that establishes the desired equivalence between DPS (GPS) and DROS (resp. WFQ) scheduling policies. Note that the result is true only for the case when all customers have identically distributed service requirements. The equivalence result is not true in general when the customer classes differ in their service requirements.

**Corollary 1.**

\[\rho P(\mathbf{S_i}(\infty) > t) = P(\mathbf{W_i}(\infty) > t)\]

where \(\mathbf{S_i}(\infty)\) denotes the sojourn time of a Class \(i\) customer in GPS system and \(\mathbf{W_i}(\infty)\) denotes the waiting time of a Class \(i\) customer in WFQ system.

### 4. DISCUSSION

In this paper, we have proposed two multiclass policies, namely MPS and MROS, that generalize some important multiclass policies from the literature. Our policies are parameterized by a vector $\bar{\alpha}$ that can be used to control performance metrics like the mean delay or mean waiting time per class. Restricting to the special case where the multi-class customers arrive according to a Poisson process and have independent and exponential service requirements, we show that the tail of the sojourn time distribution for a class $i$ customer in a system with the MPS policy is a constant multiple of the tail of the waiting time distribution of a class $i$ customer in a system with the MROS policy. As special cases, we have thus proved the above equivalence between DPS (GPS) and DROS (resp. WFQ) scheduling policies.

It is worth mentioning that Borst et al [4] have shown the sojourn time equivalence between ROS and processor sharing for a more general case when the arrival process is a general renewal process. While our analysis for MPS and MROS assumes a Poisson arrival process, it would be of interest to investigate if our equivalence result is true when the arrival process is a general renewal process. This is part of future work.
