ABSTRACT

Context. RadioAstron is a 10 m orbiting radio telescope mounted on the Spektr-R satellite, launched in 2011, performing Space Very Long Baseline Interferometry (SVLBI) observations supported by a global ground array of radio telescopes. With an apogee of ~350 000 km, it is offering for the first time the possibility to perform mm-resolution imaging in the cm-band.

Aims. The RadioAstron Active Galactic Nuclei (AGN) polarization Key Science Project (KSP) aims at exploiting the unprecedented angular resolution provided by RadioAstron to study jet launching/collimation and magnetic-field configuration in AGN jets. The targets of our KSP are some of the most powerful blazars in the sky.

Methods. We present observations at 22 GHz of 3C 273, performed in 2014, designed to reach a maximum baseline of approximately nine Earth diameters. Reaching an angular resolution of 0.3 mas, we study a particularly low-activity state of the source, and estimate the nuclear region brightness temperature, comparing with the extreme one detected one year before during the RadioAstron early science period. We also make use of the VLBA-BU-BLAZAR survey data, at 43 GHz, to study the kinematics of the jet in a ~1.5-year time window.

Results. We find that the nuclear brightness temperature is two orders of magnitude lower than the exceptionally high value detected in 2013 with RadioAstron at the same frequency (1.4x10^30 K, source-frame), and even one order of magnitude lower than the equipartition value. The kinematics analysis at 43 GHz shows that a new component was ejected ~2 months after the 2013 epoch, visible also in our 22 GHz map presented here. Consequently this was located upstream of the core during the brightness temperature peak. Fermi-LAT observations for the period 2010-2014 do not show any γ-ray flare in conjunction with the passage of the new component by the core at 43 GHz.

Conclusions. These observations confirm that the previously detected extreme brightness temperature in 3C 273, exceeding the inverse Compton limit, is a short-lived phenomenon caused by a temporary departure from equipartition. Thus, the availability of interferometric baselines capable of providing mm angular resolution does not systematically imply measured brightness temperatures over the known physical limits for astrophysical sources.

Key words. galaxies: active; galaxies: jets; galaxies: magnetic fields

1. Introduction

More than 50 years have passed since Maarten Schmidt’s discovery of the first quasi-stellar object: 3C 273 (Schmidt1963). Later classified as Flat Spectrum Radio Quasar (FSRQ), and thus belonging to the blazar population, it presents a strong and structured jet in the mm/cm band, with a viewing angle of 5-11 degrees (Liu & Shen2009), that dominates the emission up to the...
Recently, [Kovalev et al. 2016] found an extremely high brightness temperature for 3C 273, using non-imaging observations at 22 GHz from the AGN-survey KSP. In the period Dec. 2012 - Feb. 2013, values in excess of $10^{13}$ K were measured, thus again larger than the theoretical limit imposed by inverse Compton cooling. The maximum baseline reached by the experiment was 171 000 km. RA can probe structures at a resolution never achieved before, finding brightness temperature values that challenge our understanding of non-thermal emission in AGN.

This work is the first of two papers presenting observations of 3C 273 carried out in the context of the RA AGN polarization KSP. Here we focus on observations at 22 GHz, and the comparison with the results from [Kovalev et al. 2016], while 1.6 GHz observations will be presented in a future paper.

For a flat Universe with $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$, and $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$ [Planck Collaboration et al. 2014], 1 mas corresponds to 2.729 pc at the redshift of 3C 273 ($z = 0.158$).

2. Observations and data processing

The source was targeted twice during AO-1 in the framework of the AGN polarization KSP, with a global ground array plus RA. In the following, details about data correlation and calibration are given.

22 GHz observations

A global ground array of 22 antennas was used to perform observations, including VLBA (Sc, Hn, Ni, Fd, La, Kp, Pt, Ov, Br, Mk), EVN (Hh, Mc, Nt, Tr, Jb, Ef, Ys), Long Baseline Array (-LBA- At, Mp, Ho, Cd), and two Kvaraz antennas ( Sv, Zc), plus Kalyazin (managed by ASC, Russia), and Green Bank (NRAO, USA). The observations took place on January 18-19, 2014, for a total of 16.8 hours, and at three different frequencies: 15 GHz, 22 GHz, and 43 GHz. RA was involved only for the 22 GHz part, while for the other bands only the VLBA was used. Both the Green Bank and Pushchino tracking station took part in the experiment. A RA-compatible total bandwidth of 32 MHz, split into two 16-MHz IFs, was used. RA was scheduled to observe three consecutive 9.5 minute scans every 1.25 hours, to allow for antenna cooling. The maximum projected space-baseline reached during the experiment was $\sim 9$ G$\lambda$ ($\sim 117,000$ km, $\sim 9$ Earth diameters). Fig. 1 reports the scheduled UV coverage, as well as the one giving fringes with RA in the inset. Effelsberg was also used in single-dish mode, to perform total flux density and polarimetry measurements of the target and calibrators from January 10 to 28, 2014, at 5, 10, and 22 GHz.

Data processing and reduction

Correlation was performed at the MPIfR-Bonn correlator, using the ra version of DiFX for space-VLBI [Deller et al. 2011; Bruni et al. 2016]. Fringe searching for RA was attempted for every scan, covering the entire duration of the experiment, in order to optimize the centering of the correlation window. A suitable reference antenna was used depending on the available arrays (ATCA for the LBA, Effelsberg for the EVN, Green Bank for VLBA). Fringes with RA with a signal-to-noise ratio (SNR) above 10 were found only for the last hour of the experiment, when the spacecraft was near to perigee. In fact, 3C 273 had a flux density historical minimum across the observations (see Sect. 4.2). This resulted in a maximum baseline for space-VLBI detections of $\sim 1$ G$\lambda$. 

Article number, page 2 of 9
3.1. Brightness temperature estimate

The emission from the central region was modeled in Difmap to extract the flux density and linear size of the fitted Gaussian components (see Fig. 3). The extracted values are given in Table 1. The observed brightness temperature \( T_{\text{b,obs}} \) at a certain wavelength \( \lambda \) (cm) can be estimated from the measured flux density \( S \) (Jy) and size \( \theta \) (mas) of a circular Gaussian component, using the following formula (e.g., Gómez et al. 2016):

\[
T_{\text{b,obs}} = 1.36 \times 10^9 \frac{S^2}{\rho \lambda} \quad [\text{K}],
\]

and it is related to the intrinsic brightness temperature \( T_{\text{b,int}} \) of the source via the following formula:

\[
T_{\text{b,int}} = \frac{T_{\text{b,obs}}(1 + z)}{\delta} \quad [\text{K}],
\]

where \( \delta \) is the Doppler factor of the source (derived from the jet speed), estimated from variability or kinematics analysis, and \( z \) is the redshift. For 3C 273, \( z = 0.158 \), while \( \delta \) has been estimated to be \( \leq 13 \) by Jorstad et al. (2005). For our calculation, we consider the maximum value (\( \delta = 13 \)), resulting in a minimum value for our \( T_{\text{b,int}} \) estimate. The obtained values are shown in Table 1. The uncertainties for size, flux density, and position of the components have been calculated following Jorstad et al. (2005). These values are well below the one imposed by the inverse Compton cooling limit \( (10^{11} \text{ K}) \), and for the core (A) even one order of magnitude lower than the typical value in equipartition conditions \( (5 \times 10^{10} \text{ K}) \). This indicates that the source is in an exceptionally low-activity state.

We want to stress that this estimate is not limited by baseline length - and thus angular resolution - since the maximum space-baseline of the experiment was \( \sim 9 \text{ G } \lambda \), that is, comparable (even larger) to the one that led to the extreme brightness temperature measured at the same frequency by Kovalev et al. (2016) \( (7.6 \text{ G } \lambda) \). The fact that fringes are not detected at more than \( \sim 1 \text{ G } \lambda \) on RA baselines is then caused by the effective low flux density from the source in such a low-activity state.

3.2. Kinematics analysis from VLBA-BU-BLAZAR data

We also performed the analysis of VLBA data at 43 GHz taken from the VLBA-BU-BLAZAR program in the observing period between October 2012 and June 2014. To compare epochs among them, the images have been convolved with a common mean beam of \( 0.38 \times 0.15 \text{ mas} \) at \( -10^5 \), corresponding to an average spatial scale comparable with the RA map. The minor beam axis is half the one in the RA map, though. The data reduction was performed with a combination of AIPS and Difmap, as described in Jorstad et al. (2005).

The analysis of the jet kinematics and flux density variability was carried out by fitting a series of circular Gaussian components which best model the brightness distribution of the source. Identification of components across epochs was performed assuming a smooth variation in flux density and proper motion of the model fitted components. We identified superluminal as well as stationary features. The core, identified with component \( c0 \), is considered stationary among epochs. Another stationary component, labeled as \( s4 \), was found very close to the core. From the light curves of model-fit components in Fig. 4 (upper panel) we discovered that 3C 273 underwent a radio flare starting around the beginning of 2013, when the core (in black) increased its

flux density and, subsequently, a new superluminal radio component ($d5$) emerged from the core region. We inferred the time of ejection of this new component, 2013.20±0.01, that is, as expected, just after the increase of the core flux density (see Fig. 4, middle panel). We can also notice that after having increased its brightness, the core displayed a decrease, while the stationary component $s4$ reached a peak and only later on is it possible to distinguish component $d5$ in the images. This leads us to associate component $s4$ with a possible recollimation shock in the core region, that becomes brighter when a new component passes through it and slightly shifts its position when this happens, as we see in Fig. 4 (middle panel) and as predicted by numerical simulations (e.g., Gómez et al. 1997). Moreover, component $d5$ moves at an apparent velocity of $11.5 \pm 0.2c$, in agreement with the apparent motions of the other detected moving components, and the range of speeds usually observed in this source (e.g., Jorstad et al. 2011).

One of the 43 GHz epochs analyzed (19th January 2014) is only one day apart from the RA epoch presented in this work (18th January 2014). The total intensity image is shown in Fig. 5.
Table 2: Quantities from the model fit analysis of VLBA-BU-BLAZAR data: epoch, flux density at 43 GHz, distance from the core, position angle, major axis, and both observed and intrinsic $T_b$ of the circular Gaussian components $c0$, $s4$, and $d5$ are given.

At this epoch, the source displays a low-activity state, having a flux density peak at 43 GHz of ~1.58 Jy/beam. Also, component $d5$ shows a position compatible with component C from the 22 GHz RA image, visible in Fig. 3.

Assuming that component $c0$ is the core, the fact that component $d5$ ejection epoch is subsequent to the Kovalev et al. (2016) one suggests that this should have been upstream of the core in January 2013. This, assuming a simple conical shape for the jet, would imply a size smaller than component $c0$ (< 40 µas) thus similar to the size that Kovalev et al. (2016) attribute to the component producing the extreme brightness temperature (26 µas). Marscher et al. (2008) proposed that the mm-wavelength core of blazars could be a recollimation shock along the particle jet stream, while the region between the central black hole and the core would be responsible for the acceleration and collimation. In this context, we identify the $c0$ component as a recollimation shock, in addition to the one corresponding to the stationary component $s4$. The two are separated by ~0.2 mas.

In Fig. 3 (lower panel) we present the observed brightness temperature estimates for the different model fit components versus time. The core ($c0$) shows values between 10^{11} and 10^{12} K for most epochs. A similar trend is present for the stationary component $s4$, while the newly-ejected one ($d5$) starts from a $T_b$ just below 10^{11} K during the first epoch, and then progres-
Fig. 3: Zoom on the central region of 3C273 at 22 GHz (RA): image obtained using three model fit Gaussian components for the $T_b$ estimate (overplotted).

...sively decreases with time. Nevertheless, the intrinsic brightness temperatures for each component/epoch, presented in Tab. 2, result in values not exceeding the equipartition limit, in line with the estimates obtained from our RA observations at 22 GHz. The uncertainties in the flux density and distance from c0 of components have been calculated following the method described in Casadio et al. (2015), developed for VLBA observations at 43 GHz, and adopting a minimum error of 0.01 mas for the distance (half of beam size). The size uncertainty was calculated following Jorstad et al. (2005).

Lisakov et al. (2017) presented a multi-epoch (2008-2014) VLBA study of 3C 273 in the 5-43 GHz frequency range. The brightness temperature estimates therein were performed adopting a resolution limit for the model fit components; this results in slightly higher $T_b$ than what we obtain with our approach at the same frequency. Also, the number of components used was different; in our case, we tried to minimize the number of free parameters (and thus components) when modeling the emission. This more conservative approach avoids a possible overestimate of the brightness temperature that could arise from arbitrarily small model fit components. Nevertheless, the same $T_b$ trend is visible for the overlapping epochs (2013-2014), showing a maximum decrease of more than 2 orders of magnitude with respect to the Kovalev et al. (2016) epoch.

3.3. Spectral index map

Fig. 5 shows the spectral index map between 22 and 43 GHz, realized using the map from the VLBA-BU-BLAZAR epoch only one day apart from our RA observations. Image registration was performed via cross-correlation analysis of the total intensity maps, as in Gómez et al. (2016) (and references therein) applying a shift of [-0.12;0.12] mas in right ascension and declination.

Fig. 4: Results from the 43 GHz VLBA-BU-BLAZAR data from 2012-2014, for each model fit component. The gray vertical line indicates the Kovalev et al. (2016) epoch and the arrow indicates the ejection epoch for component d5. Top panel: light curves; middle panel: distance from the core versus time; d5 is the radio component ejected after the Kovalev et al. (2016) epoch; bottom panel: observed brightness temperature versus time.
respectively. Spectral index $\alpha$ is defined as positive ($S \propto \nu^\alpha$). A spectral index of $\alpha = 0 \pm 0.1$, indicating a flat/optically-thick region, is visible within the $c0$ component. This is consistent with our interpretation of $c0$ (component A in the RA map) as the core. The spectra in the regions corresponding to the position of $s4$ and $d5$ components (B and C components, respectively, in the RA map) have an $\alpha = 0.3 \pm 0.1$ and $\alpha = -1.3 \pm 0.2$, respectively, indicating another optically thick region for $s4$ (the recollimation shock), and an optically thin region for $d5$ (the newly ejected component). Finally, the more extended emission towards southwest is steep as well, as expected in this frequency range for the more adiabatically expanded, optically thin, components of the jet.

4. Discussion

In the following, we put our results in the context of previous RA observations and studies at different bands.

4.1. Comparison with previous RadioAstron observations

Drastic differences, in terms of brightness temperature estimates, are seen when comparing with previous RA observations of 3C 273 at the same frequency, performed between December 2012 and February 2013 during the early-science program (Kovalev et al. 2016). An exceptionally high brightness temperature was detected ~$10^{13}$ K, related to a component of only 26 $\mu$as - challenging our comprehension of the jet physics. The space-baselines segment of these observations was conducted using the Arecibo, Green Bank, and VLA telescopes as the ground array. The highest brightness temperature measured at 22 GHz was $1.4 \times 10^{13}$ K (rest- frame), on a baseline of 7.6 G\'. Assuming the same Doppler factor as for our observations, this gives an intrinsic brightness temperature of $\sim 10^{12}$ K. Our observations, taken one year after, show that the brightness temperature has dropped by ~2 orders of magnitudes.

It is worth noting that no other RA experiment resulted in successful space-baseline fringes on 3C 273, at 22 GHz, between the Kovalev et al. (2016) epoch and ours. In fact, the source has been regularly targeted by the RA AGN-survey KSP, spanning space-baselines between ~4.5 and ~25 G\'. This confirms the minimum-activity status of the source resulting from our observations.

These results support one of the scenarios proposed by Kovalev et al. (2016), that is, that an exceptionally high brightness temperature, over the Compton catastrophe limit, can be caused by a transient phenomenon responsible for the departure from equipartition of energy between magnetic fields and particles. In particular, following Readhead (1994), the magnetic field energy density ($u_B$) varies as:

$$u_B = \frac{B^2}{8\pi} \propto T_{b,\text{int}}^{-4},$$

where $B$ is the magnetic field, and $T_{b,\text{int}}$ is the intrinsic brightness temperature, while the particle energy density ($u_\text{p}$) varies as:

$$u_\text{p} \propto T_{b,\text{int}}^{-4.5}.$$

For values of $T_b$ near or above the inverse Compton catastrophe $B$ has very low values - significantly increasing the synchrotron loss time - and particle energy density dominates the system, while for values below the equipartition ones, $u_B$ dominates. As a rough approximation, and assuming the peak frequency of the synchrotron emission spectrum did not change, for a $T_{b,\text{int}}$ drop of two orders of magnitude between the two epochs considered...
During our observations, the source was in a γ-ray-quiet state, spanning more than 3 years in the Fermi-LAT data. The weekly light curve from the Fermi-LAT collaboration\footnote{http://fermi.gsfc.nasa.gov/ssc/data/access/lat/msl_lc/} shows no flux measurements above $1 \times 10^4$ photons/cm$^2$/s since $\sim 55500$ MJD (November 2010), while a peak up to $5 \times 10^6$ photons/cm$^2$/s was previously registered between 2009 and 2010. This seems to confirm the low-activity state of the source visible from radio data presented above (both VLBI and single-dish). Also, we notice that the passage of the newly-ejected component $d5$ in the mm-band core does not correlate with a flare in γ-ray band: Jorstad et al.\footnote{2016} reported that 62 out of the 114 superluminal knots identified in the VLBA-BU-BLAZAR observations from 2008 August to 2013 January were not associated with any significant gamma-ray flares, thus in agreement with what we observe. Furthermore, the lack of gamma-ray emission is consistent with the low $T_b$ measured.

## 5. Conclusions

We present 22-GHz RA observations of 3C 273, obtained with the support of a global ground array of radio telescopes in the context of the AGN polarization KSP. We can summarize our conclusions as follows:

- The source seems to be in a particularly low activity state, both from our observations and from OVRO single-dish monitoring at 15 GHz.
- We find a core brightness temperature at least two orders of magnitude lower than the one measured one year before by Kovalev et al.\footnote{2016} with RA SVLBI observations at the same frequency.
- From the kinematics analysis of multi-epoch mm-band data, taken by the VLBA-BU-BLAZAR program, we detected a new component, ejected from the mm-core ~2 months after the extreme brightness temperature found by Kovalev et al.\footnote{2016}. Thus, this was located upstream of the core during Kovalev et al.\footnote{2016} epoch, with an expected size <40 μas, compatible with the one estimated by those authors.
- No γ-ray flare seems to be present, either during 2013 or our epoch (2014). This is consistent with both the low measured brightness temperature of the knot and the finding by Jorstad et al.\footnote{2016} that fewer than 50% of superluminal knots in blazars are associated with gamma-ray flares.
In AGN jets, brightness temperatures above the equipartition limit, or even Compton-cooling limit, can be reached and maintained only for short periods. Our observation shows that a brightness temperature even lower than the equipartition value can be present after the extremely high value detected one year before. The access to extremely long baselines - and angular resolution - thus does not systematically find cm-band brightness temperatures larger than typical values found at lower resolution. This means that the source status still plays a principle role in the characterization of the observable physical quantities.
