Nonclassical detectors and nonclassicality

Alfredo Luis$^*$ and Laura Ares

(Dated: May 21, 2019)

According to Born’s rule quantum probabilities are given by the overlap between the system state and measurement states in a quite symmetrical way. This means that both contribute to any observed nonclassical effect that is usually attributed just to the observed light state. This is relevant since typical measurement are highly non classical by themselves, such as number states and quadrature eigenstates. We show that nonclassical effects only arise provided that the measurement is itself nonclassical. Otherwise there is a classical-like model accounting for the observed statistics.

I. INTRODUCTION

Nonclassical effects are at the heart of the quantum theory. They are relevant both from fundamental as well as from practical reasons, since nonclassicality is actually a resource for future quantum technologies [1].

Nonclassicality is always revealed by peculiar effects in observed statistics $P(m|\psi)$ where $\psi$ is the system state and $m$ the outcomes. According to Born’s rule quantum statistics are determined in a symmetrical way by the system state $|\psi\rangle$ and the measurement states $|m\rangle$, this is $P(m|\psi) = |\langle m|\psi\rangle|^2$ [2], where typically $|m\rangle$ are the eigenvectors of the measured observable. This raises the question of whether the nonclassicality revealed by $P(m|\psi)$ is a property of the observable states $|m\rangle$ or a property of the state $|\psi\rangle$ being observed. This is specially pertinent since typically $|m\rangle$ are highly nonclassical states by themselves, say number states and infinitely squeezed states, in photon-number and quadrature measurements, respectively [3].

Despite this natural and simple remark, the nonclassicality has been always ascribed to the observed state. A quite remarkable example is the photoelectric effect, that can be regarded as an observation of the light intensity. This is usually interpreted as a proof of the quantum nature of the light, although it can be satisfactorily explained exclusively in terms of the quantum properties of the light, although it can be satisfactorily explained exclusively in terms of the quantum properties of the detector, this is to say that it admits a semiclassical explanation [3][4].

In this work we demonstrate that the nonclassicality of the detector is a necessary condition to obtain nonclassical statistics $P(m|\psi)$. This can be particularized to some simple and common signatures of nonclassical light such as subPoissonian statistics, quadrature squeezing and photon anti-correlations showing that they unavoidably requires detectors that are themselves nonclassical.

Strictly speaking, a single-observable statistics $P(m|\rho)$ cannot reveal by itself nonclassical behaviour. This is because in classical physics we can always replicate any quantum probability distribution. The most clear quantum signature is the lack of a joint probability distribution for incompatible observables. This naturally includes as a particular case the flagship on nonclassical signatures is the lack of a bona fide Glauber-Sudarshan $P(\alpha)$ distribution [7]. This is not the only criterion. Actually this is a particular case of a more general approach which consider pathologies in the statistics of the joint measurement of any two observables [10][11], that can reveal nonclassical behavior even for states with bona fide Glauber-Sudarshan $P(\alpha)$ distributions such as Glauber and SU(2) coherent states [8][9][11][12].

In this work we examine the role of the nonclassicality of the measurement on the nonclassicality of observed statistics $P(m|\rho)$.

II. JOINT MEASUREMENTS

In this work we demonstrate that the nonclassicality of the detector is a necessary condition to obtain nonclassical statistics $P(m|\psi)$. This can be particularized to some simple and common signatures of nonclassical light such as subPoissonian statistics, quadrature squeezing and photon anti-correlations showing that they unavoidably requires detectors that are themselves nonclassical.

In the most general case, joint measurements take place in an enlarged space with auxiliary degrees of freedom in a fixed and known state. The statistics can be properly represented in the system space by a positive operator-valued measure (POVM) $\Delta(x,y)$

$$\hat{p}(x,y) = \text{tr} \left[ \hat{\rho} \Delta(x,y) \right],$$

and $\rho$ is the density matrix of the system state, $x,y$ are the outcomes in the measurement of two observables. More specifically we assume that the corresponding

---

marginal POVMs $\tilde{\Delta}_X(x)$ and $\tilde{\Delta}_Y(y)$

$$\tilde{\Delta}_X(x) = \int dy \tilde{\Delta}(x, y), \quad \tilde{\Delta}_Y(y) = \int dx \tilde{\Delta}(x, y), \quad (2.2)$$

provide complete information about $X$ and $Y$, respectively. This is to say that there are functions $\mu_A(a, a')$ such that

$$\Delta_A(a) = \int da' \mu_A(a, a') \tilde{\Delta}_A(a'), \quad (2.3)$$

$A = X, Y, \ a = x, y$, where the functions $\mu_A(a, a')$ are state-independent and completely known as far as we know the measurement being performed, and $\Delta_A(a)$ are the exact, true POVMs corresponding to the system observables $A = X, Y$.

The key idea is to extend this inversion (2.3) from the marginals to the complete joint distribution, to obtain an operator-valued measure [10, 11, 15]:

$$\Delta(x, y) = \int dx' dy' \mu_X(x, x') \mu_Y(y, y') \tilde{\Delta}(x', y'). \quad (2.4)$$

By construction the proper marginals are recovered

$$\Delta_X(x) = \int dy \Delta(x, y), \quad \Delta_Y(y) = \int dx \Delta(x, y). \quad (2.5)$$

Likewise, all these relations hold between the corresponding probability distributions, in particular for the observed marginals $\tilde{p}_A(a)$, the inversion procedure

$$\tilde{p}_A(a) = \text{tr} \left[ \rho \tilde{\Delta}_A(a) \right], \quad p_A(a) = \int da' \mu_A(a, a' \tilde{p}_A(a'), \quad (2.6)$$

and, finally, for the inferred joint distribution

$$p(x, y) = \text{tr} [ \rho \Delta(x, y)], \quad (2.7)$$

so that

$$p(x, y) = \int dx' dy' \mu_X(x, x') \mu_Y(y, y') \tilde{p}(x', y'). \quad (2.8)$$

This is where the difference between classical and quantum physics emerges. As recalled below, in classical physics this program derives always in a bona fide joint probability distribution $p(x, y)$. This is not the case in quantum physics, where $p(x, y)$ may not exist or take negative values as a clear signature of nonclassical behaviour.

This procedure includes all the other known approaches to nonclassical light such as pathological Glauber-Sudarshan distribution $P(\alpha)$. This is because $P(\alpha)$ pretends to be a joint distribution for incompatible field quadratures and is always determined via some kind of inversion procedure that provides always a bona fide probability distribution in the classical regime.

### B. Classical physics

Let us show that the inferred distribution obtained from the inversion procedure (2.8) leads always to a bona fide probability distribution $p(x, y)$.

Classically, the state of the system can be completely described by a legitimate probability distribution $p(\alpha)$, where $\alpha$ are all admissible states for the system, i.e., the corresponding phase space.

So the observed joint statistics can be always expressed as

$$\tilde{p}(x, y) = \int d^2 \alpha \tilde{X}(x|\alpha) \tilde{Y}(y|\alpha)p(\alpha), \quad (2.9)$$

where $\tilde{A}(a|\alpha)$ is the conditional probability that the observable $\tilde{A}$ takes the value $a$ when the state system is $\alpha$. By definition, phase-space points $\alpha$ have definite, non-contextual values for every observable so the factorized product of joint measurement probabilities $\tilde{X}(x|\alpha)\tilde{Y}(y|\alpha)$ holds. Strictly speaking they are the product of delta functions. In any case, this means that all $\tilde{A}(a|\alpha)$ exist, are nonnegative, and no more singular than a delta function. So Eq. (2.9) expresses the separability of any joint measurement in classical optics.

By construction, we know that there are $\mu_A(a, a')$ functions so that the analog of Eq. (2.6) holds and we get the exact conditional probabilities

$$A(a|\alpha) = \int da' \mu_A(a, a') \tilde{A}(a'|\alpha). \quad (2.10)$$

where $A(a|\alpha)$ is the conditional probability that the observable $A$ takes the value $a$ when the system state is $\alpha$.

Thus, because of the separable form for the observed joint statistics in Eq. (2.9) we readily get from Eqs. (2.8) and (2.10) that the result of the inversion is the actual joint distribution for $X$ and $Y$

$$p(x, y) = \int d^2 \alpha X(x|\alpha) Y(y|\alpha)p(\alpha). \quad (2.11)$$

Thus, lack of positivity or any other pathology of the retrieved joint distribution $p(x, y)$ is then a signature of nonclassical behaviour. In turn, a necessary condition for this pathological behaviour of $p(x, y)$ is the lack of separability of the observed joint probability distribution $\tilde{p}(x, y)$.

### III. THERE IS NO NONCLASSICAL LIGHT WITHOUT NONCLASSICAL DETECTORS

Let us express the inferred POVM (2.4) in the Glauber-Sudarshan representation as

$$\Delta(x, y) = \int d^2 \alpha p(x, y|\alpha) |\alpha\rangle \langle \alpha|, \quad (3.1)$$
where $|\alpha\rangle$ are the Glauber coherent states. Then
\[
p(x, y) = \pi \int d^2 \alpha \, p(x, y|\alpha)Q_\rho(\alpha),
\]  
(3.2)

being $Q_\rho(\alpha)$ the Husimi Q function of $\rho$
\[
Q_\rho(\alpha) = \frac{1}{\pi} \langle \alpha|\rho|\alpha\rangle.
\]  
(3.3)

We are attempting to describe classical measurements within a quantum scenario. The most natural way is to mimic the classical structure of statistics in Eq. (2.11), this is to say that $p(x, y|\alpha)$ factorizes with bona fide conditional probabilities
\[
p(x, y) = px(x|\alpha)p_y(y|\alpha), \quad p_A(a|\alpha) \geq 0,
\]  
(3.4)

and $Q_\rho(\alpha)$ playing the role of the classical $p(\alpha)$. These are actually the conditions considered when setting a classical-like scenario to derive the Bell inequalities.

With this the joint distribution becomes
\[
p(x, y) = \pi \int d^2 \alpha p_X(x|\alpha)p_Y(y|\alpha)Q_\rho(\alpha).
\]  
(3.5)

A key point here is that for every $\rho$ the function $Q_\rho(\alpha)$ exists and is nonnegative $Q_\rho(\alpha) \geq 0$. Thus, for classical detectors we have always a classical-like hidden-variable model where $Q_\rho(\alpha)$ plays de role of a joint distribution over the classical variables $\alpha$ so that $p(x, y)$ is always a bona fide probability distribution an there is no nonclassicality. This is to say, that there are nonclassical effects only if the observables measured are themselves nonclassical, this is that $p_A(a|\alpha)$ do not exist, take negative values or are more singular than delta functions. In other words, nonclassical distributions $p(x, y)$ are obtained only if the POVM elements $\Delta(x, y)$ are more nonclassical than Glauber coherent states.

The other way round we may consider the Glauber-Sudarshan representation for the system state $\rho$ exchanging the roles of state and observables in Eqs. (3.1) and (3.3)
\[
\rho = \int d^2 \alpha P_{\rho}(\alpha) |\alpha\rangle\langle \alpha|,
\]  
(3.6)

so that the inferred joint distribution can be expressed as
\[
p(x, y) = \pi \int d^2 \alpha P_{\rho}(\alpha)Q_{\Delta(x, y)}(\alpha),
\]  
(3.7)

being [13] [14]
\[
Q_{\Delta(x, y)} = \frac{1}{\pi} |\alpha|\Delta(x, y)|\alpha\rangle.
\]  
(3.8)

Let us note that now there is an important difference with respect to Eq. (3.5). This is that $Q_{\Delta(x, y)}(\alpha)$ may not exist, be more singular than a delta function or take negative values. An example of each one of these possibilities can be found in Ref. [11]: lack of existence for a suitably designed double homodyne detector, and negative for one-half spin-like measurements. Thus, there is room to observe nonclassical phenomena for states with well defined nonnegative $P_{\rho}(\alpha)$, such as coherent states. We may say that they are revealing the nonclassicality of the observation procedure, but let us recall that we have just demonstrated that nonclassical measurements is always a necessary condition even if the system state is more nonclassical than coherent states.

IV. SOME SIMPLE EXAMPLES

The above analysis shows that all quantum signatures must vanish whenever the measurement is classical and $\Delta(x, y)$ admits a well-behaved Glauber-Sudarshan distribution irrespective of the quantumness of the observed light state. Let us illustrate this point with some paradigmatic examples of nonclassicality.

A. SubPoissonian statistics

A classic test of nonclassicality is subPoissonian statistics, $\Delta^2 n < \langle n \rangle$ which is incompatible with a bona fide $P_{\rho}(\alpha)$. Fur projection on number states the corresponding $p_{\nu}(n|\alpha)$ is extremely singular and thus nonclassical [18], this is
\[
|n\rangle\langle n| = \int d^2 \alpha p_{\nu}(n|\alpha)|\alpha\rangle\langle \alpha|. \]  
(4.1)

where $p_{\nu}(n|\alpha)$ is actually the Glauber-Sudarshan $P$ function of a number state being extremely singular containing derivatives of the delta function
\[
p_{\nu}(n|\alpha) = \frac{n!e^{\alpha^2}}{2\pi|\alpha|^2(n!)} \partial^n|\alpha\rangle\langle \alpha|.
\]  
(4.2)

Let us examine whether the subPoissonian behavior still holds when we replace the above highly nonclassical $p_{\nu}(n|\alpha)$ by its classical version
\[
p_{\nu}(n|\alpha) = \delta (n - |\alpha|^2),
\]  
(4.3)

where $n$ is now a continuous variable. In such a case the corresponding statistics reads
\[
p_{\nu}(n|\rho) = \frac{1}{2} \int_{2\pi} d\phi Q_{\rho}(\alpha = \sqrt{n}e^{i\phi}), \]
(4.4)

where we have used that $d^2 \alpha = (1/2)d|\alpha|^2d\phi$ and $\phi$ is the phase of $\alpha$. This statistics can be related with the actual exact photon-number distribution $p_m$ in the form
\[
p_{\nu}(n) = \sum_{m=0}^{\infty} \frac{n^m e^{-n}}{m!} p_m,
\]  
(4.5)
where \( p_m = \langle m | \rho | m \rangle \) and \( | m \rangle \) are number states, \( \hat{n} | m \rangle = m | m \rangle \), being \( \hat{n} \) the number operator.

It is worth noting that this clearly resembles the formula for the number of photoelectrons recorded in a photoelectric scenario, just by replacing the classical distribution for the integrated intensity by the discrete photon-number distribution \( p_m \). The parallels are even more noticeable if we recall that the photoelectron distribution arises in a semiclassical calculus, where the light is described classically while the detector is quantum. Here the situation is just the opposite, the detector is considered classical while the light is treated quantum-mechanically. Thus, this is some kind of *semiquantum* model.

Taking into account that
\[
\int_0^\infty d n n^k e^{-n} = k!,
\]
we readily get from Eqs. (4.4) and (4.5)
\[
\langle n \rangle = \langle \hat{n} \rangle + 1,
\]
and
\[
\langle n^2 \rangle = \langle \hat{n}^2 \rangle + 3 \langle \hat{n} \rangle + 2,
\]
so that
\[
\Delta^2 n = \langle n^2 \rangle - \langle n \rangle^2 = \Delta^2 \hat{n} + \langle n \rangle \geq \langle n \rangle.
\]

So, if we replace quantum by classical-like measurement all states are Poissonian (number states) or superPoissonian (all the rest). Therefore, we may safely say that subPoissonian statistics holds only if the measurement is subPoissonian itself, and so non classical.

### B. Anticorrelation

Next we move from subPoissonian statistics to anticorrelation of photocounts in the typical scenario displayed in Fig. 1, as the flagship of quantum optics. There a single photon impinges on a lossless beam splitter and two joint intensity measurement are performed at the outputs of the beam splitter. Since the photon is indivisible, the detectors can never both trigger simultaneously so that \( \langle \hat{n}_1 \hat{n}_2 \rangle = 0 \). This is maybe the most clear and simple evidence of the quantum nature of light [19].

Thus we consider a two-mode version of the classical measurement described by the \( P_N(n|\alpha) \) function in Eq. (4.3) to obtain the statistics when the field is in the one-photon state
\[
p(n_1, n_2 | \rho) = (R n_1 + T n_2) e^{-n_1 - n_2},
\]
where \( R, T \) are the transmission and reflection coefficients with \( T + R = 1 \). We simply get
\[
\langle n_1 n_2 \rangle = 2,
\]
so that the alleged quantum effect would be never observed if the detectors were classical-like devices.

Along the same lines we may examine the Hong-Ou-Mandel effect illustrated in Fig. 2 [20], where two photons impinge simultaneously on the input ports of a lossless 50% beam splitter. The quantum theory predicts the result \( \langle \hat{n}_1 \hat{n}_2 \rangle = 0 \) again, as an evidence of the quantum nature of light.

However, this result is not preserved if we replace the detectors by classical-like measurements as before, since the joint statistics would be:
\[
p(n_1, n_2 | \rho) = \frac{1}{4} (n_1^2 + n_2^2) e^{-n_1 - n_2},
\]
leading to
\[
\langle n_1 n_2 \rangle = 3.
\]

### C. Quadrature squeezing

As a further test of nonclassicality it is known that quadrature squeezing, \( \Delta^2 x < 1/4 \) where \( x \) represents a
field quadrature $x = \Re\{\alpha\}$, is incompatible with a 
*bona fide* $P_x(\alpha)$. Here again the statistics of a quadrature 
measurement results by projection on the quadrature 
eigenstates, that are highly nonclassical being infinitely 
squeezed. We carry out the closest classical measurement 
by replacing the strongly quantum $p_X(x|\alpha)$ by

$$p_X(x|\alpha) = \delta(x - \Re\{\alpha\}). \quad (4.14)$$

so that the corresponding statistics reads

$$p_X(x|\rho) = \int_{-\infty}^{\infty} dy Q(\alpha = x + iy), \quad (4.15)$$

this is

$$p_X(x|\rho) = \sqrt{\frac{2}{\pi}} \int_{-\infty}^{\infty} dx' e^{-2(x-x')^2} p(x'), \quad (4.16)$$

where $p(x) = \langle x|\rho|x\rangle$, being $|x\rangle$ the quadrature 
eigenstates, is the true quantum quadrature distribution associated to $\rho$.

Here again, computing the first two moments we get

$$\langle x \rangle = \langle \hat{X} \rangle, \quad \langle x^2 \rangle = \langle \hat{X}^2 \rangle + \frac{1}{4}, \quad (4.17)$$

so that

$$\Delta^2 x = \Delta^2 \hat{X} + \frac{1}{4} \geq \frac{1}{4}. \quad (4.18)$$

Therefore, with classical quadrature measurements there 
would be no nonclassical behavior regarding this physical variable.

V. CONCLUSIONS

We have demonstrated that the nonclassicality of the 
detector is a necessary condition to obtain nonclassical 
statistics. We have shown explicitly that this is the case 
in the most typical signatures of nonclassical behavior, 
such as subPoissonian statistics, quadrature squeezing 
and photon anti-correlations showing that they unavoid-
ablly requires detectors that are themselves nonclassical. 
Moreover we have demonstrated that it is possible to ob-
serve nonclassical phenomena for states with well defined 
nonnegative Glauber-Sudarshan distribution, such as co-
herent states.
