ABSTRACT

Aims. We wish to clarify the origin of the multiple jet features emanating from the binary protostar SVS 13A (= VLA4A/VLA4B). Methods. We used the Plateau de Bure Interferometer to map at 0.3–0.8′′ (~70–190 au) dust emission at 1.4 mm, CO(2–1), SiO(5–4), SO(6–5), and SiO(6–5). Revised proper motions for VLA4A/4B and jet wiggling models are computed to clarify their respective contribution. Results. VLA4A shows compact dust emission suggestive of a disk <50 au, and is the hot corino source, while CO/SiO/SO counterparts to the small-scale H2 jet originate from VLA4B and reveal the jet variable velocity structure. This jet exhibits >3′′ wiggling consistent with orbital motion around a yet undetected ≃20–30 au companion to VLA4B, or jet precession. Jet wiggling combined with velocity variability can explain the large apparent angular momentum in CO bullets. We also uncover a synchronicity between CO jet bullets and knots in the HH7–11 chain demonstrating that they trace two distinct jets. Their ≃300 yr twin outburst period may be triggered by close perihelion approach of VLA4A in an eccentric orbit around VLA4B. A third jet is tentatively seen at PA ≃0°. Conclusions. SVS 13A harbors at least 2 and possibly 3 distinct jet sources. The CO and HH7–11 jets are launched from quasi-coplanar disks, separated by 20–70 au. Their synchronous major events every 300 yr favor external triggering by close binary interactions, a scenario also invoked for FU Or outbursts.

1. Introduction

The role of close stellar encounters in accretion and ejection bursts in young stars is a debated issue [Reipurth et al. 2014, and references therein]. An interesting target of study in this context is SVS 13A, a 0.3′′ (70 au) binary solar-type protostar (VLA4A, VLA4B; Anglada et al. 2000) in NGC 1333 (d = 235 pc, Hirota et al. 2008) with multiple signs of ejection bursts. SVS 13A is the candidate source of the HH7–11 chain of optical/H2 knots (Davis et al. 2000), drives high-velocity CO bullets (Bachiller et al. 2000, hereafter B00), and hosts small scale [FeII] jet with H2 arcs (see Hodapp & Chini 2014, hereafter HC14, and references therein). An unusually large angular momentum extraction by CO outbursts, compared to other rotating outflows like DG Tau, was recently claimed from SMA maps at 3′′ resolution (Chen et al. 2016). Here we present the highest angular resolution (0.3′′–0.8′′) study of the SVS13 A system in dust continuum, CO, SiO and SO, obtained in the frame of the CALYPSO (Continuum And Lines in Young ProtoStellar Objects) Large Program at the IRAM Plateau de Bure interferometer (hereafter PdBI, Maury et al. in prep). The high astrometric precision, angular resolution, and sensitivity reveal the jet structure in unprecedented details and the key role of multiplicity in its outstanding outflow properties.

2. Observations and data reduction

CALYPSO data of SVS 13A were taken with the 6 antennas of the PdBI in A and C configurations in the winters of 2011, 2012, and 2013, with baselines ranging from 24 m to 760 m. The typical system temperature and water vapor were 140 K and ~2 mm. We used the WideX backend with 2 MHz channels (~2.8 km s⁻¹) to extract a range of ±300 km s⁻¹ around SO(5–4), SO(6–5), and CO(2–1) at 217.10498, 219.949442, and 230.53800 GHz, respectively. Data calibration was performed with the GILDAS–CLIC software. continuum was obtained by averaging line-free channels over the 4 GHz WideX band centered at 219 GHz. Self-calibration was performed on the continuum r-data. the same gain tables were then applied to all WideX r-tables, and images cleaned using natural weighting, with a synthesized beam of 0.83′′×0.56′′ in continuum, SiO and SO and 0.76′′×0.5′′ in CO. Each line cube was continuum-subtracted by baseline fitting in the image plane, and also corrected from primary beam attenuation. A high-resolution continuum image was generated from A configuration data alone with uniform weighting, resulting in a 0.52′′×0.31′′ beam. The absolute astrometric precision based on phase calibrators is ±20 mas. Absolute flux calibration was based on MWC349, with an uncertainty of 20%. The 1σ noise level is 0.7 and 1.2 mJy/beam in continuum for A and A+C configurations, respectively, and 1.7 mJy/beam ± 0.1 K per channel for the lines.

3. Results

3.1. Dust and COM distribution in SVS 13A

The 1.4 mm continuum maps are presented in Fig. 1. The A-configuration map reveals an EW elongation indicating similar
peak fluxes towards both sources of the close (0.3″) binary system VLA4A/B, marginally resolved by our longest baselines. To estimate the flux of each component, we computed updated proper motions including the latest data of Tobin et al. (2016) and deduced accurate positions at the time of the CALYPSO observations (Appendix A). By fitting source models at these positions the A and A+C uv-data, we find that VLA4B is extended, while VLA4A can be reproduced by an unresolved component alone (radius < 0.2″ ≈ 50 au) of flux ≈ 40 ± 10 mJy (where error bars include position and calibration uncertainties). The free-free contamination of VLA4A at 1.4 mm, extrapolating the 3.6–1 cm fluxes of Anglada et al. (2000) and Tobin et al. (2016), is only ≈ 1.5 mJy. Hence, we find that VLA4A harbors compact circumstellar dust, suggestive of a disk of radius < 50 au, unlike previously believed (Anglada et al. 2004). Assuming optically thin emission from compact disk or inner envelope, and using Eqs. (1) and (2) of Motte & André (2001) with $L_\star = 28 L_\odot$ (from Herschel 70μm, André et al. 2010), we estimate an inner circumstellar mass of $0.01 M_\odot$ $M_{\text{dust}}$ ~ 40–100 K at 50 au, with uncertainties of a factor three mostly from dust emissivity. Interestingly, complex organic molecules (COMs) from the hot corino of SVS13A (eg. López-Sepulcre et al. 2013, De Simone et al. 2017) peak on or close to VLA4A (see Fig. 2 and Belloche et al., in prep.), confirming VLA4A has dense circumstellar material. Residuals after removing the point source on VLA4A (Fig. 1 bottom row) show dust emission extended on scales of at least ~2″ peaking on VLA4B (total flux ~ 200 ± 25 mJy, free-free contamination < 10 mJy). This component may be reproduced by the inner parts of a larger circumbinary envelope (with details to be developed in Maury et al., in prep).

3.2. Origin and kinematics of the blueshifted molecular jet

Fig. 2 left column, shows that the extremely-high velocity (hereafter EHV) blueshifted (with respect to $V_{\text{sys}}$ = 8.5 km s$^{-1}$) CO jet formed by B00 is resolved into a series of knots, also detected in SiO and SO. It also reveals an excellent correspondence with the H$_2$ outflow features of HC14 – namely a small circular “bubble” (denoted (a)), two H$_2$ arcs (denoted (b) and (c)), and a fainter “linear feature” joining (a) and (b) – when these features are registered on VLA4B (see Fig. 2). In contrast, a systematic shift appears if they are registered on VLA4A (see Appendix B). Hence, the CALYPSO data unambiguously identify VLA4B as the base of the small-scale CO/H$_2$ jet from SVS 13A, and hence confirming previous assumption by HC14 that VLA4B was the near-infrared (NIR) source in their observations. The spatial agreement between tracers with very different excitation conditions (2000 K for H$_2$, less than a few 100 K for CALYPSO) implies emission in shock fronts with strong temperature gradients below our angular resolution. CALYPSO data thus reveal the kinematics of H$_2$ features at unprecedented spectral resolution (apart from bubble (a) that is strongly beam diluted).

Position-Velocity (PV) diagrams along the mean jet axis (PA=155°, B00) are shown in Fig. 3 and individual channel maps in Appendix B. The EHV jet velocity fluctuates strongly with distance. Along the linear H$_2$ feature it shows apparent deceleration from $V_{\text{LSR}}$ ≈ -100 km s$^{-1}$ near bubble (a) to -75 ± 5 km s$^{-1}$ at arc (b), then increases again to -90 ± 3 km s$^{-1}$ at arc (c). Combined with the arc (c) proper motion of 31.4 mas yr$^{-1}$ = 35 km s$^{-1}$ (HC14) we infer an inclination $i$ = 20° for this feature, similar to the center of the inner bubble (i ≈ 18°, HC14). The jet velocity further increases beyond arc (c) up to -115 km s$^{-1}$ at 4″ and oscillates between -115 and -90 km s$^{-1}$ on larger scale (see Fig. 3). No redshifted EHV counterjet is detected, as noted by B00.

The intermediate and standard high–velocity ranges (IHV, SHV) show an apparent accelerating pattern from $V_{\text{LSR}}$ ≈ -20 km s$^{-1}$ near the source to -70 km s$^{-1}$ at arc (b) (Fig. 3). CALYPSO maps in this velocity range (Fig. 2) reveal U-shaped cavities opening

![Fig. 1. Top: 1.4 mm continuum maps of SVS13 A using A configuration (left) and A+C (right). Contours start at 3σ and 10σ respectively, and increase by 10σ. Crosses show the positions of VLA4B and VLA4A, corrected for our proper motions (Appendix A). The synthesized beam is plotted in the bottom left corner. Bottom: residuals after removal of a point source fitted to the A config. Residuals after removal of a point source fitted to the A config. Residuals after removal of a point source fitted to the A config. The free-contamination $u$-data at the position of VLA4A. The color scale is in mJy/beam.](image1)

![Fig. 2. Maps of CO, SiO and SO integrated over three $V_{\text{LSR}}$ ranges: EHV = -150 to -68 km s$^{-1}$, IHV = -68 to -28 km s$^{-1}$, SHV = 28 to -3 km s$^{-1}$. Red and black crosses denote VLA4B and VLA4A, respectively. The compact emission peaked on VLA4A is entirely due to COMs (identified in Figs. E.2 and E.3). The bottom right panel shows Fig. 4 of HC14 registered on VLA4B. Their main H$_2$ features are outlined in white (cf. text and expanded view in Fig. C.1). They are reported in red in the other panels. The black line displays PA=155° (B00).](image2)
3.3. Jet wiggling and limits on jet rotation

Figure 4 shows a slightly enlarged region of the blueshifted jet in CO and SiO. It reveals that the S-shaped morphology seen in H$_2$ (HC14) is part of a coherent wiggling pattern traced in SiO and CO out to 5–6$'\!$, with a (projected) half-amplitude $\sigma_{\text{obs}} \approx 10''$ and wavelength $\lambda_{\text{obs}} \approx 3''$ (700 au), shorter than the 8.5$''$ suggested by Chen et al. (2016). We show in Fig. 4 that this pattern is very well reproduced by simple models of circular orbital motion or jet precession of period $\approx 100$ yr (see Appendix C for details). In the orbital scenario, a separation of 70 au (i.e. VLA4A) would imply, through Kepler’s third law, a total mass $M_{\text{tot}} \approx 7.35 M_\odot$ (for eccentricity $e=0.8-0$), which is excluded. A realistic $M_{\text{tot}} < 4 M_\odot$ would thus require a (so far unseen) closer companion 20–32 au from VLA4B, making SVS13A a hierarchical triple. Its non-detection in NIR images (HC14) implies it would be substantially fainter than VLA4B. Alternatively, CO jet wiggling could be due to jet precession, with the physical cause remaining unclear: rigid disk precession induced by a planetary mass body at 0.5 au, or non-rigid precession of a larger disk, for which models are still lacking (see Appendix C). Both the orbiting and precessing jet models originating from VLA4B reproduce the [FeII] micro-jet observed by HC14 within 0.3$''$, while if the CO jet originates from a companion to VLA4B, the truncation of the [FeII] jet might be explained by jet collision near the H$_2$ bubble center (see zoom in Fig. C.1).

3.4. Evidence for multiple jets and origin of HH7–11

B00 noted that the CO EHV jet at PA $\approx 155^\circ$ lies in a markedly different direction from the chain of optical Herbig-Haro (hereafter HH) objects HH7–11, at PA $\approx 130^\circ$, and interpreted it as a recent change of ejection direction in a single jet. Below we argue that these two flows are actually driven by two distinct sources. First, ejection along HH7–11 still seems active: Figure 4(c) reveals an unresolved SiO knot of unknown origin
chain of red-shifted knots is present in the blue outflow lobe, and a symmetric blue-shifted chain in the northern red lobe. Such velocity sign reversal is not expected for outflow rotation about the VLA4B jet axis. Hence, it might trace a third jet at PA $\approx 0^\circ$.  

4. Discussion and conclusions

The CALYPSO view reveals the coexistence of at least two, and possibly three distinct jets from SVS 13A = VLA4A/4B: (1) a wiggling CO/H$_2$ jet of mean PA $\approx 155^\circ$, confirmed to originate from the vicinity of VLA4B (as suggested by HC14); (2) the HH7–11 chain, quasi-synchronous with CO jet bullets but in a different PA $\approx 130-140^\circ$; (3) a tentative jet at PA $\approx 0^\circ$. In line with this, SVS13A is found to host two, and up to three possible jet sources: VLA4A (where we find 0.01M$_\odot$ of dusty material within 50 au, and hot corino emission), the NIR source VLA4B, and a putative 20–30 au stellar companion VLA4Bc, if CO/SiO jet wiggling is due to orbital motion.

The close pairing we uncover between major ejection episodes in the “twin” CO and HH7–11 jets implies a common external trigger, making SVS 13A a strong case for the role of stellar encounters in accretion/ejection bursts in young stars [Reipurth et al. 2014; Audard et al. 2014]. Based on the event period $P \approx 300$ yr (bullet projected separation $\approx 10'$), we propose that synchronous disk instabilities are triggered by close perihelion approach of VLA4A in an eccentric orbit around VLA4B. Kepler’s third law yields an orbit semi-major axis $a = 45 (M_{300}/M_{\odot})^{1/3} (P/300$ yr$)^{2/3}$ au, consistent with this scenario. No small-scale jet being currently visible from VLA4A, the origin of HH7–11 remains ambiguous. It could be episodically launched from VLA4A at periastron passage, and the CO jet from VLA4B; or the HH7–11 and CO jets could both arise from the putative 20-30 au close binary VLA4B/4Bc, with VLA4A acting merely as external destabilizing agent, and possibly driving the third jet at PA $\approx 0^\circ$. Searches for the tentative companion are needed to pin-point the source of each jet in this complex system. In either scenario, SVS 13A is launching the twin CO and HH7–11 jets from quasi-coplanar disks $^3$ separated by 20-70 au, making it highly reminiscent of L1551-IRS5 (Lim & Takakuwa 2006).

References

Reipurth, B., Clarke, et al. 2014, Protostars and Planets VI, 267

$^3$ i.e. 20$^\circ$ for the CO jet, i.e 16$^\circ$ for HH11 (Noriega-Crespo & Garnavich 2001) scaled to 235 pc) and $\Delta$PA $\approx 20^\circ$ yield $\Delta$VA(3D) = 9$^\circ$.  

$^4$ it requires a ratio of rotation to poloidal speeds $V_p/V_r > 1/\tan(i)$ $\approx 3$, unlike current MHD wind models (Casse & Ferreira 2000).
Appendix A: Revised proper motions

Fig. A.1. Revised proper motions of VLA4A and VLA4B. This figure is identical to Fig. 2 of CG08 with additional data. Reference positions are 03:29:03.732 31:16:03.974 (J2000) for VLA4A, and 03:29:03.7566 31:16:04.000 (J2000) for VLA4B. Dotted grey lines display CG08 proper motions based on their measurements (grey points). Solid blue lines are our best linear fit to all VLA radio data including the positions of Tobin et al. (2016). Vertical blue dashed lines identify the weighted date of fit to all VLA radio data for VLA4A, and (03:29:03.7648, 31:16:03.812) for VLA4B (J2000). Using 3.6 cm Anglada et al. (2003) and 8.65 mm Anglada et al. (2004) we obtained the proper motions be-
tween 3.6 cm (pure free-free emission) and λ ≤ 10 mm for proper motions would not signifi-
cantly change our results.

Refs: \(^{11}\) Carrasco-González et al. (2008)

Fig. B.1. Channel maps of CO, SiO and SO at \(V_{\text{LSR}}\) = 92.15 km s\(^{-1}\) (blue contours) with the positions of the [FeII] jet (green segment), \(H_{\alpha}\) inner bubble, arcs and vertical linear feature (in red) from HC14 superimposed. The NIR source was assumed to be either VLA4A (top row) or VLA4B (bottom row). The latter is unambiguously favored.

Appendix B: Source of the NIR continuum and jet

As noted by HC14, the NIR position measured by 2MASS in 1999 better agrees with VLA4B than VLA4A (Fig. A.1 pink stars), hence VLA4B is the source of the \(\approx 1990\) outburst. Assuming that the dominant source in the NIR remained the same in 2011-2013 as in 1999, HC14 concluded that VLA4B was also the source of the [FeII] jet and \(H_{\alpha}\) outflow features (re-produced and sketched in Fig. [C.1]). However, given the intrinsic variability of young stars and the fact that VLA4B is in decline phase, one cannot totally exclude VLA4A as the dominant NIR source in 2012. Our CALYPSO data have sufficient angular resolution, sensitivity, and astrometric quality to check this independently. This test is shown in Fig. B.1 on a single channel map. The morphology of the CO, SiO, and SO emission shows a systematic shift from \(H_{\alpha}\) features when the NIR source is registered on VLA4A (top row of Fig. B.1), whereas they match very well when the NIR source is registered on VLA4B (bottom row of Fig. B.1). This good match is also seen in other individual channel maps in Appendix E, and in the integrated velocity ranges in Fig. 2. Implications are discussed in Section 3.2.

Appendix C: Wiggling models for the CO/\(H_{\alpha}\) jet

We computed simple ballistic models of CO/\(H_{\alpha}\) jet wiggling in three scenarios: (1) orbital motion of VLA4B as the CO jet source, (2) orbital motion of a (so far unseen) companion of VLA4B as the CO jet source, (3) precessing jet from VLA4B. We used the equations of Masciadri & Raga (2002), where we added projection effects at small view angles. We explored a grid of parameters to find the smallest mean \(\chi^{2}\) deviation from the \(H_{\alpha}\) linear feature, the apex of arc \((b)\), and the EHV SiO peak ahead of arc \((c)\) (see Fig. C.1). The CO EHV jet at \(4^\circ\) to \(6^\circ\) was not used as a constraint in the \(\chi^{2}\), as numerical simulations show increased deviations from ballistic trajectories beyond the first wiggle wavelength (Masciadri & Raga 2002), but it was used to constrain the wiggling period. Given the complex “loop” effects at small view angle, the temporal variation of jet velocity could
not be inverted separately from the trajectory like for edge-on systems. Since a global inversion procedure lies well beyond the scope of this Letter, we approximated the CO jet velocity variations by a simple piece-wise model, with $V_{jet} = V_{LSR} - V_{sys} = -98.5 \text{ km s}^{-1}$ out to $\approx 3''$, and $V_{jet} = -123.5 \text{ km s}^{-1}$ from 4 to 6'', based on Figure B.3 and discussion in Section 3.2. To restrict parameter space, we fixed $i = 20^\circ$ and considered only circular orbits perpendicular to the jet axis (for the orbital case).

We could find a good match to the observed H$_2$/CO jet wiggling in each of the 3 scenarios. Our best models are plotted in Figure C.1 on top of the H$_2$ jet features from Fig. 4 of HC14, and in Figure B.4 on top of the CO and SiO EHV integrated maps. The good match despite our simplifying assumptions suggests that they should not be too far from the actual solution. The corresponding parameters are listed in Table C.1.

We checked a posteriori if the [FeII] micro-jet extending $0.3''$ from VLA4B at PA = $145^\circ$ (HC14, black segment in Fig. C.1) is consistent with our models. We find that our jet models arising from VLA4B automatically reproduce it to within a few degrees (green and orange in Fig. C.1) where we took $V_{jet} = -148.5 \text{ km s}^{-1}$ within $0.3''$, cf. HC14). Alternatively, when the H$_2$/CO jet comes from a companion, our best model (see red curve in Figure C.1) intersects in projection the [FeII] jet near the center of inner H$_2$ bubble (a). Both the H$_2$ bubble and the sudden disappearance of the [FeIII] jet might then result from jet collison. In conclusion, the [FeII] jet coming from VLA4B appears consistent with all 3 scenarios.

Orbital models of CO jet wiggling clearly require a closer (so far unseen) companion to VLA4B than VLA4A. A separation of 70 au (ie. VLA4A) with an orbital period $\sim 93$ yr would imply a total mass $M_{tot} \approx 7.35 M_\odot$ (for eccentricity $e = 0.8 - 0$) that is clearly excluded. This directly stems from Kepler's third law $M_{tot}/M_\odot = (a/au)^3 (e/yr^{-1})^{-2}$ with a semi-major axis $a \geq D/(1 + e)$. The second part of Table C.1 lists the constraints on binary separation and individual masses for a more realistic $M_{tot} < 4 M_\odot$ (compatible with the observed luminosity) and a minimum CO jet source mass $M_{COjet} \geq 0.1 M_\odot$. A companion separation 20–32 au is needed, and the CO jet source would be the less massive. The predicted companion positions are marked in Figure C.1.

If CO jet wiggling is instead due to jet precession, the current popular interpretation proposed by Terquem et al. [1999] is that it results from inner disk precession induced by a companion on an inclined orbit. In the case of rigid precession of a uniform disk, truncated at $R = a/3$, Equ. (1) of Terquem et al. [1999] relates the precession period $\tau_p$ to the orbital period as $\tau_p = 0.1 \mu \mu/\sqrt{1 - \mu} \approx M_2/M_{tot}$, with orbital velocity $V_o \leq 1.2 \text{ km s}^{-1}$ (orbital wiggles $\leq 2''$) we infer a planet-mass companion at $\leq 0.5$ au (see Table C.1). However, a disk truncated at 0.15 au seems unlikely to produce a bright CO jet. The condition for rigid precession (Terquem et al. 1999) translates here as $(R/a)\mu \leq (H/0.01R)(\tau_p/100yr)(M_{COjet}/M_\odot)^{1/2}$, with $H$ the scale height. Hence, non-rigid precession of a larger disk induced eg. by VLA4A cannot be excluded, by lack of predictions in this regime.

Fig. E.2. SiO(5–4) channel maps over the same field of view as in Fig. 2 with H$_2$ features from HC14 drawn in red, and PA=155° shown as a black line of length 5″. Red and black crosses mark VLA4B (east) and VLA4A (west), respectively. Complex organic molecules present in this range are identified by red labels in their central emission channel (from Belloche et al., in prep).
Fig. E.3. SO(6_2 – 5_2) channel maps over the same field of view as in Fig. 2, with H\textsubscript{2} features from HC14 drawn in red, and PA=155° shown as a black line of length 5″. Red and black crosses mark VLA4B (east) and VLA4A (west), respectively. Complex organic molecules present in this range are identified by red labels in their central emission channel (from Belloche et al., in prep).
