Abstract

We give polynomial-time algorithms for computing bounds on some of the smaller energy eigenvalues in a spin-1/2 ferromagnetic Heisenberg model with any graph $G$ for the underlying interactions. An important ingredient is the connection between Heisenberg models and the symmetric products of $G$. Our algorithms for computing upper and lower bounds are based on generalized diameters of graphs and isoperimetric inequalities on graphs respectively. Computing the upper bounds amounts to solving the minimum assignment problem on $G$, which has well-known polynomial-time algorithms from the field of combinatorial optimization. Computing the lower bounds amounts to estimating the isoperimetric inequalities of the symmetric product of graphs. By using connections with discrete Sobolev inequalities, we show that this can be performed by considering just the vertex-induced subgraphs of $G$. If we specialize our attention to certain graphs, we can, using a combinatorial perspective, exactly solve the mean-field model and give lower bounds for the spectral gaps of long-range interaction models and percolated mean-field models.

1 Introduction

The Heisenberg model (HM) is a quantum theory of magnetism [Hei28], and is prevalent in many naturally occurring physical systems such in various cuprates [MEU96, CMM01], in solid Helium-3 [Tho65], and more generally in systems with interacting electrons [Blu03]. The HM can also be engineered in ultracold atomic gases [DDL03] and quantum dots [TST04]. Apart from describing actual physical systems, the HM is also especially suited for storing quantum information. This is because by storing quantum information in the symmetric subspace of the underlying spins, the quantum data necessarily resides in a decoherence-free-subspace [ZR97] of any spin-half HM, and is immune from errors. In fact, by using spin-half Heisenberg ferromagnets, quantum information stored in the symmetric subspace of the underlying spins necessarily resides in the system’s ground space [Ouy14]. In practice, there are often small unpredictable perturbations to the system Hamiltonian, and necessitates using quantum error correction [LBW99]. Fortunately, there exists the possibility of quantum error correction within the symmetric subspace by using permutation-invariant codes [Rus00, Ouy14, OF16, Ouy17]. Moreover, if the spectral gap of a Heisenberg ferromagnet can be made to grow with the system size, then excitations from the ground space ought to be suppressed and thereby enable robust storage of quantum information. Here, the spectral gap of a Hamiltonian is the energy difference between its ground state and first excited state. In this sense, the Heisenberg model

Key words and phrases. Spectral graph theory, Quantum Heisenberg ferromagnets.
could allow us to sidestep the need to realize complex four-way interactions to store quantum information in Kitaev’s physical model [Kit03, BK02]. Given the widespread applicability of magnetic material in classical information processing [CG11, Jil15], quantum magnets based on the HM could similarly enable quantum technologies. In addition, the HM also can be used for quantum computation [DBK00], quantum simulation, and has connections with other fields of physics such as string theory [MZ03, AFS04, Kru04, BS05, Dor06]. All this points to the importance of understanding the Heisenberg model.

The central object in this paper is the Heisenberg Hamiltonian (HH). It is the mathematical embodiment of the HM’s energy level structure, and contains all information necessary to derive every property of the HM. More precisely, the HH for spin-half particles in the absence of an external magnetic field is a matrix given by

\[
\hat{H} = -\sum_{\{i,j\}} J_{\{i,j\}} \left( \sigma_i^x \sigma_j^x + \sigma_i^y \sigma_j^y + \sigma_i^z \sigma_j^z - 1 \right),
\]

where \( \mathbf{1} \) is the identity matrix, \( \sigma_i^x, \sigma_i^y \), and \( \sigma_i^z \) as the usual Pauli matrices acting on the \( i \)-th particle, the sets \( \{i, j\} \) are included in the sum whenever particles \( i \) and \( j \) interact, and \( J_{\{i,j\}} \) is an exchange constant which quantifies the strength and nature of the coupling between the particles. Here, we restrict our attention to ferromagnetic HHs, where every exchange constant is non-negative. We write the Hamiltonian in this way because we want the smallest eigenvalue of \( \hat{H} \) to be zero.

Most studies on the HM rely on the Bethe ansatz [Bet31]. In approaches relying on the Bethe ansatz, the structure of the eigenvectors is assumed, and later verified to hold by solving for some of the previously undetermined parameters. This approach has proved hugely successful in 1D Heisenberg models [Hal83, FT84, Kom87, EAT94, Ken85, Ken90, MEU96, Oga16]. Recently, lower bounds have been proved on the average free energy of the HM on lattices with any dimension [CGS15], but bounds on the spectrum of the Heisenberg ferromagnet have yet to be directly addressed. Moreover, while certain other 2D HMs have been studied [SS81, Sha88, BJGER67, CMM01], the question of how to address HMs of potentially arbitrary geometry remains unresolved.

In recent years, there has been a growing interest in determining the computational complexity of solving certain problems in mathematical physics, such as that of computing the ground state energy or the partition function of a physical model. One such study proves that computing the ground state energy of a XY-Heisenberg model of arbitrary geometry is QMA-complete, and thus is likely to be hard to compute [CGW15]. Another study proves that computing partition function of the XY-Heisenberg model within a good approximation can be achieved using polynomial-time algorithms on classical computers [BG17]. One may then wonder how easily the spectrum of the isotropic HM can be computed. In this paper, our objective is considerably more modest; we give efficient polynomial-time algorithms to compute both upper and lower bounds on the eigenvalues of the spin-half isotropic ferromagnetic Heisenberg model in the absence of an external magnetic field.

The main message of this paper is that combinatorics can be useful in analyzing the Heisenberg model, and that bounds on the spectrum of the HM can be easily computed. In a nutshell, we introduce combinatorial tools and algorithms from combinatorial optimization to evaluate bounds for the eigenvalues of HH, using the geometric properties of the underlying graph of interactions. To the best of our knowledge, this is the first time graph-theoretic methods are used to obtain bounds on the eigenvalues of the HH. Our analysis relies mainly on the fact that a ferromagnetic HH can be written as a sum of graph Laplacians (see Theorem 2.1). The graphs of each of these Laplacians are in turn symmetric products of the underlying graph of interactions. We then utilize algorithms from combinatorial optimization to obtain efficiently computable upper and lower bounds for the eigenvalues of the HH.

We begin our paper by explaining how the HH is connected to the symmetric power of graphs in Section 2. These graphs were introduced by Rudolph [Rud02] and subsequently studied [AGRR07] in part because
of their connection with the HH. Once we establish this connection, we turn our attention to the simple problem of determining the spectrum of the mean-field Heisenberg ferromagnet, where every pair of spins interacts with the same exchange constant. It turns out that the language of algebraic combinatorics allows us to determine all the eigenvalues and eigenprojectors of this HH using well-known facts about association schemes.

Generalized diameters of graphs play a central role in deriving upper bounds on the spectrum of HHs, as we shall see in Section 4.2. These generalized diameters can be thought of as the widths of a body when it is interpreted to have a given dimension. The most important feature of our algorithms is that they run much more efficiently than algorithms that attempt to directly evaluate the eigenvalues of the HH. It turns out that computing these generalized diameters is related to a well-known combinatorial problem known as the assignment problem. This can in turn be solved efficiently using the Kuhn-Munkres algorithm [Sch04][Page 52]. Together with analytical bounds on the eigenvalues of a graph based on its generalized diameters by Chung, Yau and Grigoryan [CGY97], we thereby obtain a polynomial-time algorithm for evaluating upper bounds on the eigenvalues of the ferromagnetic HH, which gives us our result in Theorem 4.1. If we are only interested in the smaller eigenvalues of the HH, we can rely on the Alon-Milman bound which just requires a lower bound on the diameters of the symmetric products of the underlying graph of interaction (see Theorem 4.2).

Isoperimetric inequalities play a central role in deriving lower bounds on the spectrum of HHs in this paper. An isoperimetric inequality essentially gives a lower bound on the minimum boundary size of a body with a fixed volume in a given manifold. Specializing this to graphs, we require a lower bound on the minimum cut-size of a subset of k vertices, for every possible choice of k. Such bounds are then called edge-isoperimetric inequalities, which we introduce in Section 5. Based on edge-isoperimetric inequalities of the symmetric products of graphs, we present lower bounds on the eigenvalues of the ferromagnetic HH (see Theorem 5.11). Because deriving edge-isoperimetric inequalities on the symmetric product of graphs, can be potentially difficult, we also derive isoperimetric inequalities on the symmetric product of graphs based on the isoperimetric inequalities on their vertex-induced subgraphs (see Theorem 5.7). The proof of this type of result was first introduced by Chung and Yau in their seminal work on the Sobolev inequalities on graphs [CY95], and naturally requires an introduction to Sobolev inequalities on graphs, which we supply in Section 5.1. Theorem 5.7 then allows us to easily compute lower bounds for some of the eigenvalues of the ferromagnetic HH, as can be seen from Theorem 5.10.

We give lower bounds on the spectral gap of some specialized Heisenberg models that might be of independent interest in Section 6. Namely, we show (i) how the spectrum of the mean-field HH can yield lower bounds on the spectral gaps of D-dimensional Heisenberg ferromagnets with long range interactions, and (ii) how lower bounds on the spectral gap of certain percolated mean-field HMs can be obtained from Corollary 5.9.

Finally in Section 7, we discuss some potential implications of our bounds and algorithms. We then remark on the potential to improve both the upper and lower bounds that we present, by further investigation using a combinatorial approach. We also point out how an advance in the field of approximation algorithms could help to make computing lower bounds for the spectrum of the ferromagnetic HH much more efficient.

2 Graphs and the Heisenberg model

Since we investigate the spectrum of HHs with graphs of varying dimensions, we need to explain what these graphs and their dimensions are. Here, a graph corresponding to a HH comprises of vertices from 1 to n which label the particles, and edges \{u, v\} which label the interaction between particles u and v. A graph’s dimension generalizes from the dimension of continuous manifolds. The edge-boundary of any set of vertices X denoted by ∂X is the set of edges in G with exactly one vertex in X. Suppose that every set
Figure 1: On the left is a graph $G$ with six vertices, and on the right is its symmetric square $G^{[2]}$. The symmetric cube $G^{[3]}$ is depicted in Fig. 4.

$X$ with $k$ vertices in $G$ satisfies the bound $|\partial X| \geq ck^{1-1/\delta}$ for some positive constant $c$ for every $k \leq n/2$. Then we say that $G$ has a dimension of $\delta$ with isoperimetric number $c$. This is analogous to the situation where a manifold with fixed volume $k$ and a surface area of at least $ck^{1-1/\delta}$ for some positive constant $c$ has a dimension of $\delta$. The dimension of a physical system is then the dimension of the corresponding graph of interactions. When the graph has infinite dimensions, we say that its corresponding isoperimetric number is also its expansion constant. The expansion constant is important, because the spectral gap of a graph’s Laplacian is at least its expansion constant.

To understand how precisely HH is related to graphs, we need to define the symmetric product of a graph. The $k$-th symmetric product of a graph $G$ with vertices $V$ and edges $E$ denoted by $G^{[k]}$ is a graph with the following properties. First, $G^{[k]}$ has as its vertices all possible subsets of $V$ of size $k$. Second, the edges of $G^{[k]}$ are the sets $\{X,Y\}$ where (i) $X$ and $Y$ are subsets of $V$ with $k$ vertices, (ii) $X$ and $Y$ have $k-1$ common elements, and (iii) their symmetric difference, the union of the sets without their intersection, is an edge in $E$. In short, $\{X,Y\}$ is an edge in $G^{[k]}$ only if the symmetric difference of $X$ and $Y$ is an edge in $E$, i.e. $X \triangle Y \in E$. Examples of the symmetric product of graphs can be seen in Figure 1 and Figure 4.

Now we proceed to define the Laplacians of $G^{[k]}$. By denoting $|X\rangle$ as a state with the spins labeled by $X$ in the up state and the remaining spins in the down state where $X$ is a subset of vertices in $G$, the Laplacians of $G^{[k]}$ are

$$L_k = \sum_{|X| = k} |\partial X\rangle \langle X| - \sum_{X \triangle Y \in E} (|X\rangle \langle Y| + |Y\rangle \langle X|).$$

(2.1)

Here, each $L_k$ is the Laplacian of the graph $G^{[k]}$ and has rank $\binom{n}{k}$. If we interpret $G^{[k]}$ as a discrete manifold, the eigenvectors and eigenvalues of $L_k$ are its normal modes and associated resonance frequencies.
If we normalize the HH so that every non-zero exchange constant is equal to 1, we get the normalized Hamiltonian

\[
\hat{H}_1 = - \sum_{\{i,j\} \in E} \frac{\sigma_i^+ \sigma_j^- + \sigma_i^- \sigma_j^+ + \sigma_i^z \sigma_j^z - 1}{2}.
\]  

(2.2)

This normalized Hamiltonian \(\hat{H}_1\) is just a sum of pairwise orthogonal matrices \(L_k\) [AGRR07], as we can see from the following theorem.

**Theorem 2.1.** Let \(G = (V, E)\) be a graph with \(n\) vertices. Then \(\hat{H}_1 = L_0 + \cdots + L_n\) where \(L_k\) are as given in Eq. (2.1) and \(\hat{H}_1\) is as given in Eq. (2.2).

This decomposition of the ferromagnetic HH with graph \(G\) as sum of pairwise orthogonal matrices, with each matrix associated with the symmetric products of \(G\), has already been known for years [AGRR07]. It is here where we make this connection explicit.

The decomposition of the normalized Hamiltonian as given in Theorem 2.1 holds because of its fundamental connections with Laplacians in graph theory [Mer98]. Using a graph-theoretic perspective, some trivial properties this normalized Hamiltonian can be easily seen. For example, when the graph \(G\) is connected, each \(L_k\) has exactly one eigenvalue equal to zero with eigenvector equal to the all ones vector on its support [Mer98]. Hence the ground state energy of \(\hat{H}_1\) is zero with degeneracy \(n + 1\), and the ground space is spanned by the Dicke states \(|D^n_k\rangle\) [Ouy14], where \(|D^n_k\rangle\) is a normalized superposition of all \(|X\rangle\) for which \(X\) is a subset of \(\{1, \ldots, n\}\) of size \(k\). Moreover, for any graph, the Laplacians \(L_k\) and \(L_{n-k}\) are unitarily equivalent, because of the equivalence of \(G^k\) and \(G^{(n-k)}\) under set complementation. To see this, denote \(\overline{X}\) as the set complement of \(X \subseteq V\), and note that \(L_{n-k} = U_kL_kU_k^\dagger\) where

\[
U_k = \sum_{X \subseteq V : |X| = k} |\overline{X}\rangle \langle X|.
\]

(2.3)

Hence it suffices to only study Laplacians \(L_k\) for which \(k \leq \frac{n}{2}\).

In this paper, we will focus on the obtaining bounds of the eigenvalues of every \(L_k\), which we denote as \(\lambda_0(L_k), \lambda_1(L_k), \ldots, \lambda_{(n)}(L_k)\). We call \(\lambda_1(L_k)\) the spectral gap of \(L_k\) and \(\lambda_{\max}(L_k) = \lambda_{(n)}(L_k)\) the largest eigenvalue of \(L_k\). We order these eigenvalues so that

\[
0 = \lambda_0(L_k) \leq \cdots \leq \lambda_{(n)}(L_k).
\]

(2.4)

Now we proceed to give the proof of Theorem 2.1.

**Proof of Theorem 2.1.** The first step is to notice that the swap operator two qubits can be written as

\[
(|0\rangle \otimes |0\rangle)(|0\rangle \otimes |0\rangle) + (|0\rangle \otimes |1\rangle)(|1\rangle \otimes |0\rangle) + (|1\rangle \otimes |0\rangle)(|0\rangle \otimes |1\rangle) + (|1\rangle \otimes |1\rangle)(|1\rangle \otimes |1\rangle),
\]

(2.5)

and is identical to the sum

\[
\frac{\sigma_i^+ \sigma_j^- + \sigma_i^- \sigma_j^+ + \sigma_i^z \sigma_j^z + 1}{2}.
\]

(2.6)

Then denoting the operator that swaps qubits \(i\) and \(j\) as \(\pi_{i,j}\), we have the identity

\[
\pi_{i,j} - 1 = \frac{\sigma_i^+ \sigma_j^- + \sigma_i^- \sigma_j^+ + \sigma_i^z \sigma_j^z - 1}{2}.
\]

(2.7)
This allows us to rewrite the normalized HH with a graph $G = (V, E)$ in terms of swap operators, so that
\[
\hat{H}_1 = \sum_{\{i,j\} \in E} (1 - \pi_{i,j}).
\] (2.8)

Next, we let $X$ denote any subset of vertices $V = \{1, \ldots, n\}$. Then for any distinct $i$ and $j$ from the set $V$, we have
\[
\pi_{i,j}|X\rangle = \begin{cases} |X\rangle & , i, j \in X \\ |X\rangle & , i, j \notin X \\ |X\triangle\{i,j\}\rangle & , \{i,j\} \in \partial X \end{cases}.
\] (2.9)

This allows us to obtain
\[
\sum_{\{i,j\} \in E} \pi_{i,j}|X\rangle = \sum_{\{i,j\} \in \partial X} \pi_{i,j}|X\rangle + \sum_{\{i,j\} \notin \partial X} \pi_{i,j}|X\rangle = \sum_{\{i,j\} \in \partial X} |X\triangle\{i,j\}\rangle + \sum_{\{i,j\} \notin \partial X} |X\rangle
\]
\[
= \sum_{\{i,j\} \in \partial X} |X\triangle\{i,j\}\rangle + (m - |\partial X|)|X\rangle,
\] (2.10)

where $m$ denotes the number of edges in $E$. Hence
\[
\hat{H}_1|X\rangle = \sum_{\{i,j\} \in E} |X\rangle - \sum_{\{i,j\} \notin \partial X} \pi_{i,j}|X\rangle
\]
\[
= |\partial X||X\rangle - \sum_{\{i,j\} \in \partial X} |X\triangle\{i,j\}\rangle.
\] (2.11)

Clearly if $Y$ is a subset of $V$ that has a different size from $X$, then $\langle Y|\hat{H}_1|X\rangle = 0$. This immediately implies that $\hat{H}_1$ can be written as a sum of orthogonal matrices, each of them supported on the space spanned by $|X\rangle$ where $X$ have constant size. Next, note that $\langle X|\hat{H}_1|X\rangle = |\partial X|$, which implies that the diagonal entries of $L$ are given by the sizes of the corresponding edge-boundaries of $k$-sets. Finally, note that if $Y$ has the same size as $X$, then $\langle Y|\hat{H}_1|X\rangle = 0$ whenever $X \triangle Y \notin E$ and $\langle Y|\hat{H}_1|X\rangle = 0$ whenever $X \triangle Y \in E$. This proves the result. \hfill \Box

### 3 Exact solutions for the mean-field model

We begin with a combinatorial approach for producing the exact solution for a mean-field HM. Such a HM has $n$ spins, and every pair of spin interacts with exactly the same exchange constant $J$. In this case, the normalized Hamiltonian is
\[
\hat{H}_1 = -\sum_{i=1}^{n} \sum_{j=1}^{i-1} \frac{\sigma_i^x \sigma_j^x + \sigma_i^y \sigma_j^y + \sigma_i^z \sigma_j^z - 1}{2}.
\] (3.1)

Moreover, the graph of interactions is precisely the complete graph on $n$ vertices. The symmetric products of the complete graph are the Johnson graphs for which the spectral problem has been exactly solved using association schemes [Del73, BI84]. Using this connection, we can use prior knowledge of the Johnson schemes to conclude that $L_k$ has exactly one eigenvalue equal to zero, and its other eigenvalues are $j(n+1-j)$ with multiplicities $m_j = \binom{n}{j} - \binom{n}{j-1}$ for $j = 1, \ldots, k$ [BH11, Section 12.3.2]. Hence the positive eigenvalues of $\hat{H}_1$ are
\[
j(n+1-j)
\] (3.2)
with multiplicities

\[(n + 1 - 2j)m_j, \quad (3.3)\]

where \(j = 1, \ldots, \lfloor n/2 \rfloor\). Thus, the mean-field Heisenberg ferromagnet’s spectral gap grows linearly with the number of spins in the system.

What is most remarkable about the connection between association schemes and the mean-field Heisenberg model is that we can assign a combinatorial interpretation to the matrices \(L_k\). In particular, we can analytically decompose \(L_k\) as a linear combination of eigenprojectors, where each eigenprojector is in turn a linear combination of generalized adjacency matrices. We proceed to explain what these generalized adjacency matrices are. Now the adjacency matrix of \(L\) is

\[A_{k,1} = \sum_{|X \triangle Y| = 2} (|X\rangle \langle Y| + |Y\rangle \langle X|). \quad (3.4)\]

Namely, the matrix element of \(A_{k,1}\) labeled by \(|X\rangle \langle Y|\) has a coefficient of 1 if \(X\) is adjacent to \(Y\) in \(G^{(k)}\), and equal to zero otherwise. Since two vertices in a graph are adjacent if and only if they are a distance of one apart, we can define the generalized adjacency matrices by having

\[A_{k,z} = \sum_{X, Y \in \{1, \ldots, n\}} \sum_{|X \triangle Y| = 2z} |X\rangle \langle Y|. \quad (3.5)\]

Here, the matrix element of \(A_{k,z}\) labeled by \(|X\rangle \langle Y|\) has a coefficient of 1 if \(X\) is a distance of \(z\) from \(Y\) in \(G^{(k)}\), and equal to zero otherwise. We call \(A_{k,z}\) the \(z\)-th generalized adjacency matrix of the Johnson graph associated with \(L_k\) relating \(k\)-sets a distance of \(z\) apart. For completeness, let \(A_{k,0}\) denote a size \(\binom{n}{k}\) identity matrix. Now let

\[h_{k,j}(z) = m_j \sum_{a=0}^{j} (-1)^{a} \binom{d}{a} \binom{n+1-j}{a} \binom{z}{a} \quad (3.6)\]

denote a Hahn polynomial. Then, properties of the Johnson scheme given in Ref. [DL98] imply that for \(k = 1, \ldots, \lfloor n/2 \rfloor\), the Laplacians \(L_k\) have the spectral decomposition

\[L_k = \sum_{j=1}^{k} j(n + 1 - j)P_{k,j} \quad (3.7)\]

where

\[P_{k,j} = \frac{1}{\binom{n}{k}} \sum_{z=0}^{\lfloor n/2 \rfloor} h_{k,j}(z)A_{k,z} \quad (3.8)\]

are pairwise orthogonal projectors. To make the spectral decomposition of the normalized mean-field HH explicit, we present the following theorem.

**Theorem 3.1.** Let \(G = (V, E)\) be a complete graph. Then a normalized HH on this graph \(\hat{H}_1\) has the spectral decomposition

\[\hat{H}_1 = \sum_{j=1}^{(n-1)/2} j(n + 1 - j) \sum_{k=j}^{(n-1)/2} \left( P_{k,j} + U_k P_{k,j} U_k^\dagger \right) \quad (3.9)\]

when \(n\) is odd, and

\[\hat{H}_1 = \sum_{j=1}^{n/2-1} j(n + 1 - j) \sum_{k=j}^{n/2-1} \left( P_{k,j} + U_k P_{k,j} U_k^\dagger \right) + \frac{n}{2} \left( \frac{n}{2} + 1 \right) P_{n/2,n/2} \quad (3.10)\]

when \(n\) is even.
4 Upper bounds for the Heisenberg spectrum

4.1 Simple two-sided bounds on the largest eigenvalue

We obtain bounds on the largest eigenvalue of ferromagnetic HHs with graphs having dimension $\delta$, isoperimetric number $c$, and maximum vertex degrees $\beta$. Note that obtaining bounds on the largest eigenvalue of the normalized HH $\hat{H}_1$, amounts to obtaining bounds on $\lambda_{\text{max}}(L_k)$. Now the largest eigenvalue of the Laplacian of any graph is at least its maximum vertex degree [Mer94] and at most twice its maximum vertex degree [Ger31, Var04]. Thus,

\[ c k^{1-1/\delta} \leq \lambda_{\text{max}}(L_k) \leq 2k\beta \tag{4.1} \]

for $1 \leq k \leq n/2$. Since $\hat{H}_1 = L_0 + \cdots + L_n$, we get

\[ c \lfloor n/2 \rfloor^{1-1/\delta} \leq \lambda_{\text{max}}(\hat{H}_1) \leq n\beta. \tag{4.2} \]

4.2 Upper bounds from graph diameters

In this subsection, we outline an algorithmic approach for finding upper bounds on the smaller eigenvalues of the HH. This approach relies crucially on the generalizations of the diameter of a graph. The diameter of a graph is the length of its shortest path, and intuitively measures the size of the graph. In the case when the graph has the geometry of a hypercube of dimension $d$, its diameter will be the length between the vertices of the hypercube that are furthest apart. The generalization of the diameter that we will consider allows us to quantify, in the case of the hypercube, the length of its sides. In particular, the $d$-diameter of a $d$-dimensional hypercube will be precisely the length of its side. Intuitively, the $d$-diameter of a body is its width when it is interpreted to have $d$ dimensions. The generalized diameters are important because they can give upper bounds on the eigenvalues of a graph Laplacian [CGY96, CGY97].

The generalized diameter of a graph quantifies its sparsity. It is then reasonable to expect that the larger the generalized diameter, the smaller the upper bound on the eigenvalues can be, since a sparse graph ought to have smaller eigenvalues than a highly connected graph. In the extreme case when a graph comprises of disconnected vertices, its generalized distances are all infinite, and every eigenvalue is equal is zero. Thus in this case, we would anticipate that the upper bound we get from the diameter is also equal to zero. This is indeed the case. Hence, in this sense, the bound of [CGY97] can be said to be tight.

To understand the generalized diameter of a graph, we need to review the concept of the distance amongst a subset of its vertices. Now, the distance between a pair of vertices $v_a$ and $v_b$ is the just the length of the shortest path connecting them, which we denote as $d(v_a, v_b)$. The distance between a set of vertices $K = \{v_1, \ldots, v_k\}$ is then the minimum pairwise distance between distinct vertices $v_a$ and $v_b$, which we denote as

\[ d(K) = \min\{d(v_a, v_b) : 1 \leq a < b \leq k\}. \tag{4.3} \]

The $j$-diameter of a graph $G = (V, E)$ has been defined [CGY97] as the maximum distance of subsets $K$ with $(j + 1)$ vertices, and we denote it as

\[ d_j(G) = \max\{d(K) : K \subseteq V, |K| = j + 1\}. \tag{4.4} \]

Upper bounds on the eigenvalues of $L_k$ can be obtained $d_{j,k}(G^{[k]})$, the $j$-diameter of $G^{[k]}$ using the graph-theoretic results of Ref. [CGY97][Corollary 4.4]. Namely, whenever $d_{j,k} \geq 2$, then

\[ \lambda_j(L_k) \leq \lambda_{\text{max}}(L_k) \left(1 - 2/ \left(1 + \binom{n}{k}^{1/(d_{j,k}-1)}\right)\right). \tag{4.5} \]
Clearly \( d_{j,k} \) decreases with increasing \( j \), and thus our upper bounds on \( \lambda_j(L_k) \) are increasing with \( j \) as one would expect.

Since the \( j \)-diameter of \( G^{(k)} \) may be unwieldy to calculate directly, we outline a polynomial time algorithm to obtain lower bounds on it. At the heart of our algorithm is the fact that the distances between vertices in \( G^{(k)} \) can be computed using only information about the distances between vertices in \( G \). This makes it possible to estimate the \( j \)-diameter of \( G^{(k)} \) solely by computing on the graph \( G \). Before diving into the specifics of our algorithm, we briefly outline its inner workings.

1. Pick any \( j + 1 \) distinct vertices \( X_1, \ldots, X_{j+1} \) from \( G^{(k)} \). Note that each of these vertices are subsets of \( V \), each with \( k \) elements.
2. Loop over all \( a, b \) such that \( 1 \leq a < b \leq j + 1 \).
3. Compute \( d(X_a, X_b) \).
4. Exit loop.
5. A lower bound for \( d_j(G^{(k)}) \) is the minimum \( d(X_a, X_b) \).

This procedure can in principle be repeated for all possible choices of \( X_1, \ldots, X_{j+1} \) to obtain the value of \( d_j(G^{(k)}) \) exactly. Since this may be computationally expensive, we propose just to randomly select the vertices \( X_1, \ldots, X_{j+1} \) a constant number of times. Obviously the complexity of such an algorithm depends on the complexity of Step 3 of this procedure, where the \( d(X_a, X_b) \) is evaluated.

A direct attack on evaluating \( d(X_a, X_b) \) might seem to take time with complexity \( O(k!) \) and hence not be polynomial in \( n \). This is because the distance between \( X_a = \{x_1, \ldots, x_k\} \) and \( X_b = \{y_1, \ldots, y_k\} \) with respect to \( G^{(k)} \) is the sum of the distances with respect to \( G \) between \( x_j \) and \( y_{\pi(j)} \), minimized over all permutations \( \pi \) that permute \( k \) symbols. There are then \( k! \) possible permutations and \( k \) distances to sum for each instance. This however is not the case, since the problem of evaluating \( d(X_a, X_b) \) is actually equivalent to the minimum assignment problem, which can be solved in \( O(k^3) \) time using the celebrated Kuhn-Munkres algorithm [Sch04][Page 52], after one first computes all pairwise distances in \( G \).

We now explain how combinatorial optimization algorithms from graph theory can be used to compute lower bounds on \( d_{j,k} \) can be evaluated in polynomial time.

1. Algorithm 1 computes the all pairwise distances in \( G \). This is achieved using breath-first-search on every vertex. Since breath-first search on any vertex produces a shortest path tree in linear time [Sch04][Theorem 6.4], and there are \( n \) such vertices, Algorithm 1 runs in \( O(n^2) \) time.
2. Algorithm 2 evaluates distances between given vertices in \( G^{(k)} \). It turns out that the evaluation of \( d(X_a, X_b) \) is equivalent to the well-known minimum assignment problem in the field of combinatorial optimization. First, evaluate \( Z = X_a \cap X_b \) and set \( X = X_a \setminus Z \) and \( Y = X_b \setminus Z \). Consider a complete bipartite graph with every vertex in \( x \in X \) is connected to a vertex for \( y \in Y \) by a weighted edge. The weight of the edge \( \{x,y\} \) in the bipartite graph is equal to the distance between \( x \) and \( y \) given by \( d(x,y) \). The problem of computing \( d(X_a, X_b) \) is then equivalent to finding the perfect matching (set of edges such that every vertex belongs to exactly one edge) on this bipartite graph, such that the sum of the weights on these matchings is minimized. But this is precisely equal to the minimum assignment problem, which can be solved using the Kuhn-Munkres algorithm. We therefore just need to generate the cost matrix for the minimum assignment problem in this algorithm to utilize the Kuhn-Munkres algorithm.

We would be able to easily compute the generalized diameter of \( G^{(k)} \) exactly, if we only knew how to optimally select \( j + 1 \) of its vertices in \( G^{(k)} \). Without such knowledge, we can use Algorithm 3 to randomly select \( j + 1 \) vertices in \( G^{(k)} \).
Algorithm 1 \texttt{Dist}(G = (V,E)), Compute pairwise distances in G.

\begin{algorithm}
\begin{algorithmic}

\ENDFOR
\ENDFOR
\STATE $d \leftarrow \text{output of Kuhn-Munkres algorithm on the cost matrix } C$
\RETURN $d$
\end{algorithmic}
\end{algorithm}

We completely describe our algorithm to compute upper bounds on the eigenvalues of $L_k$ in Algorithm 4. Since there are $\binom{j+1}{2}$ possible pairwise distances amongst $X_1, \ldots, X_{j+1}$ that we must consider, the time complexity of running Algorithm 4 is

$$O(n^2) + O(j^2k^3).$$

This thereby leads to an algorithm that evaluates a lower bound for $d_{j,k}$ in time polynomial in $n$, $j$ and $k$. This then leads to our formal result, which we give in the following theorem.

**Theorem 4.1.** Let $G = (V,E)$ be any graph with $n$ vertices. Let $2 \leq k \leq n/2$ and $1 \leq j \leq \binom{n}{k} - 1$. Then Algorithm 4 can compute an upper bound on $\lambda_j(L_k)$ in $O(n^2) + O(j^2k^3)$ time.

Thus for all $k$ and $j$ polynomial in $n$, upper bounds on the eigenvalues of the ferromagnetic HH can be computed in time polynomial in $n$. Such an algorithm would outperform a direct solver for Laplacians [ST14] whenever $k \geq 3$. When $j$ is a constant, upper bounds can be evaluated in $O(n^3)$ time, even for $k$ linear in $n$. We illustrate the performance of our upper bound with respect to the discrete torus in Figure 2. Because we intuitively understand the geometry of the discrete torus, we can make strategic selections of $X_1, \ldots, X_{j+1}$ instead of resorting to random selections.

At this point, we want to point out that if we want upper bounds on the spectral gap $\lambda_1(L_k)$, we only need to compute a lower bound on the graph diameter of $L_k$. There is a plethora of known results of such types of bounds, and as an example, we introduce one by Alon and Milman [AM85][Theorem 2.7].

**Theorem 4.2** (Alon and Milman [AM85]). For a connected graph with $n$ vertices with maximum vertex degree $d$ and diameter at least $\rho$, then the spectral gap of its Laplacian is at most $8d \log_2(n)^2 \rho^{-2}$. 

10
Algorithm 3 \( \text{SEL}_k(j, V) \). Select \( j + 1 \) distinct vertices in \( G^{(k)} \)

\[
\begin{align*}
X_1 &\leftarrow \text{a random } k\text{-vertex subset of } V \\
c &\leftarrow 1 \\
\text{while } c \leq j + 1 \text{ do} \\
&\quad Y \leftarrow \text{a random } k\text{-vertex subset of } V \\
&\quad \text{if } Y \cup X_a \neq Y \text{ for all } a = 1, \ldots, c \text{ then} \\
&\quad \quad X_{c+1} \leftarrow Y \\
&\quad \quad c \leftarrow c + 1 \\
&\quad \text{end if} \\
\text{end while} \\
\text{return } (X_1, \ldots, X_{j+1})
\end{align*}
\]

If we further restrict our attention to the spectral gap of \( L_2 \), it is trivial to arrive at analytical bounds for HMs on families of graphs with bounded vertex degree and growing graph diameter.

**Corollary 4.3.** Let \( H_1 \) be the normalized Hamiltonian for a Heisenberg model on \( \mathbb{Z}_n^2 \) or grid \( \{1, \ldots, n\}^2 \) with \( n^2 \) spins, then \( \lambda_1(n_2) \leq O(\log_2(n^2)^2 / n^2) \).

In Figure 2, we can see how the Alon-Milman bound can be superior to the generalized diameter bounds on \( L_2 \) on a discrete torus of sufficiently large size.

5 Lower bounds for the Heisenberg spectrum

A property of graphs that we focus on are their associated isoperimetric inequalities. These isoperimetric inequalities on graphs allow us to define the notion of the dimension of a graph. Now let \( X \) be a set of vertices and \( \partial X \) be its boundary. In this case, the edge boundary of \( X \) is just the set of edges in \( E \) with exactly one vertex in \( X \) and one vertex in \( V \setminus X \). Then the edge-isoperimetric inequality on graphs \([\text{Alo86}]\) is any lower bound of the form

\[
|\partial X| \geq c|X|^{1-1/d}
\]

that holds for every vertex subset \( X \) of size at most half the cardinality of \( V \). The utility of these isoperimetric inequalities in the case of continuous manifolds lies in their applicability for example to give bounds on the principal frequency of a vibrating membrane \([\text{Pay67}]\). The rationale behind seeking edge-isoperimetric inequalities for the graphs \( G^{(k)} \) lies in the fact that such inequalities can yield spectral bounds on the eigenvalues of the normalized Laplacians of \( G^{(k)} \) \([\text{CY95}]\), and hence also of the Laplacians. Since the Heisenberg Hamiltonian is just a direct sum of these Laplacians, these edge-isoperimetric inequalities can then yield bounds on the corresponding energy eigenvalues of the Heisenberg Hamiltonian.

In this section, we prove several technical results relating to the edge-isoperimetric inequalities on the symmetric products of graphs. Roughly speaking, our results allow us to establish the isoperimetric properties of \( G^{(k)} \) in terms of the isoperimetric properties of certain subgraphs of graphs \( G \). In particular, these subgraphs are vertex induced subgraphs of \( G \) where a number of vertices and their corresponding edges are deleted from \( G \). Our first technical result applies to graphs with a countably infinite number of vertices. Our technical result applies to graphs with a finite number of vertices. In Theorem 5.7, we prove that that if deleting any \( k - 1 \) vertices from a finite graph \( G \) yields a vertex induced subgraph that has an isoperimetric number \( C \) and dimension \( \delta \), then a lower bound on the size of the edge-boundary of a subset of vertices \( \Omega \) in \( G^{(k)} \) is given in terms of the size of the edge-boundary of \( \Omega \) in the Johnson graph that is the \( k \)-th symmetric
Figure 2: Here we focus on the spectral gap of $L_2$ for a Heisenberg Hamiltonian on a discrete torus $\mathbb{Z}_n^2$ with $n^2$ qubits. The solid line below gives our lower bound of $\lambda_1(L_2)$ using Theorem 5.10. The solid line above gives our upper bound on $\lambda_1(L_2)$ using a modification of Algorithm 4 where $X_1 = \{0, 1\}$ and $X_2 = \{\lfloor n/2 \rfloor, \lfloor n/2 \rfloor + 1\}$. The dotted line is an upper bound on $\lambda_1(L_2)$ using the distance between $X_1$ and $X_2$ and Alon-Milman upper bound of Theorem 4.2.
Algorithm 4 \texttt{Upp}(j,k,G = (V,E)), Upper bounds on $\lambda_j(L_k)$.

The product of the complete graph. This leads us to Corollary 5.8 and 5.9 which give the corresponding isoperimetric bounds on the $G^{(k)}$, in both cases where $G$ has infinite dimensions and when the vertex-induced subgraphs of $G$ have finite dimensions.

The proof relies crucially on the fact that the size of an edge boundary of a set $X$ can be written as a Sobolev seminorm of the indicator function of $X$. This implies that edge-isoperimetric inequalities can be written in terms of the Sobolev seminorm of an indicator function and an appropriate functional of that indicator function, as we shall see in Section 5.1. Also, we use Tillich’s observation of a one-to-one correspondence between edge-isoperimetric inequalities and inequalities relating the Sobolev seminorm of functions and an appropriate functional evaluated on those functions. Together, these insights allow us to obtain lower bounds on the size of the edge-boundary of the subsets of vertices in $G^{(k)}$.

5.1 Sobolev inequalities on graphs

Recall that an edge-isoperimetric inequality for a graph $G = (V,E)$ has the form
\begin{equation}
|\partial X| \leq C|X|^{1-1/d}, \quad \forall X \subseteq V : |X| = k,
\end{equation}
where $k = 1, \ldots, |V|/2$. The point of this section is that the size of the edge-boundary $|\partial X|$ can be written in terms of a discrete Sobolev seminorm, and this allows us to obtain some interesting insights. Namely, given a graph $G = (V,E)$ and a function $f : V \to \mathbb{R}$ on the vertex set, the discrete Sobolev seminorm of $f$ corresponding to the edge set $E$ is defined by
\begin{equation}
\|f\|_E = \sum_{\{u,v\} \in E} |f(u) - f(v)|.
\end{equation}
Now consider the case where \( f = 1_X \) where \( 1_X : V \rightarrow \{0, 1\} \) is an indicator function on \( X \) so that for all \( X \subseteq V \), \( 1_X(x) = 1 \) if \( x \in X \) and \( 1_X(x) = 0 \) if \( x \in V \setminus X \). Then it is clear that

\[
|\partial X| = \|1_X\|_E. \tag{5.3}
\]

We call any inequality which involves the seminorm \( \| \cdot \|_E \), such as the one above, a discrete Sobolev inequality.

The analytic inequalities of Tillich [Til00] establish the equivalence between edge-isoperimetric inequalities and discrete Sobolev inequalities on functionals that map functions from \( \Phi_V \) to non-negative real numbers, where \( \Phi_V \) denotes the set of all functions \( f : V \rightarrow \mathbb{R} \). To state Tillich’s theorem succinctly, we introduce the following definition.

**Definition 5.1.** Given \( C > 0 \) and a functional \( \rho : \Phi_V \rightarrow \mathbb{R} \), we say that \( G \) is \((C, \rho)\)-isoperimetric if for every \( X \subseteq V \), \( \|1_X\|_E \geq C\rho(1_X) \).

We state Tillich’s result on functionals that are also seminorms in the following theorem.

**Theorem 5.2** (Tillich [Til00]). Let \( G = (V, E) \) be a graph, \( C > 0 \), and \( \rho \) be a seminorm on \( \Phi_V \). Then \( G \) is \((C, \rho)\)-isoperimetric if and only if \( \|f\|_E \geq C\rho(f) \) for every function \( f : V \rightarrow \mathbb{R} \).

Tillich used the co-area formula to prove Theorem 5.2. The co-area formula is well known, and its proof can be found in [Til00] for instance.

**Lemma 5.3.** [Co-area formula] Let \( G = (V, E) \) be a graph and \( f : V \rightarrow \mathbb{R} \) be a non-negative function. Let \( \Omega_t = \{ x \in V : f(x) > t \} \). Then

\[
\|f\|_E = \int_0^\infty |\partial \Omega_t|dt = \int_0^\infty \|1_{\Omega_t}\|_E dt.
\]

We prove Theorem 5.2 for completeness because we could not find the complete proof in print.

**Proof of Theorem 5.2.** If \( \|f\|_E \geq C\rho(f) \), substituting \( f = 1_X \) for any subset \( X \subseteq V \) implies that \( \|1_X\|_E \geq C\rho(1_X) \) and hence \( G \) is \((C, \rho)\)-isoperimetric.

To prove the converse, Tillich used Lemma 5.3 to prove that

\[
\|f\|_E \geq C \left\{ \int_0^\infty \rho(1_{\Omega^+_t})dt + \int_0^\infty \rho(1_{\Omega^-_t})dt \right\},
\]

where \( \Omega^+_t = \{ x \in V : \max(f(x), 0) \geq t \} \) and \( \Omega^-_t = \{ x \in V : \max(-f(x), 0) \geq t \} \). Linearity of the integral and the seminorm properties of \( \rho \) then gives

\[
\int_0^\infty \rho(1_{\Omega^-_t})dt + \int_0^\infty \rho(1_{\Omega^-_t})dt = \int_0^\infty \rho(1_{\Omega^+_t})dt + \int_0^\infty \rho(-1_{\Omega^-_t})dt
\]

\[
\geq \int_0^\infty \rho(1_{\Omega^+_t} - 1_{\Omega^-_t})dt
\]

\[
= \rho \left( \int_0^\infty (1_{\Omega^+_t} - 1_{\Omega^-_t})dt \right).
\]

Noting that \( \int_0^\infty (1_{\Omega^+_t} - 1_{\Omega^-_t})dt = f(x) \) for all \( x \in V \) completes the proof.
In this article, we restrict our attention to the functionals \( g_p \) and \( \rho_p \) for \( p \geq 1 \), where

\[
g_p(f) = \left( \frac{1}{|V|} \sum_{x,y \in V} |f(x) - f(y)|^p \right)^{1/p}, \tag{5.4}
\]

\[
\rho_p(f) = \left( \sum_{x \in V} |f(x) - \mathbb{E}(f)|^p \right)^{1/p}, \tag{5.5}
\]

where

\[
\mathbb{E}(f) = \frac{1}{|V|} \sum_{v \in V} f(v) \tag{5.6}
\]
denotes the expectation value of \( f \). It is then easy to show that

\[
g_p(1_X) = \left( \frac{2|X||V \setminus X|}{|V|} \right)^{1/p}, \tag{5.7}
\]

\[
\rho_p(1_X) = \left( \sum_{x \in V} |1_X(x) - |X||^p \right)^{1/p}. \tag{5.8}
\]

The discrete Sobolev inequality is closely related to the isoperimetric number and dimension of a graph as given in the following proposition, which is obvious from definitions.

**Proposition 5.4.** Let \( G = (V, E) \) be graph and \( C > 0 \) and \( \delta > 1 \). Then the following are true.

1. If \( V \) is finite and \( G \) is \((C, g_{\delta/(\delta-1)})\)-isoperimetric, then \( G \) has a dimension of \( \delta \) with isoperimetric number \( C \).

2. If \( V \) is finite and \( G \) has a dimension of \( \delta \) with isoperimetric number \( C \), then \( G \) is \((2^{-\delta/(\delta-1)}C, g_{\delta/(\delta-1)})\)-isoperimetric.

Hence we can address finite-sized graphs with the functionals \( \rho_p \) using the two-sided bounds on \( \rho_p(1_X) \) in terms of \( g_p(1_X) \) as given in the following lemma.

**Lemma 5.5.** Let \( G = (V, E) \) be a graph, \( X \subseteq V \) and \( p \geq 1 \). Then

\[
\frac{1}{2^{1-1/p}} g_p(1_X) \leq \rho_p(1_X) \leq g_p(1_X).
\]

**Proof.** By definition, \( \rho_p(1_X) = \left( \sum_{x \in V} \left| 1_X(x) - \frac{|X|}{|V|} \right|^p \right)^{1/p} \). Splitting the summation over \( V \) into the disjoint subsets \( X \) and \( V \setminus X \) yields

\[
\rho_p(1_X) = \left( |X| \left( 1 - \frac{|X|}{|V|} \right)^p + (|V| - |X|) \left( \frac{|X|}{|V|} \right)^p \right)^{1/p}. \tag{5.9}
\]

Since \( \left( 1 - \frac{|X|}{|V|} \right)^p \leq \left( 1 - \frac{|X|}{|V|} \right) \) and \( \left( \frac{|X|}{|V|} \right)^p \leq \left( \frac{|X|}{|V|} \right)^p \) for \( p \geq 1 \), we get \( \rho_p(1_X) \leq g_p(1_X) \). Since both \( |X| \left( 1 - \frac{|X|}{|V|} \right)^p \) and \( |V \setminus X| \left( \frac{|X|}{|V|} \right)^p \) are at least \( \left( \frac{|X||V \setminus X|}{|V|} \right)^{1/2} \), we get \( \rho_p(1_X) \geq g_p(1_X) (1/2^{p-1})^{1/p} \).

Lemma 5.5 implies the following for \( C > 0 \) and \( \delta > 1 \).

1. If a graph is \((C, g_{\delta/(\delta-1)})\)-isoperimetric, the graph also has a dimension of \( \delta \) with an isoperimetric number of \( 2^{-\delta}C \).

2. If a graph has a dimension of \( \delta \) with an isoperimetric number of \( C \), the graph is also \((2^{-\delta/(\delta-1)}C, g_{\delta/(\delta-1)})\)-isoperimetric.

In what follows, we use Theorem 5.2 where \( \rho = \rho_p \) for \( p \geq 1 \).
5.2 The symmetric product of finite graphs

Now we address the edge-isoperimetric problem on the graph $G^{(k)}$ when $G$ has a finite number of vertices, for a fixed positive integer $k = 2, \ldots, |V|/2$. Again we rely on the edge-isoperimetric properties of the vertex-induced subgraphs of a graph $G$. Here, we use the seminorm $\rho_p$ with Theorem 5.7 for $p \geq 1$. A key ingredient of our proof is a bijection between sets, described by the following proposition.

**Proposition 5.6.** Let $V$ be a countable set and $k$ be an integer such that $k = 1, \ldots, |V|$. Then the sets $\mathcal{A} = \{(W,x) : W \subseteq V, |W| = k - 1, x \in V \setminus W\}$ and $\mathcal{A}' = \{(X,x) : W \subseteq V, |X| = k, x \in X\}$ have the same cardinality.

**Proof.** Let $f : \mathcal{A} \rightarrow \mathcal{A}'$ where $f \rightarrow (W,x) = (W \cup \{x\}, x)$ for all $W \subseteq V$ and $x \in V \setminus W$. The map $f$ is invertible, and is therefore a bijection from $\mathcal{A}$ to $\mathcal{A}'$. Hence $\mathcal{A}$ and $\mathcal{A}'$ have the same cardinality. \hfill $\Box$

We obtain here a lower bound on $|\partial \Omega|$, which is the size of the edge boundary of any vertex subset $\Omega$ in $G^{(k)}$. Our lower bound on $|\partial \Omega|$ is provided in terms of $|\partial_J \Omega|$, which is the size of the edge boundary of $\Omega$ in the Johnson graph $J(n,k)$.

**Theorem 5.7.** Let $G = (V,E)$ be a graph with $n$ vertices, and let $p \geq 1$ and $C > 0$. Suppose that every vertex-induced subgraph of $G$ with $n - k + 1$ vertices is $(C, \rho_p)$-isoperimetric. Then for every $\Omega \subseteq V^{(k)}$, 

$$|\partial \Omega| \geq \frac{C}{n-k+1} (|\partial_J \Omega|)^{1/p}. $$

Note that the inequality in Theorem 5.7 is tight. To see this, consider the symmetric product of the complete graph.

**Proof of Theorem 5.7.** For all $\Omega \subseteq V^{(k)}$, note that $|\partial \Omega| = \|\Omega \|_{E(V)}$. Two $k$-sets $X$ and $Y$ in $\Omega$ are adjacent in the graph $G^{(k)}$ if and only if the symmetric difference of $X$ and $Y$ is an edge in $E$. Hence 

$$|\partial \Omega| = \sum_{W \subseteq V} \sum_{|W| = k - 1} |\Omega(W \cup \{u\}) - \Omega(W \cup \{v\})|. \tag{5.10}$$

Applying Theorem 5.2 with seminorm $\rho_p$ on each induced subgraph $G[V \setminus W]$ for every $(k-1)$-set $W$ with respect to the function $\Omega(W \cup \{\cdot\})$, we get

$$|\partial \Omega| \geq \sum_{W \subseteq V} C \left( \sum_{x \in V \setminus W} |\Omega(W \cup \{x\}) - \sum_{y \in V \setminus W} \Omega(W \cup \{y\})|^{p} \right)^{1/p}. \tag{5.11}$$

By subadditivity of the function $(\cdot)^{1/p}$ for all $p \geq 1$, the inequality (5.11) becomes

$$|\partial \Omega| \geq C \left( \sum_{W \subseteq V} \sum_{x \in V \setminus W} |\Omega(W \cup \{x\}) - \sum_{y \in V \setminus W} \Omega(W \cup \{y\})|^{p} \right)^{1/p}. \tag{5.12}$$

By Proposition 5.6 we can reorder the summation in (5.12) to get

$$|\partial \Omega| \geq C \left( \sum_{X \in V^{(k)}} \sum_{x \in X} |\Omega(X) - \sum_{y \in V \setminus (X \setminus \{x\})} \Omega(X \setminus \{x\})|^{p} \right)^{1/p}. \tag{5.13}$$
Each $k$-set $X$ appearing in the inequality (5.13) either belongs to $\Omega$ or not. Applying simple arithmetic on the right hand side of (5.13) above then yields

$$C \left( \sum_{x \in \Omega} \left( \sum_{y \in V \setminus (X \setminus \{x\})} \frac{1 - \mathbf{1}_\Omega(X \triangle \{x, y\})}{n - k + 1} \right)^p \right) + C \sum_{x \in \Omega} \left( \sum_{y \in V \setminus (X \setminus \{x\})} \frac{\mathbf{1}_\Omega(X \triangle \{x, y\})}{n - k + 1} \right)^p \right)^{1/p} = (5.14)$$

Using the inequality $(\sum_i x_i)^p \geq \sum_i x_i^p$ for non-negative $x_i$, the expression (5.14) becomes

$$C \left( \sum_{x \in \Omega} \sum_{y \in V \setminus (X \setminus \{x\})} \sum_{j=1}^n \frac{1 - \mathbf{1}_\Omega(X \triangle \{x, y\})}{(n - k + 1)^p} \right) + C \sum_{x \in \Omega} \sum_{y \in V \setminus (X \setminus \{x\})} \frac{\mathbf{1}_\Omega(X \triangle \{x, y\})}{(n - k + 1)^p} \right)^{1/p}$$

$$= \frac{C}{n - k + 1} \left( \sum_{x \in \Omega} \sum_{y \in V \setminus (X \setminus \{x\})} \sum_{j=1}^n \mathbf{1}_\Omega(X \triangle \{x, y\}) \right)^{1/p}$$

To complete the proof, note that

$$\sum_{x \in \Omega} \sum_{y \in V \setminus (X \setminus \{x\})} \mathbf{1}_\Omega(X \triangle \{x, y\}) = |\partial_j \Omega|.$$

The eigenvalues of the combinatorial Laplacian of the Johnson graph $J(n,k)$ for $k = 0, \ldots, \lfloor n/2 \rfloor$ are $j(n+1-j)$ with multiplicities $\binom{n}{j} - \binom{n}{j+1}$, where $j = 0, \ldots, k$ [BH11, Section 12.3.2]. If $\lambda$ is the second smallest eigenvalue of the combinatorial Laplacian of a graph, then that graph is $(\frac{n}{2}, g_1)$-isoperimetric [GR01, Lemma 13.7.1]. Since the second smallest eigenvalue of the combinatorial Laplacian of the Johnson graph $J(n,k)$ is always $n$, $|\partial_j \Omega| \geq \frac{n}{2} g_1(1_\Omega)$ for every $\Omega \subseteq V^{(k)}$. Hence

$$\left(2 |\partial_j \Omega|\right)^{1/p} \geq \left( ng_1(1_\Omega) \right)^{1/p} = n^{1/p} g_p(1_\Omega).$$

Using (5.15) with Theorem 5.7 together with Lemma 5.5 yields the following corollary.

**Corollary 5.8.** Let $G = (V,E)$ be a graph with $n$ vertices, and let $p \geq 1$ and $C > 0$. Suppose that every vertex-induced subgraph of $G$ with $n - k + 1$ vertices is $(C, \rho_p)$-isoperimetric. Then $G^{(k)}$ is $(\frac{Cn}{n-k+1}, g_p)$-isoperimetric and $(\frac{Cn}{n-k+1}, p_p)$-isoperimetric.

If a graph is $(C, \rho_1)$-isoperimetric, its vertex-induced subgraphs $G[V \setminus W]$ are $(C - |W|, \rho_1)$-isoperimetric for every $W \subseteq V$ [GR01, Theorem 13.5.1]. This together with (5.15) and the fact that $g_1(1_\Omega) = \rho_1(1_\Omega)$ from Lemma 5.5 yields the following corollary.

**Corollary 5.9.** Let $G = (V,E)$ be a graph with $n$ vertices that is $(C, \rho_1)$-isoperimetric, and let $k = 2, \ldots, \lfloor n/2 \rfloor$. Then $G^{(k)}$ is $(\frac{n C^{k+1}}{n-k+1}, \rho_1)$-isoperimetric.

These two corollaries will play a central role in the next subsection.

### 5.3 Lower bounds from isoperimetric considerations

If one were to compute the eigenvalues of $L_k$ directly, one may quickly run into computational difficulties. The reason is twofold. First, the size of the matrix $L_k$ is $\binom{n}{k}$, and in general scales exponentially with $n$. This leads to the difficulty in evaluating the eigenvalues of $L_k$ when one does not desire to utilize a computer with both exponential memory that runs in exponential time. In view of this problem, our methodology of obtain
lower bounds on the eigenvalues of $L_k$ will be handy. The algorithms to compute lower bounds that we introduce from graph theory will considerably outperform algorithms that directly compute the eigenvalues of $L_k$.

There are two important types of lower bounds that we will focus our attention on. The first type of lower bound will be on the spectral gaps of $L_k$, and the second type of lower bound will be on all other eigenvalues of $L_k$. The first type of lower bound will, as one would intuitively expect, be much easier to compute than the second type. This is because the second type of lower bound gives far more information than the first type of lower bound. Underlying these two types of bound though, is a common methodology; instead of studying the symmetric products $G^{(k)}$, we may restrict our attention to the vertex-induced subgraphs of $G$, using results from the previous subsection.

When one deletes vertices from a graph $G$ along with the corresponding edges, one obtains a vertex-induced subgraph of $G$. We denote the set of all graphs obtained by deleting exactly $k−1$ vertices from $G$ as $\mathcal{Y}(G,k)$. Clearly, there are $\binom{n}{k−1}$ graphs in the set $\mathcal{Y}(G,k)$. From Corollary 5.8, we know that if $C$ is less than the isoperimetric number of every graph in $\mathcal{Y}(G,k)$ with corresponding dimension $\delta$, then the graph $G^{(k)}$ has an isoperimetric dimension of $\delta$ with isoperimetric number at least

\[
C \frac{n−1−1/\delta}{n−k+1}.
\]  

Specializing this result to the case where $\delta = \infty$, the graph $G^{(k)}$ then has an expansion constant that is at least $C \frac{n}{n−k+1}$. Since the expansion constant of a connected graph is also its spectral gap, we thereby can obtain a lower bound on the spectral gap of $L_k$ in terms of the spectral gaps of the graphs in $\mathcal{Y}(G,k)$. In particular, we have the following.

**Theorem 5.10.** Let $G$ be a graph with $n$ vertices. Then for all $k = 1, \ldots, n/2$,

\[
\lambda_1(L_k) \geq \frac{n}{n−k+1} \min_{K \in \mathcal{Y}(G,k)} \lambda_1(K).
\]

In the special case of $k = 2$, the lower bound of Theorem 5.10 becomes extremely simple. It is

\[
\lambda_1(L_2) \geq \lambda_1(K)
\]

for any $K \in \mathcal{Y}(G,2)$. This means that the spectral gap of the symmetric square of $G$ is just the minimum spectral gap of all graphs obtained from $G$ by deleting a single vertex.

One might wonder if having to consider so many vertex-induced subgraphs of $G$ in order to compute bounds on its spectral gap might seem excessively cumbersome. To address this possible concern, we emphasize that in the case of translational-invariant graphs, to obtain the spectral gap of $L_2$, it suffices to evaluate the spectral gap of the graph obtained from $G$ by deleting any one of its vertices. Therefore in this case, evaluating Eq. (5.17) involves finding the spectral gap of size $n$ matrix, which outperforms a direct evaluation of $\lambda_1(L_2)$ which would involve finding the spectral gap of a size $n^2$ matrix. To illustrate the performance of our bound, we plot the exact spectral gaps of $L_2$ versus the bounds obtained from Eq.5.17 in Figure 3, using the graph with the geometry of a 2D torus.

We now proceed to outline how lower bounds on the eigenvalues of $L_k$ can be obtained from geometric considerations the graphs $G^{(k)}$. To achieve this, we will first illustrate how lower bounds on the spectrum of a graph Laplacians can depend only on the graph’s geometry. We begin by introducing some notation. Let $D_G = \sum_{v \in V} d_v |v\rangle \langle v|$ denote the degree matrix of a graph $G = (V,E)$. Let $A_G$ denote the adjacency matrix of a graph, which means that it is a matrix with matrix elements equal to either 0 or 1, and where $\langle u|A_G|v\rangle = 1$ iff the vertex $u$ is adjacent to $v$. Let $L_G$ denote the Laplacian of a graph, which can be written as $D_G - A_G$. In this subsection, we have the following theorem.
Figure 3: The line above give the precise spectral gap of $L_2$ for a Heisenberg Hamiltonian on a discrete torus $\mathbb{Z}_n^2$ with $n^2$ qubits. The line below gives the lower bounds on the spectral gap of $L_2$ using our algorithm.
Theorem 5.11. Let a graph \( G = (V, E) \) have dimension \( \delta > 2 \) with isoperimetric number \( c \). Let \( b \) and \( \beta \) be the minimum and maximum vertex degrees of \( G \) respectively. Then

\[
\lambda_j(L_G) \geq \frac{bc^2}{16e\beta^2} \left( \frac{\delta - 2}{\delta - 1} \right)^2 \left( \frac{i}{6|E|} \right)^{2/\delta}. \tag{5.18}
\]

When a graph is connected, its degree matrix is non-singular, and we can write its normalized Laplacian of \( G \) as

\[
\tilde{L}_G = D_G^{-1/2}L_GD_G^{-1/2} \tag{5.19}
\]

The proof of Theorem 5.11 relies trivially on the result on the corresponding result for lower bounds on the spectrum of normalized Laplacians. The connection is given by the following lemma.

Lemma 5.12. Namely if the graph has minimum and maximum vertex degrees given by \( b \) and \( \beta \) respectively,

\[
b\lambda_j(\tilde{L}_G) \leq \lambda_j(L_G) \leq \beta \lambda_j(\tilde{L}_G). \tag{5.20}
\]

Proof. Denoting the \( i \)-th largest singular value of a matrix \( A \) of size \( d_a \) as \( s_i(A) \) with \( s_1(A) \geq \cdots \geq s_{d_a}(A) \), we have from Ref [Bha97, Problem III.6.5] the inequalities

\[
s_i(AB) \leq s_i(A)s_1(B), \quad s_i(AB) \leq s_1(A)s_i(B). \tag{5.21}
\]

Applying the above inequalities iteratively, it follows that

\[
s_i(\tilde{L}_G) = s_i(D_G^{-1/2}L_GD_G^{-1/2})
\leq s_i(D_G^{-1/2}L_G)s_1(D_G^{-1/2})
\leq s_1(D_G^{-1/2})s_i(L_G)s_1(D_G^{-1/2})
= s_i(L_G)s_1(D_G^{-1/2}). \tag{5.22}
\]

Similarly, we have

\[
s_i(L_G) = s_i(D_G^{1/2}\tilde{L}_GD_G^{1/2})
\leq s_i(D_G^{1/2}\tilde{L}_G)s_1(D_G^{1/2})
\leq s_1(D_G^{1/2})s_i(L_G)s_1(D_G^{1/2})
= s_i(L_G)s_1(D_G). \tag{5.23}
\]

Since the matrices \( D_G, D_G^{-1}, L_G \) and \( \tilde{L}_G \) are positive semidefinite, their singular values are equivalent to their eigenvalues. The largest eigenvalue of \( D_G \) and \( D_G^{-1} \) are \( \beta \) and \( b^{-1} \) respectively. Hence the inequalities (5.22) and (5.23) then give the result.

Lower bounds on the eigenvalues of the normalized Laplacian can be obtained from the graph’s Sobolev inequalities, as shown in the seminal work of Chung and Yau [CY95]. Because of a gap in the proof in [CY95] as shown by Ostrovskii [Ost05], we have to take Ostrovskii’s correction into account when we prove the corresponding lower bounds on the graph’s Laplacian as stated in Theorem 5.11.

Proof of Theorem 5.11. We now review the connection between the isoperimetric properties of a graph and the eigenvalues of its normalized Laplacian. For a graph \( G = (V, E) \), denote the volume of a subset of vertices \( X \) as \( \operatorname{vol}(X) = \sum_{v \in X} d_v \). The isoperimetric inequality we focus on is

\[
|\partial X| \geq c_\delta (\operatorname{vol}(X))^{1-1/\delta} \tag{5.24}
\]
where \( \text{vol}(X) \leq \text{vol}(\bar{X}) \).

The Sobolev inequality on graphs has the form

\[
\sum_{\{u,v\} \in E} |f(u) - f(v)|^2 \geq A \min_{\mu \in \mathbb{R}} \left( \sum_{v \in V} |f(v) - \mu|^\alpha d_v \right)^{2/\alpha}.
\]

(5.25)

Typically \( A \) depends on \( c_\delta \) and \( \delta \). Chung and Yau proved when the above Sobolev inequality holds for a graph, the eigenvalues of the graph’s normalized Laplacians satisfy the lower bound

\[
\lambda_j(\tilde{L}) \geq \frac{A}{e^{3/\delta}} \left( j/\text{vol}(G) \right)^{2/\delta}.
\]

(5.26)

Now Ostrovskii’s Sobolev inequality has for \( \delta > 2 \), we get

\[
A = \frac{c_\delta^2}{16} \left( \frac{\delta - 2}{\delta - 1} \right)^2.
\]

(5.27)

Hence

\[
\lambda_j(\tilde{L}_G) \geq \frac{c_\delta^2}{16} \left( \frac{\delta - 2}{\delta - 1} \right)^2 \left( j/\text{vol}(G) \right)^{2/\delta}.
\]

(5.28)

Combining this with Lemma 5.12 we get

\[
\lambda_j(L_G) \geq b \frac{c_\delta^2}{16} \left( \frac{\delta - 2}{\delta - 1} \right)^2 \left( j/\text{vol}(G) \right)^{2/\delta}.
\]

(5.29)

It remains to relate \( c_\delta \) to \( c \). Note that if a graph \( G \) has \( \delta \) and \( a\beta \) as its isoperimetric dimension and number respectively, then the vertex subsets \( X \) of \( V \) satisfy the bound

\[
|\partial X| \geq a\beta \min\{ |X|, |V| - |X| \}^{1-1/\delta}
\]

\[
\geq a \min\{ \text{vol}_X, \text{vol}_{V\setminus X} \}^{1-1/\delta}.
\]

(5.30)

Hence we can take \( c_\delta = c/\beta \), where \( \beta \) is the maximum vertex degree of the graph. This yields

\[
\lambda_j(L_G) \geq b \frac{c^2 \delta^2}{16e^{3/\delta}} \left( \frac{j}{\text{vol}(G)} \right)^{2/\delta},
\]

(5.31)

where \( m \) is the number of edges in the graph.

\( \square \)

Armed with Theorem (5.11), we can easily obtain lower bounds on the eigenvalues of \( L_k \) using the relevant parameters of the graph \( G^{(k)} \). We now give a procedure for estimating the relevant parameters of \( G^{(k)} \). Now denote \( b_k \) and \( \beta_k \) as the minimum and maximum vertex degrees of \( G^{(k)} \) respectively. To bound these vertex degrees in \( G^{(k)} \), note that every vertex in \( G^{(k)} \) is a set of vertices in \( G \) with \( k \) elements. Therefore the vertex degree of \( \{x_1, \ldots, x_k\} \) in \( G^{(k)} \) is just the edge-boundary of \( \{x_1, \ldots, x_k\} \) in \( G \). It hence follows that if the graph \( G \) has a dimension \( \delta \) with isoperimetric number \( c \), we must have \( b_k \geq ck^{1-1/\delta} \) just by definition. Also, when \( \beta \) is the maximum vertex degree of \( G \), we trivially have and \( \beta_k \leq k\beta \).

Estimating the isoperimetric number \( c_k \) of \( G^{(k)} \) given a fixed dimension \( \delta_k \) is considerably more challenging. We will estimate \( c_k \) using the isoperimetric numbers of the graphs in \( \mathcal{V}(G,k) \). For any graph
K ∈ \mathcal{V}(G,k) with vertex set V(K) and edge set E(K), isoperimetric numbers can be determined by solving the so-called edge-isoperimetric problem (EIP) on K, which involves finding solving
\[
\min\{|\partial X| : X \subseteq V(K), |X| = j\} \tag{5.32}
\]
for every 1 ≤ j ≤ |V(K)|/2. If every K has dimension δ_k and isoperimetric number a_k, then \(c_k \geq a_k n^{1/\delta_k}\) from Corollary 5.8. While solving the EIP exactly is NP-hard [GJS76, BF09], we conjecture that there can be approximation algorithms to approximately solve the EIP in polynomial time.

**Conjecture 5.13.** Let \(G = (V,E)\) be a graph. For every \(k = 1, \ldots, |V|/2\), let \(e_k = \min\{|\partial X| : X \subseteq V, |X| = k\}\). Then for every \(\varepsilon > 0\) and for every \(k = 1, \ldots, |V|/2\), there exists a polynomial time approximation algorithm that computes \(c_k\) such that \((1 - \varepsilon)e_k \leq c_k \leq e_k\).

A reason why Conjecture 5.13 might be true is because for a multitude of different NP-hard problems, there do exist approximation algorithms that have efficient runtimes [Hoc96]. If our Conjecture 5.13 holds, then lower bounds on the eigenvalues can be evaluated in \(O(\text{poly}(n)n^{k-1})\) time with \(O(n)\) memory. In contrast, computing the eigenvalues of \(L_k\) directly in practice requires a computer in \(O(n^{3k})\) time and \(O(n2^k)\) memory. Even using the best asymptotic algorithm for matrix multiplication would require at least \(O(n^{2k})\) time [DDH07] and \(O(n2^k)\) memory.

### 6 Bounds on some specific Heisenberg models

#### 6.1 Long-range interactions

With the spectrum of the mean-field HM, we can easily address the spectrum of certain HMs with long-range interactions. In particular, we consider HMs where every pair of spins separated by distance \(r\) interacts with exchange constant at least \(Jr^{-\alpha}\). To unravel this HH’s spectrum, we utilize the spectrum of the mean-field HH with an inequality from matrix analysis. For any Hermitian matrix \(A\) of size \(n\), let \(\lambda_j(A)\) be its eigenvalues where \(\lambda_0(A)\) is its smallest eigenvalue of \(A\) and \(\lambda_{n-1}(A) \geq \cdots \geq \lambda_1(A) \geq \lambda_0(A)\). By Weyl’s monotonicity theorem, \(\lambda_j(A + B) \geq \lambda_j(A)\) whenever \(A\) and \(B\) are positive semidefinite matrices with the smallest eigenvalue of \(B\) equal to zero. Now let \(\hat{H}_1\) denote the normalized Hamiltonian of the mean-field HM, and maximize \(J_0\) for which the matrix \(B\) in the decomposition \(\hat{H} = J_0\hat{H}_1 + B\) is positive semidefinite. Then \(B\) will have smallest eigenvalue equal to zero and \(\lambda_j(\hat{H}) \geq J_0\lambda_j(\hat{H}_1)\). In particular, the \(J_0\) that optimizes this bound is the smallest exchange constant in the long-range interaction model. We can apply this inequality to the HM has a geometry of a \(D\)-dimensional lattice with \(n\) spins arranged in a grid with lattice spacing \(a\). In this case, the largest separation of the spins is \(n^{1/D}a\sqrt{D}\), and hence every exchange constant is at least \(J_0 = J(n^{1/D}a\sqrt{D})^{-\alpha}\). The spectral gap of such a Heisenberg ferromagnet thus satisfies the bound
\[
g \geq J_0n = J(a\sqrt{D})^{-\alpha}n^{1-\alpha/D}. \tag{6.1}
\]

Similarly for general \(D\)-dimensional systems where pairs of spins are at most a distance of \(cn^{1/D}\) apart for some positive constant \(c\), the spectral gap similarly satisfies the bound \(g \geq Je^{-\alpha}n^{1-\alpha/D}\). Hence if the dimension \(D\) of the system is larger than the exponent \(\alpha\), the spectral gap of such HHs grows with the number of the system’s spins.

We now turn our attention to ferromagnetic HHs with \(n\) spins that is percolated from the mean-field HM. If the number of percolations is sufficiently few, the underlying graph of interactions can have infinite dimensions with a strictly positive expansion constant. We restrict our attention to the case when the expansion constant is large. In particular, we obtain lower bounds on the spectral gap of the normalized Hamiltonian \(\hat{H}_1\) when \(n \geq 4\) and the graph’s expansion constant \(e\) is at least \(n(\frac{1}{2} + \varepsilon)\) for some positive \(\varepsilon\).
Note that because some pairs of spins need not interact, such a HH is no longer strongly interacting, and the spectral gap of $\hat{H}_1$ cannot be obtained from that of the mean-field HH. Instead, we appeal to the bound

$$\lambda_1(L) \geq \beta - \sqrt{\beta^2 - \theta^2} \geq \frac{\theta^2}{2\beta}$$  \hspace{1cm} (6.2)

proved by Mohar [Moh88, Moh89]. Mohar’s bound applies to graphs with at least four vertices and expansion constant, maximum vertex degree and given by $\theta$, $\beta$ and Laplacian $L$ respectively. Now, the expansion constant of $G^{(k)}$ is at least $n\left(\frac{c-k+1}{n-k+1}\right)$ for $1 \leq k \leq n/2$ from Corollary 5.9, and the maximum vertex degree of $G^{(k)}$ is trivially at most $k(n-k)$. Combining these inequalities, we find that

$$\lambda_1(L_k) \geq \frac{n^2}{2k(n-k)} \left(\frac{c-k+1}{n-k+1}\right)^2.$$  \hspace{1cm} (6.3)

Thus the spectral gap of $\hat{H}_1$ in this case is at least $3\varepsilon^2$ which does not depend on $n$.

7 Discussions

In this paper, we obtain many bounds on the spectrum of the ferromagnetic HHs. For this, we rely on tools from graph theory and matrix analysis. Obviously, with these bounds on the eigenvalues of the Heisenberg ferromagnet, one can easily compute bounds on thermodynamic quantities of the corresponding Heisenberg models such as free energy.

With regards to upper bounds based on graph distances, there remains a potential to further tighten our bounds by optimizing over the partitions used in Eq. (4.22) of Corollary 4.4 in Ref. [CGY97]. This is however beyond the scope of the current paper and we leave this for future investigation. With regards to the lower bounds based on isoperimetric inequalities, we wish to point out that the edge-isoperimetric problem for the Johnson graph, also known as the problem of Kleitman and West [Har91], remains unsolved. Given this fact, better edge-isoperimetric inequalities for the Johnson graph will improve the edge-isoperimetric inequalities of the symmetric product of finite graphs given in Corollaries 5.8 and 5.9. Also advances in the theory of the graph expansion properties of vertex induced subgraphs will certainly also improve the bounds given in Corollaries 5.8 and 5.9. Directly deriving lower bounds on the combinatorial Laplacian of a graph from discrete Sobolev inequalities can also help to improve the constants involved in the bound. We also like to emphasize that if we have a polynomial-time approximation algorithm for solving the edge-isoperimetric problem for graphs (Conjecture 5.13), then together with the methods already in this paper, we will have a polynomial-time algorithm for computing lower bounds for the eigenvalues of the ferromagnetic HH.

Finally, we wish to also point out that our bounds on the spectrum of the ferromagnetic HM are also relevant to other physical systems. For example, the spectrum of the Heisenberg antiferromagnet obviously has a one-to-one correspondence with that of the Heisenberg ferromagnet. The Heisenberg antiferromagnet has received widespread interest partially because of its relevance to also to the widely studied the Hubbard model [Ess10, Aue12]. Moreover, other than the spin-$\frac{1}{2}$ Heisenberg ferromagnet, we anticipate that graph-theoretic techniques will also apply in other physical systems.
