Abstract We measure the distance to the supernova remnant G15.4+0.1 which is likely associated with TeV source HESS J1818-154. We build the neutral hydrogen (H\textsc{i}) absorption and \textsuperscript{13}CO spectra to supernova remnant G15.4+0.1 by employing the data from the Southern Galactic Plane Survey (SGPS) and the H\textsc{i}/OH/Recombination line survey (THOR). The maximum absorption velocity of about 140 km s\textsuperscript{-1} constrains its lower limit distance of about 8.0 kpc. Further, the fact that the H\textsc{i} emission feature at about 95 km s\textsuperscript{-1} seems no corresponding absorption suggests that G15.4+0.1 has likely an upper limit distance of about 10.5 kpc. \textsuperscript{13}CO spectrum to the remnant supports our measurement. The new distance revises parameters on its associated pulsar wind nebula and TeV source.

Key words: ISM: supernova remnants – methods: data analysis – stars: distances

1 INTRODUCTION

The supernova remnant (SNR) G15.4+0.2, also called G15.42+0.18 (G15 hereafter), has a break-out morphology toward its south and a northern shell with a radius of about 6\arcmin in 1420 MHz. The spectral index of G15 is $\alpha = -0.62 \pm 0.03$ from 330 to 4800 MHz \cite{Supan2015, Sun2011} with its peak flux density of 5.6 Jy at 1 GHz. G15 has a morphological correspondence with the TeV $\gamma$-ray source HESS J1818-154 \cite{Adrian-Martinez2011}. The high energy radiation possibly originates from a pulsar wind nebula (PWN) although the pulsar has not been detected. Multiwavelength studies have been performed to explore their properties \cite{Abramowski2014, Castelletti2013}.

Distance is a key to further study this TeV SNR. A near distance for the remnant G15 was suggested by Castelletti et al. \cite{Castelletti2013} by analyzing a noisy H\textsc{i} absorption spectrum to the remnant. We make a further effort to obtain its reliable distance by taking advantage of new-released H\textsc{i}/OH/Recombination line survey (THOR, Beuther et al. \cite{Beuther2016}), the archive Southern Galactic Plane Survey (SGPS, McClure-Griffiths et al. \cite{McClure-Griffiths2005}), the Very Large Array Galactic Plane Survey (VGPS, Stil et al. \cite{Stil2006}), and the Galactic Ring Survey (GRS, Jackson et al. \cite{Jackson2006}) data.
The SGPS has a resolution of 100′′ and a sensitivity of less than 1 mJy beam$^{-1}$ and were observed by The Australia Telescope Compact Array (ATCA) and Parkes telescopes. The SGPS survey has a reliable absolute flux scale by including the Parkes data. The continuum data of SGPS near G15 region is currently not available. The THOR survey observed H1, four OH, 19 H$_α$ recombination lines, and the L-band continuum covering the northern Galactic plane ($15 < l < 67°$ and $|b| < 1°$). The THOR data has an angular resolution about 20′′. We convert the unit of Jy beam$^{-1}$ in the THOR data to Kelvin (K) using factors of 1536.20 for the cube data. The absolute scale of the surface brightness in the THOR data is not reliable due to lacking zero baseline. However, the relative scale is good enough for us to do H1 absorption analysis. In addition, we adopt the $^{13}$CO data from the GRS to confirm the reality of the absorption peaks, because $^{13}$CO is a tracer of cold and dense H$_2$ molecular cloud.

2 SPECTRA ANALYSIS

We use well-tested methods in order to build a reliable H1 absorption spectrum to G15 as possible (Tian et al., 2007; Tian & Leahy, 2011; Zhu et al., 2013).

We improve the absorption spectrum extraction by two steps. We choose a background region which is an annulus around the source region. Our background is adjacent to the source region, which makes that the background spectrum in the source direction. We remove six point-like sources from both the continuum map and the data cube to avoid contamination (see Fig. [1]). We show the H1 emission, the H1 absorption, and the $^{13}$CO emission spectra of G15 (see Fig. [2] and [3]). We extract the H1 emission spectra from our source and background regions and then calculate the difference between the two spectra. This difference spectrum is actually proportional to the absorption spectrum, which is used to do absorption analysis. We extract the $^{13}$CO spectrum in our selected background region from the GRS data and compare with our absorption spectrum.

The maximum velocity H1 absorption feature appears at about 140 km s$^{-1}$ (see Fig. [2] and [3]). The $^{13}$CO has data between -5 km s$^{-1}$ and 135 km s$^{-1}$. There is, in fact, a $^{13}$CO emission feature at 135 km s$^{-1}$ which seems corresponding with the H1 maximum velocity absorption feature. The rms of 0.009 K is obtained by averaging no $^{13}$CO emission-line velocity ranges from -5 to 10 km s$^{-1}$ and from 60 to 120 km s$^{-1}$. The $^{13}$CO peak temperature at 135 km s$^{-1}$ is 0.047 K, which is a 5σ detection. This supports the H1 absorption feature at about 140 km s$^{-1}$ is real. The velocity of 140 km s$^{-1}$ corresponds to a distance of about 8 kpc based on the Galactic rotation model with $\Theta_⊙= 220$ km s$^{-1}$ and $R_⊙= 8.5$ kpc (Fich et al., 1989). Thus, the lower limit distance of G15 is 8 kpc.

The H1 emission at a velocity of about 95 km s$^{-1}$ seems no responsible absorption, which means G15 is likely located in front of this H1 cloud. This velocity corresponds to a far side distance of about 10.5 kpc. The absorption peak at the velocity of about -20 km s$^{-1}$ is possibly caused by H1 emission fluctuation so likely not a real feature (see the H1 emission spectra in Figs. [2] and [3]). Similar fake absorption feature is often seen in faint SNRs (e.g. Leahy & Tian 2008).

3 RESULTS AND BRIEF DISCUSSION

We obtain a new distance of $9.3 \pm 1.3$ kpc for G15. This is consistent with the $10 \pm 3$ kpc derived from the surface brightness vs. diameter relation of Galactic SNRs (Adrián-Martínez et al., 2011). Castelletti et al.
The distance of supernova remnant G15.4+0.1 showed an HI absorption spectrum and suggested a smaller distance for the remnant. However, we do not find a clue from their paper to reproduce their spectrum, so we believe our careful measurement is more reliable.

The HI shell of G15 is 16.5 pc in radius (for 61 arcmin) at a distance of 9.3 kpc. The PWN inside G15 has a total energy of less than $1.2 \times 10^{50}$ erg scaled from the value derived in Abramowski et al. (2014).

We revise the parameters of G15 using the shell-type model of SNR in Sturmer et al. (1997). We assume the progenitor supernova of G15 has an explosion energy of $10^{51}$ erg, a mass of 8 $M_\odot$, a magnetic field strength of 1 $\mu$G, and an interstellar medium (ISM) density of 7 hydrogen atoms per cube centimeter, so we get the expansion velocity of about 700 km s$^{-1}$, an age of 11 kyr, and a total atomic gas mass that forms the G15 shell of $3.3 \times 10^3 M_\odot$. The estimated parameters may have a 50 percent uncertainty due to the large variance of the interstellar medium density.

**ACKNOWLEDGEMENTS**

We thank Dr. Wenwu Tian for his initial questioning the SNR G15.4+0.1’s distance issue and helpful comments during our writing the paper. We acknowledge support from the NSFC (11473038, 11273025). This publication makes use of molecular line data from the Boston University-FCRAO Galactic Ring Survey (GRS).

Fig. 1 The image of G15 at 1420 MHz from the VGPS data. The black dashed circle shows the source region (‘ON’ direction) with its center at (g, l) = (15.43°, 0.17°) and a radius of 6.1. The region between the white solid circle and the white dashed circle is the background region (‘OFF’ direction). The black circles show point-like sources from the THOR continuum image, which are excluded from our analysis. The black solid ellipse shows a bright source in the SGPS H I channel maps, which is also flagged in our spectra analysis. The gray contour levels are 20.5, 21.0, and 21.2 Kelvin.
