LETTER

On Answer Substitutions in Logic Programming

Keehang KWON†, Member

SUMMARY Answer substitutions play a central role in logic programming. To support selective answer substitutions, we refine \( \exists x \) in goals into two different versions: the noisy version \( \exists^o x \) and the silent version \( \exists^s x \). The main difference is that only the instantiation in \( \exists^s x \) will be recorded in the answer substitutions. Similarly for \( \forall x \). In addition, we discuss the notion of don’t-care constants and don’t-know constants.

key words: Prolog, answer substitution, choice quantifiers.

1. Introduction

The notion of answer substitutions plays a key role in logic programming. Unfortunately, the notion of answer substitutions in traditional logic languages is unsatisfactory in the sense that every instantiation is visible to the user. For example, consider the program

\[
\text{phone}(\text{tom}, \text{cs}, 4450)
\]

which represents that \text{tom} is a CS major and his phone number is 4450. Now solving a query \( \exists x \exists y \text{phone}(\text{tom}, x, y) \) is a success with the answer substitutions \( x = \text{cs}, y = 4450 \). What if we want to see only \text{tom}’s phone number, but not his major? It is not possible to specify this in traditional logic programming.

To fix this problem, inspired by [2], we extend Prolog to include the following new formulas (called noisy universal/existential quantifiers):*

- \( \forall^o x D \) where \( D \) is a definite clause.
- \( \exists^o x G \) where \( G \) is a goal formula in Prolog.

In the above, \( \exists^o x G \) is identical to \( \exists x G \) with the difference that, in the former, the instantiation \( t \) for \( x \) is visible and recorded in the answer substitution, but not in the latter. Thus the latter is a silent version of the former that chooses a term \( t \) for \( x \) silently. Similarly for \( \forall^o x D \).

Thus it is \( \exists^o x G \), rather than \( \exists x G \), that adequately captures the notion of answer substitution. Furthermore, it is the notion of answer substitution instead of proof theory that really counts when dealing with logic programming.

Fortunately, in a simple setting such as Prolog, operational semantics for these new quantifiers can be easily obtained from \( \forall, \exists \) by additionally recording each instantiation during execution**. To be specific, we adopt the following operational semantics for \( \exists^o \) and \( \exists^s \):

- \( pv(D, \exists^o x G, \text{nil}) \) if \( pv(D, [t/x] G, \_ ) \)
- \( pv(D, \exists^s x G, (x, t)) \) if \( pv(D, [t/x] G, \_ ) \)

where the third argument is used to record the instantiation (if any) at the current proof step.

This paper also deals with anonymous variables. Anonymous variables in a clause \( D \) can be interpreted as \( \forall x D \), but not \( \forall^o x D \), while anonymous variables in a goal \( G \) can be interpreted as \( \exists x G \).

This paper proposes Prolog\(^\dagger\), an extension of Prolog with new quantifiers. The remainder of this paper is structured as follows. We describe Prolog\(^\dagger\) in the next sections. Section 5 concludes the paper.

2. The Language

The language is a version of Horn clauses with noisy quantifiers. It is described by \( \bar{\forall} \)- and \( \bar{\exists} \)-formulas given by the syntax rules below:

\[
G ::= A | G \land G | \exists^o x G | \exists^s x G
\]

\[
D ::= A | G \lor A | \forall x D | \forall^o x D | D \land D
\]

In the rules above, \( A \) represents an atomic formula. A \( D \)-formula is called a Horn clause with noisy quantifiers.

We describe a proof procedure based on uniform proofs [5]. Note that proof search alternates between two phases: the goal-reduction phase and the backchaining phase. In the goal-reduction phase (denoted by \( pr(D, G, \theta) \)), the machine tries to solve a goal \( G \) from a clause \( D \) by simplifying \( G \). If \( G \) becomes an atom, the machine switches to the backchaining mode. In the backchaining mode (denoted by \( bc(D_1, D, A, \theta) \)), the machine tries to solve an atomic goal \( A \) by first reducing a Horn clause \( D_1 \) to simpler forms and then backchaining on the resulting clause (via rule (1)) and

**In a more general setting where \( \exists x D, \exists^o x D \) are allowed, there is a subtle but critical difference between \( \exists \) and \( \exists^o \). That is, in \( \exists^o x, x \) must be instantiated to a ground term, while \( x \) can be instantiated to an arbitrary term (a new constant, for example) in \( \exists \).
(2). Below, _ represents a don’t-care value.

A proof of \( (D, G) \) is a sequence of \( P_1, \ldots, P_n \) where each \( P_i \) is either \( bc(D_1, D, G, \theta_i) \) or \( pv(D_1, G, \theta_i) \), with \( P_n = pv(D, G, \theta_n) \). Each \( P_i \) is called a proof step. Each \( \theta_i \) records an instantiation (if any) performed at the ith proof step.

**Definition 1.** Let \( G \) be a goal and let \( D \) be a program. Then the notion of proving \( (D, G) \) with recording the answer substitution performed at the last proof step \( \theta \) – \( pv(D, G, \theta) \) – is defined as follows:

1. \( bc(A, D, A, nil) \). % This is a success.
2. \( bc((G_0 \supset A), D, A, nil) \) if \( pv(D, G_0, \_) \). % backchaining
3. \( bc(D_1 \land D_2, D, A, nil) \) if \( bc(D_1, D, A, \theta_1) \) or \( bc(D_2, D, A, \theta_2) \). % \( \land \)-L
4. \( bc(\forall x D_1, D, A, \_) \) if \( bc([t/x]D_1, D, A, \theta) \). % \( \langle x, t \rangle \) is not recorded in the answer substitution.
5. \( bc(\forall^o x D_1, D, A, \langle x, t \rangle) \) if \( bc([t/x]D_1, D, A, \_) \). % \( \langle x, t \rangle \) is recorded in the answer substitution.
6. \( pv(D, A, nil) \) if \( bc(D, D, A, \_) \). % switch to backchaining mode
7. \( pv(D, G_1 \land G_2, nil) \) if \( pv(D, G_1, \_) \) and \( pv(D, G_2, \_) \).
8. \( pv(D, \exists x G, nil) \) if \( pv(D, [t/x]G, \_) \) % \( \langle x, t \rangle \) is not included in the answer substitution.
9. \( pv(D, \exists^o x G, \langle x, t \rangle) \) if \( pv(D, [t/x]G, \_) \) % \( \langle x, t \rangle \) is included in the answer substitution.

These rules are straightforward to read.

Once a proof tree is built, execution is simple. It simply displays its proof steps with the corresponding answer substitution in a bottom-up manner.

### 3. An Example

As an example, consider solving a query \( \exists x \exists^o y \) phone(tom, x, y) from the program \( A \) of the form phone(tom, cs, 4450). Note that this query can be rewritten as \( \exists^o y \) phone(tom, _, y) using an anonymous variable.

Below is its proof with answer substitution \( \langle y, 4450 \rangle \).

1. \( bc(A, A, A, nil) \)
2. \( pv(A, A, nil) \)
3. \( pv(A, \exists^o y \) phone(tom, cs, y), \( \langle y, 4450 \rangle \) \)
4. \( pv(A, \exists x \exists^o y \) phone(tom, x, y), nil) \)

### 4. Don’t-Know Constants

In this section, we additionally propose a new class of constants called *don’t-know constants*. This class of constants is dual of don’t-care constants (a.k.a don’t-care variables) and is not introduced properly in the literature. To see why we need this class, consider the following database which contains the phone numbers of the employees.

```plaintext
module emp.
phone(tom,434433)
phone(pete,200312)
phone(sue,*)
phone(tim,*)
```

In the above, * represents the don’t-know constants in that we do not know the phone numbers of sue, john and tim. Now suppose that sue and john share the same number for some reason. In this case, how do we represent this? Representing this turns out to be tricky and a reasonable solution is to use \( \exists x \) as shown below:

```plaintext
module emp.
\exists x \exists y
phone(tom,434433)
phone(pete,200312)
phone(sue,x)
phone(tim,y)
```

It is worth noting that the class of don’t-know constants is closely related to the class of private/local constants. Over the years, the notion of private/local constants has been a central concept in information hiding. However, we believe that this concept is rather unnatural and the former class is a more fundamental and natural notion than the latter in information hiding and the latter can be derived from the former.

Processing these prefixes within a module is not too difficult. In the initialization phase, the machine needs to replace \( \exists x D \) with \( D[\alpha/x] \) where \( D \) is a module and \( \alpha \) is a new Greek letter. Greek symbols are used to denote that these constants are in fact unknown to us. For example, the above will be changed to the following during execution.

```plaintext
module emp.
phone(tom,434433)
phone(pete,200312)
phone(sue,\alpha_1)
phone(john,\alpha_1)
phone(tim,\alpha_2)
```
5. Conclusion

In this paper, we have considered an extension to Prolog[1] with new noisy quantifiers. This extension makes Prolog programs more versatile. If we allow $\exists x, \exists^o x$ in $D$-formulas (and $\forall x, \forall^o x$ in $G$-formulas), some important features – information hiding [5] and user interaction [2], etc – can be achieved. However, implementation becomes way more complicated.

In the near future, we plan to investigate this possibility of including these features into logic programming.
