Nonparametric regression using deep neural networks with ReLU activation function

Johannes Schmidt-Hieber*

Abstract

Consider the multivariate nonparametric regression model. It is shown that estimators based on sparsely connected deep neural networks with ReLU activation function and properly chosen network architecture achieve the minimax rates of convergence (up to log $n$-factors) under a general composition assumption on the regression function. The framework includes many well-studied structural constraints such as (generalized) additive models. While there is a lot of flexibility in the network architecture, the tuning parameter is the sparsity of the network. Specifically, we consider large networks with number of potential network parameters exceeding the sample size. The analysis gives some insights why multilayer feedforward neural networks perform well in practice. Interestingly, the depth (number of layers) of the neural network architectures plays an important role and our theory suggests that for nonparametric regression scaling the network depth with the logarithm of the sample size is natural. It is also shown that under the composition assumption wavelet estimators can only achieve suboptimal rates.

Keywords: nonparametric regression; multilayer neural networks; ReLU activation function; minimax estimation risk; additive models; wavelets.

1 Introduction

In the nonparametric regression model with random design, we observe $n$ i.i.d. vectors $X_i \in [0,1]^d$ and $n$ responses $Y_i \in \mathbb{R}$ from the model

$$Y_i = f_0(X_i) + \varepsilon_i, \quad i = 1, \ldots, n.$$  \hspace{1cm} (1.1)

The noise variables $\varepsilon_i$ are assumed to be i.i.d. standard normal and independent of $(X_i)_i$. The statistical problem is to recover the unknown function $f_0 : [0,1]^d \rightarrow \mathbb{R}$ from the sample $(X_i, Y_i)_i$. Various methods exist that allow to estimate the regression function nonparametrically, including kernel smoothing, series estimators/wavelets and splines, cf. [14, 49, 47]. In this work, we consider fitting a multilayer feedforward artificial neural network to the data. It is shown that the estimator achieves nearly optimal convergence rates under various constraints on the regression function.

Multilayer (or deep) neural networks have been successfully trained recently to achieve impressive results for complicated tasks such as object detection on images and speech recognition. Deep learning is now considered to be the state-of-the-art for these tasks. But there is a lack of mathematical understanding. One problem is that fitting a neural network to data is highly non-linear in the parameters. Moreover, the function class is non-convex and different regularization methods are combined in practice.

This article is inspired by the idea to build a statistical theory that provides some understanding of these procedures. As the full method is too complex to be theoretically tractable, we need to make some selection of important characteristics that we believe are crucial for the success of the procedure.

To fit a neural network, an activation function $\sigma : \mathbb{R} \rightarrow \mathbb{R}$ needs to be chosen. Traditionally, sigmoidal activation functions were employed. Recall that an activation function is called sigmoidal if it can be written as cumulative distribution function of a real valued random variable. For deep neural networks, however, there is a clear gain using the non-sigmoidal rectifier linear unit (ReLU) $\sigma(x) = \max(x, 0) = (x)_+$. Indeed, in practice the ReLU outperforms other activation functions with respect to the statistical performance and the computational cost, cf. [12]. Whereas earlier statistical work focuses mainly on shallow networks with sigmoidal activation functions, we provide statistical theory specifically for deep ReLU networks.

The statistical analysis for the ReLU activation function is quite different from earlier approaches and we discuss this in more detail in the overview on related literature in Section 6. Viewed as a nonparametric method, ReLU networks have some surprising properties. To explain this, notice that deep networks with ReLU activation produce functions that are
piecewise linear in the input. Nonparametric methods which are based on piecewise linear approximations are typically not able to capture higher-order smoothness in the signal and are rate-optimal only up to smoothness index two. Interestingly, we can show that the ReLU combined with a deep network architecture achieves near minimax rates for arbitrary smoothness of the regression function.

The number of hidden layers of state-of-the-art network architectures has been growing over the past years, cf. [15]. There are versions of the recently developed deep network ResNet which are based on 152 layers, cf. [17]. Our analysis indicates that for the ReLU activation function the network depth should scale with the logarithm of the sample size. This suggests, that for larger samples, additional hidden layers should be added.

Recent deep architectures include more network parameters than training samples. The well-known AlexNet [28] for instance is based on 60 million network parameters using only 1.2 million samples. We account for high-dimensional parameter spaces in our analysis by assuming that the number of potential network parameters is much larger than the sample size. For noisy data generated from the nonparametric regression model overfitting does not lead to good generalization errors and incorporating regularization or sparsity in the estimator becomes essential. In the deep networks literature, one option is to make the network thinner assuming that only few parameters are non-zero (or active), cf. [13], Section 7.10. Our analysis shows that the number of non-zero parameters plays the role of the effective model dimension and - as common in non-parametric regression - needs to be chosen carefully.

Existing statistical theory often requires that the size of the network parameters tends to infinity as the sample size increases. In practice, estimated network weights are, however, rather small. We can incorporate small parameters in our theory, proving that it is sufficient to consider neural networks with all network parameters bounded in absolute value by one.

Multilayer neural networks are typically applied to high-dimensional input. Without additional structure in the signal besides smoothness, nonparametric estimation rates are then slow because of the well-known curse of dimensionality. This means that no statistical procedure can do well regarding pointwise reconstruction of the signal. Multilayer neural networks are believed to be able to adapt to many different structures in the signal, therefore avoiding the curse of dimensionality and achieving faster rates in many situations. In this work, we stick to the regression setup and show that deep networks can indeed attain faster rates under a hierarchical composition assumption on the regression function, which includes (generalized) additive models and the composition models considered in [20, 21, 3, 25, 6].
Parts of the success of multilayer neural networks can be explained by the fast algorithms that are available to estimate the network weights from data. These iterative algorithms are based on minimization of some empirical loss function using stochastic gradient descent. Because of the non-convex function space, gradient descent methods might get stuck in a saddle point or converge to one of the potentially many local minima. It is now widely believed that the risk of most of the local minima is not much larger than the risk of the global minimum, cf. [8]. Despite the huge number of variations of the stochastic gradient descent, the common objective of all approaches is to reduce the empirical loss. In our framework we associate to any network reconstruction method a parameter quantifying the expected discrepancy between the achieved empirical risk and the global minimum of the energy landscape. The main theorem then states that a network estimator is minimax rate optimal (up to log factors) if and only if the method almost minimizes the empirical risk.

We also show that wavelet series estimators are unable to adapt to the underlying structure under the composition assumption on the regression function. By deriving lower bounds it is shown that the rates are suboptimal by a polynomial factor in the sample size $n$. This provides an example of a function class for which fitting a neural networks outperforms wavelet series estimators.

Our setting deviates in two aspects from the computer science literature on deep learning. Firstly, we consider regression and not classification. Secondly, we restrict ourselves in this article to multilayer feedforward artificial neural networks, while most of the many recent deep learning applications have been obtained using specific types of networks such as convolutional or recurrent neural networks. Although these are limitations, one should be aware that our setting is much more general than previous statistical work on the topic and provides, to the best of our knowledge, for the first time nearly optimal estimation rates for multilayer neural networks with ReLU activation function.

The article is structured as follows. Section 2 introduces multilayer feedforward artificial neural networks and discusses mathematical modeling. This section also contains the definition of the network classes. The considered function classes for the regression function and the main result can be found in Section 3. Specific structural constraints such as additive models are discussed in Section 4. In Section 5 it is shown that wavelet estimators can only achieve suboptimal rates under the composition assumption. We give an overview of relevant related literature in Section 6. The proof of the main result together with additional discussion can be found in Section 7.

Notation: Vectors are denoted by bold letters, $\mathbf{x} := (x_1, \ldots, x_d), \ldots$ As usual, we define $|\mathbf{x}|_p := (\sum_{i=1}^d |x_i|^p)^{1/p}$, $|\mathbf{x}|_\infty := \max_i |x_i|$, $|\mathbf{x}|_0 := \sum_i 1(x_i \neq 0)$, and write $\|f\|_p := \|f\|_{L^p(D)}$ for the $L^p$-norm on $D$, whenever there is no ambiguity of the domain $D$. For two sequences
(aₙ)ₙ and (bₙ)ₙ, we write \( aₙ \lesssim bₙ \) if there exists a constant \( C \) such that \( aₙ \leq Cbₙ \) for all \( n \). Moreover, \( aₙ \asymp bₙ \) means that \( aₙ \lesssim bₙ \) and \( bₙ \lesssim aₙ \).

2 Mathematical definition of multilayer neural networks

**Definitions:** Fitting a multilayer neural network requires the choice of an activation function \( σ : \mathbb{R} \rightarrow \mathbb{R} \) and the network architecture. Motivated by the importance in deep learning, we study the rectifier linear unit (ReLU) activation function

\[
σ(x) = \max(x, 0).
\]

For \( v = (v₁, ..., v_r) \in \mathbb{R}^r \), define the shifted activation function \( σ_v : \mathbb{R}^r \rightarrow \mathbb{R}^r \) as

\[
σ_v\left(\begin{array}{c}
y₁ \\
⋮ \\
yᵣ
\end{array}\right) = \left(\begin{array}{c}
σ(y₁ - v₁) \\
⋮ \\
σ(yᵣ - vᵣ)
\end{array}\right).
\]

The network architecture \((L, p)\) consists of a positive integer \( L \) called the *number of hidden layers* or *depth* and a *width vector* \( p = (p₀, ..., p_{L+1}) \in \mathbb{N}^{L+2} \). A neural network with network architecture \((L, p)\) is then any function of the form

\[
f : \mathbb{R}^{p₀} \rightarrow \mathbb{R}^{p_{L+1}}, \quad x \mapsto f(x) = W_{L+1}\sigma_{v_L}W_Lσ_{v_{L-1}}⋯W₂σ_{v₁}W₁x,
\]

where \( W_i \) is a \( p_i \times p_i-1 \) weight matrix and \( v_i \in \mathbb{R}^{p_i} \) is a shift vector. Network functions are therefore build by alternating matrix-vector multiplications with the action of the non-linear activation function \( σ \). In [2.1], it is also possible to omit the shift vectors by considering the input \((x, 1)\) and enlarging the weight matrices by one row and one column with appropriate entries. For our analysis it is, however, more convenient to work with representation [2.1].

To fit networks to data generated from the \( d \)-variate nonparametric regression model we must have \( p₀ = d \) and \( p_{L+1} = 1 \).

In computer science, neural networks are more commonly introduced via their representation as directed acyclic graph, cf. Figure 1. Using this equivalent definition, the nodes in the graph (also called *units*) are arranged in layers. The input layer is the first layer and the output layer the last layer. The layers that lie in between are called hidden layers. The number of hidden layers corresponds to \( L \) and the number of units in each layer generates the width vector \( p \). Each node/unit in the graph representation stands for a scalar product of the incoming signal with a weight vector which is then shifted and applied to the activation function.
Figure 1: Representation as a direct graph of a network with two hidden layers $L = 2$ and width vector $p = (4, 3, 3, 2)$.

**Mathematical modeling of deep network characteristics:** Given a network function $f(x) = W_{L+1} \sigma_{v_{L}} W_{L} \sigma_{v_{L-1}} \cdots W_{2} \sigma_{v_{1}} W_{1} x$, the network parameters are the entries of the matrices $(W_{j})_{j=1,...,L+1}$ and vectors $(v_{j})_{j=1,...,L}$. These parameters need to be estimated/learned from the data.

The aim of this article is to consider a framework that incorporates essential features of modern deep network architectures. In particular, we allow for large depth $L$ and large number of potential network parameters. For the main result no upper bound on the number of network parameters is needed. Thus we consider high-dimensional settings with more parameters than training data.

Another characteristic of trained networks is that the size of the learned network parameters is typically not very large. In practice, this is incorporated as prior knowledge to initialize the network, cf. [13], Section 8.4. Existing approximation theoretic results, however, often require that the size of the network parameters tends to infinity. If large parameters are allowed one can for instance easily approximate step functions by ReLU networks. To be more in line with what is observed in practice, we consider networks with all parameters bounded by a constant, which for convenience is set to one. If $\|W_{j}\|_{\infty}$ denotes the maximum-entry norm of $W_{j}$, the space of network functions with given network architecture and network parameters bounded by one is

$$\mathcal{F}(L, p) := \left\{ f \text{ of the form } (2.1) : \max_{j \in 1,...,L+1} \|W_{j}\|_{\infty} \vee |v_{j}|_{\infty} \leq 1 \right\}, (2.2)$$

with the convention that $v_{L+1}$ is a vector with coefficients all equal to zero.

In deep learning, sparsity of the neural network is enforced through regularization or specific forms of networks. Dropout for instance sets randomly units to zero and has the effect that each unit will be active only for a small fraction of the data, cf. [41], Section 7.2. In our notation this means that each entry of the vectors $\sigma_{v_{k}} W_{k} \cdots W_{2} \sigma_{v_{1}} W_{1} x$, $k = 1, \ldots, L$ is...
zero over a large range of the input space \( x \in [0, 1]^d \). Convolutional neural networks filter the input over local neighborhoods. Rewritten in the form (2.1) this essentially means that the \( W_i \) are banded Toeplitz matrices. All network parameters corresponding to higher off-diagonal entries are thus set to zero.

In this work we model the network sparsity assuming that there are only few non-zero/active network parameters. If \( \| W_j \|_0 \) denotes the number of non-zero entries of \( W_j \), then the \( s \)-sparse networks are given by

\[
F(L, p, s) := F(L, p, s, F) := \left\{ f \in F(L, p) : \sum_{j=1}^{L+1} \| W_j \|_0 + |v_j| \leq s, ||f||_\infty \leq F \right\}. \tag{2.3}
\]

The upper bound on the uniform norm of \( f \) is most of the time dispensable and therefore omitted in the notation. We consider cases where the number of network parameters \( s \) is small compared to the total number of parameters.

In deep learning, it is common to apply variations of stochastic gradient descent combined with other techniques such as drop-out to the loss induced by the log-likelihood (see Section 6.2.1.1 in [13]). For nonparametric regression with normal errors, this coincides with the least-squares loss (in machine learning terms this is the cross-entropy for this model, cf. [13], p.129). The common objective of all reconstruction methods is to find networks \( f \) with small empirical risk

\[
1/n \sum_{i=1}^{n} (Y_i - f(X_i))^2.
\]

For any estimator \( \hat{f}_n \) that returns a network in the class \( F(L, p, s, F) \) we define the corresponding quantity

\[
\Delta_n(\hat{f}_n, f_0) := E_{f_0} \left[ \frac{1}{n} \sum_{i=1}^{n} (Y_i - \hat{f}_n(X_i))^2 - \arg \min_{f \in F(L, p, s, F)} \frac{1}{n} \sum_{i=1}^{n} (Y_i - f(X_i))^2 \right]. \tag{2.4}
\]

The sequence \( \Delta_n(\hat{f}_n, f_0) \) measures the difference between the expected empirical risk of \( \hat{f}_n \) and the global minimum over all networks in the class. The subscript \( f_0 \) in \( E_{f_0} \) indicates that the expectation is taken with respect to a sample generated from the nonparametric regression model with regression function \( f_0 \). Notice that \( \Delta_n(\hat{f}_n, f_0) \geq 0 \) and \( \Delta_n(\hat{f}_n, f_0) = 0 \) if \( \hat{f}_n \) is an empirical risk minimizer.

We will see later that \( \Delta_n(\hat{f}_n, f_0) \) is the key quantity that together with the minimax estimation rate sharply determines the convergence rate of \( \hat{f}_n \) (up to log \( n \)-factors). Determining the decay of \( \Delta_n(\hat{f}_n, f_0) \) in \( n \) for commonly employed methods such as stochastic gradient descent is an interesting problem in its own. We only sketch a possible proof strategy here. Because of the potentially many local minima and saddle points of the loss surface or energy landscape, gradient descent based methods have only a small chance to reach the global minimum without getting stuck in a local minimum first. By making a link to spherical
spin glasses, [8] provide a heuristic suggesting that the loss of any local minima lies in a band that is lower bounded by the loss of the global minimum. The width of the band depends on the width of the network. If the heuristic argument can be made rigorous, then the width of the band provides an upper bound for \( \Delta_n(\hat{f}_n, f_0) \) for all methods that converge to a local minimum. For more on the energy landscape, see [31].

To evaluate the statistical performance of this estimator, we derive bounds on the prediction error

\[
R(\hat{f}_n, f_0) := E_{f_0}[ (\hat{f}_n(X) - f_0(X))^2 ],
\]

with \( X \overset{d}{=} X_1 \) being independent of the sample \((X_i, Y_i)\).

### 3 Main results

The theoretical performance of neural networks depends on the underlying function class. The classical approach in nonparametric statistics is to assume that the regression function is \( \beta \)-smooth. The minimax estimation rate for the prediction error is then \( n^{-2\beta/(2\beta+d)} \).

Since the input dimension \( d \) in neural network applications is very large, these rates are extremely slow. The huge sample sizes often encountered in these applications are by far not sufficient to compensate the slow rates.

We therefore consider a function class that is natural for neural networks and exhibits some low-dimensional structure that leads to input dimension free exponents in the estimation rates. We assume that the regression function \( f_0 \) is a composition of several functions, that is,

\[
f_0 = g_q \circ g_{q-1} \circ \ldots \circ g_1 \circ g_0 \tag{3.1}
\]

with \( g_i : [a_i, b_i]^{d_i} \to [a_{i+1}, b_{i+1}]^{d_{i+1}} \). Denote by \( g_i = (g_{ij})_{j=1}^{d_i+1} \) the components of \( g_i \) and let \( t_i \) be the maximal number of variables on which each of the \( g_{ij} \) depends on. Thus, each \( g_{ij} \) is a \( t_i \)-variate function. As an example consider the function \( f_0(x_1, x_2, x_3) = g_{11}(g_{01}(x_3), g_{02}(x_2)) \) for which \( d_0 = 3, t_0 = 1, d_1 = t_1 = 2, d_2 = 1 \). We always must have \( t_i \leq d_i \) and for specific constraints such as additive models, \( t_i \) might be much smaller than \( d_i \). The single components \( g_0, \ldots, g_q \) are obviously not identifiable. As we are only interested in estimation of \( f \) this causes no problems. In the \( d \)-variate regression model

\[
f_0 : [0,1]^d \to \mathbb{R}
\]

and thus \( d_0 = d, a_0 = 0, b_0 = 1 \) and \( d_{q+1} = 1 \). One should keep in mind that (3.1) is an assumption on the regression function that can be made independently of whether neural networks are used to fit the data or not. In particular, the number of layers \( L \) in the network has to be the same as \( q \).
It is conceivable that for many of the problems for which neural networks perform well a hidden hierarchical input-output relationship of the form (3.1) is present with small values $t_i$, cf. [39, 35]. Slightly more specific function spaces, which alternate between summations and composition of functions, have been considered in [20, 6]. We provide below an example of a function class that can be decomposed in the form (3.1) but is not contained in these spaces.

Recall that a function has Hölder smoothness index $\beta$ if all partial derivatives up to order $\lfloor \beta \rfloor$ exist and are bounded and the partial derivatives of order $\lfloor \beta \rfloor$ are $\beta - \lfloor \beta \rfloor$ Hölder, where $\lfloor \beta \rfloor$ denotes the largest integer strictly smaller than $\beta$. The ball of $\beta$-Hölder functions with radius $K$ is then defined as

$$C^\beta_r(D, K) = \{ f : D \subset \mathbb{R}^r \to \mathbb{R} : \sum_{\alpha : \|\alpha\| < \beta} \|\partial^\alpha f\|_\infty + \sum_{\alpha : \|\alpha\| = \lfloor \beta \rfloor} \sup_{x, y \in D, x \neq y} \frac{\|\partial^\alpha f(x) - \partial^\alpha f(y)\|}{|x - y|^{\beta - \lfloor \beta \rfloor}} \leq K \},$$

where we used multi-index notation, that is, $\partial^\alpha = \partial^{\alpha_1} \ldots \partial^{\alpha_r}$ with $\alpha = (\alpha_1, \ldots, \alpha_r) \in \mathbb{N}^r$ and $\|\alpha\| := |\alpha|_1$.

We assume that each of the functions $g_{ij}$ has Hölder smoothness $\beta_i$. Since $g_{ij}$ is also $t_i$-variate, $g_{ij} \in C^\beta_{t_i}([a_i, b_i]^{t_i}, K_i)$ and the underlying function space becomes

$$G(q, d, t, \beta, K) := \{ f = g_q \circ \ldots \circ g_0 : g_i = (g_{ij})_j : [a_i, b_i]^{d_i} \to [a_{i+1}, b_{i+1}]^{d_{i+1}},
\quad g_{ij} \in C^\beta_{t_i}([a_i, b_i]^{t_i}, K_i), \text{ for some } |a_i|, |b_i| \leq K \},$$

with $d := (d_0, \ldots, d_{q+1})$, $t := (t_0, \ldots, t_q)$, $\beta := (\beta_0, \ldots, \beta_q)$.

For estimation rates in the nonparametric regression model, the crucial quantity is the smoothness of $f$. Imposing smoothness on the functions $g_i$, we must then find the induced smoothness on $f$. If, for instance, $q = 1$, $\beta_0, \beta_1 \leq 1$, $d_0 = d_1 = t_0 = t_1 = 1$, then $f = g_1 \circ g_0$ and $f$ has smoothness $\beta_0 \beta_1$, cf. [21, 40]. We should then be able to achieve at least the convergence rate $n^{-2/2\beta_0 \beta_1/(2\beta_0 \beta_1 + 1)}$. For $\beta_1 > 1$, the rate changes. Below we see that the convergence of the network estimator is described by the effective smoothness indices

$$\beta^*_i := \beta_i \prod_{\ell=i+1}^q (\beta_\ell \wedge 1)$$

via the rate

$$\phi_n := \max_{i=0, \ldots, q} n^{-2\beta^*_i/(2\beta^*_i + 1)}.$$  \hspace{1cm} (3.2)

Recall the definition of $\Delta_n(\tilde{f}_n, f_0)$ in (2.4). We can now state the main result.
Theorem 1. Consider the $d$-variate nonparametric regression model (1.1) for composite regression function (3.1) in the class $G(q, d, t, \beta, K)$. Let $\hat{f}_n$ be an estimator taking values in the network class $F(L, (p_i)_{i=0, \ldots, L+1}, s, F)$ satisfying

(i) $F \geq \max(K, 1),$
(ii) $\sum_{t=0}^{d} \log(4t_i) \log_2 n \leq L \lesssim \log n,$
(iii) $n \phi_n \lesssim \min_{i=1, \ldots, L} p_i,$
(iv) $s \asymp n \phi_n \log n.$

There exist constants $C, C'$ only depending on $q, d, t, \beta, F$, such that if $\Delta_n(\hat{f}_n, f_0) \leq C \phi_n \log^3 n,$ then

$R(\hat{f}_n, f_0) \leq C' \phi_n \log^3 n,$ \hspace{1cm} (3.3)

and if $\Delta_n(\hat{f}_n, f_0) \geq C \phi_n \log^3 n,$ then

$\frac{1}{C'} \Delta_n(\hat{f}_n, f_0) \leq R(\hat{f}_n, f_0) \leq C' \Delta_n(\hat{f}_n, f_0).$ \hspace{1cm} (3.4)

The convergence rate in Theorem 1 depends on $\phi_n$ and $\Delta_n(\hat{f}_n, f_0)$. Below we show that $\phi_n$ is a lower bound for the minimax estimation risk over this class. Recall that the term $\Delta_n(\hat{f}_n, f_0)$ is large if $\hat{f}_n$ has a large empirical risk compared to the empirical risk minimizer. Having this term in the convergence rate is unavoidable as it also appears in the lower bound in (3.4). Since for the empirical risk minimizer the $\Delta_n$-term is zero by definition, we have the following direct consequence of the main theorem.

Corollary 1. Let $\tilde{f}_n \in \arg\min_{f \in F(L, p, s, F)} \sum_{i=1}^{n} (Y_i - f(X_i))^2$ be the empirical risk minimizer. Under the same conditions as for Theorem 1, there exists a constant $C'$, only depending on $q, d, t, \beta, F$, such that

$R(\tilde{f}_n, f_0) \leq C' \phi_n \log^3 n.$ \hspace{1cm} (3.5)

Condition (i) in Theorem 1 is very mild and only states that the network functions should have at least the same supremum norm as the regression function. From the other assumptions in Theorem 1 it becomes clear that there is a lot of flexibility in picking a good network architecture as long as the number of active parameters $s$ is taken to be of the right order. Interestingly, the depth $L$ of the network can be chosen without knowledge of the smoothness indices and it is sufficient to know an upper bound on the $t_i \leq d_i$. The network width can also be chosen independent of the smoothness indices by taking for instance $n \lesssim \min_i p_i$. One might wonder whether for the empirical risk minimizer the sparsity $s$ can be made adaptive by minimizing a penalized least squares problem with sparsity inducing
penalty on the network weights. It is conceivable that a complexity penalty of the form \( \lambda s \) will lead to adaptation if the regularization parameter \( \lambda \) is chosen of the correct order. From a practical point of view, it is more interesting to study \( \ell^1/\ell^2 \)-weight decay. As this requires much more machinery, the question will be moved to future work.

The number of network parameters in a fully connected network is of the order \( \sum_{i=0}^{L} p_i p_{i+1} \). This shows that Theorem 1 requires sparse networks. More specifically, the network has at least \( \sum_{i=1}^{L} p_i - s \) completely inactive nodes, meaning that all incoming signal is zero. The choice \( s \approx n \phi_n \log n \) in condition (iv) balances the squared bias and the variance. From the proof of the theorem convergence rates can also be derived if \( s \) is chosen of a different order.

For convenience, Theorem 1 is stated without explicit constants. The proofs, however, are non-asymptotic although we did not make an attempt to minimize the constants. It is well-known that deep learning outperforms other methods only for large sample sizes. This indicates that the method might be able to adapt to underlying structure in the signal and therefore achieving fast convergence rates but with large constants or remainder terms which spoil the results for small samples.

The proof of the risk bounds in Theorem 1 are based on the following oracle-type inequality.

**Theorem 2.** Consider the \( d \)-variate nonparametric regression model \((1.1)\) with unknown regression function \( f_0 \), satisfying \( \|f_0\|_\infty \leq F \) for some \( F \geq 1 \). Let \( \hat{f}_n \) be any estimator taking values in the class \( F(L, p, s, F) \) and let \( \Delta_n(\hat{f}_n, f_0) \) be the quantity defined in (2.4). For any \( \varepsilon \in (0, 1] \), there exists a constant \( C_\varepsilon \), only depending on \( \varepsilon \), such that

\[
(1 - \varepsilon)^2 \Delta_n(\hat{f}_n, f_0) - C_\varepsilon F^2 (s + 1) \log(n(s + 1) L p_0 p_{L+1}) \leq R(\hat{f}_n, f_0) \leq (1 + \varepsilon)^2 \left( \inf_{f \in F(L, p, s, F)} \|f - f_0\|_\infty^2 + \Delta_n(\hat{f}_n, f_0) \right) + C_\varepsilon F^2 (s + 1) \log(n(s + 1) L p_0 p_{L+1}) \frac{n}{n}.
\]

One consequence of the oracle inequality is that the upper bounds on the risk become worse if \( L \gg \log n \). In practice it also has been observed that too many layers lead to a degradation of the performance, cf. [17], [16], Section 4.4 and [42], Section 4. Residual networks can overcome this problem. But they are not of the form (2.1) and will need to be analyzed separately.

Let us remark on the optimality of the term \( \phi_n \log^2 n \) in the convergence rate (3.3). The \( \log^3 n \)-factor in the upper bound is not optimal. Next we show that \( \phi_n \) is a lower bound for the minimax estimation risk over the class \( G(q, d, t, \beta, K) \) in the interesting regime if \( t_i \leq \min(d_0, \ldots, d_{i-1}) \). This means that no dimensions are added on deeper abstraction
levels in the composition of functions. In particular, it avoids that \( t_i \) is larger than the input dimension \( d_0 \).

**Theorem 3.** Consider the nonparametric regression model \( f(x) = x^\beta \) with \( X_i \) drawn from a distribution with Lebesgue density on \([0, 1]^d\) which is lower and upper bounded by positive constants. For any non-negative integer \( q \), any dimension vectors \( \mathbf{d} \) and \( \mathbf{t} \) satisfying \( t_i \leq \min(d_0, \ldots, d_{i-1}) \) for all \( i \), any smoothness vector \( \beta \) and all sufficiently large constants \( K > 0 \), there exists a positive constant \( c \), such that

\[
\inf \sup_{\hat{f}_n, f_0} R(\hat{f}_n, f_0) \geq c\phi_n,
\]

where the inf is taken over all estimators \( \hat{f}_n \).

The proof is deferred to the appendix. To illustrate the main ideas, we provide a sketch here. For simplicity assume that \( t_i = d_i = 1 \) for all \( i \). In this case, the functions \( g_i \) are univariate and real-valued. Define \( i^* \in \arg\min_{i=0}^n q \beta_i^*/(2\beta_i^* + 1) \) as an index for which the estimation rate is obtained. For any \( \alpha > 0 \), \( x^\alpha \) has Hölder smoothness \( \alpha \) and for \( \alpha = 1 \), the function is infinitely often differentiable and has finite Hölder norm for all smoothness indices. Set \( g_\ell(x) = x^\beta_i \) for \( \ell < i^* \) and \( g_\ell(x) = x \beta_i \) for \( \ell > i^* \). Then,

\[
\hat{f}_n(x) = g_{i^*} \circ g_{i^*-1} \circ \ldots g_1 \circ g_0(x) = (g_{i^*}(x))^{(2\beta_{i^*} + 1)}.
\]

Assuming for the moment uniform random design, the Kullback-Leibler divergence is \( KL(P_f, P_g) = \frac{n}{2} \| f - g \|^2 \). Take a kernel function \( K \) and consider \( \tilde{g}(x) = h^{\beta_{i^*}} K(x/h) \). Under standard assumptions on \( K \), \( \tilde{g} \) has Hölder smoothness index \( \beta_{i^*} \). Now we can generate two hypotheses \( f_{00}(x) = 0 \) and \( f_{01}(x) = (h^{\beta_{i^*}} K(x/h))^{\prod_{\ell=0}^{i^*} \beta_i^{\wedge 1}} \) by taking \( g_{i^*}(x) = 0 \) and \( g_{i^*}(x) = \tilde{g}(x) \). Therefore, \( |f_{00}(0) - f_{01}(0)| \geq h^{\beta_{i^*}} \) assuming that \( K(0) > 0 \). For the Kullback-Leibler divergence, we find \( KL(P_{f_{00}}, P_{f_{01}}) \leq n h^{2\beta_{i^*} + 1} \). Using Theorem 2.2 (iii) in [47], this shows that the pointwise rate of convergence is \( n^{-2\beta_{i^*} / (2\beta_{i^*} + 1)} = \max_{i=0}^n n^{-2\beta_{i^*} / (2\beta_{i^*} + 1)} \).

This matches with the upper bound since \( t_i = 1 \) for all \( i \). For lower bounds on the prediction error, we generalize the argument to a multiple testing problem.

The \( L^2 \)-minimax rate coincides in most regimes with the sup-norm rate obtained in Section 4.1 of [21] for composition of two functions. But unlike the classical nonparametric regression model, the minimax estimation rates for \( L^2 \)-loss and sup-norm loss differ for some setups by a polynomial power in the sample size \( n \).

There are several recent results in approximation theory that provide lower bounds on the number of required network weights \( s \) such that all functions in a function class can be approximated by a \( s \)-sparse network up to some prescribed error, cf. for instance [7].
Results of this flavor can also be quite easily derived by combining the minimax lower bound with the oracle inequality. The argument is that if the same approximation rates would hold for networks with less parameters then we would obtain rates that are faster than the minimax rates, which clearly is a contradiction. This provides a new statistical route to establish approximation theoretic properties.

**Lemma 1.** Given $\beta, K > 0$, $d \in \mathbb{N}$, there exist constants $c_1, c_2$ only depending on $\beta, K, d$, such that if

$$s \leq c_1 \frac{\varepsilon^{-d/\beta}}{L \log(1/\varepsilon)}$$

for some $\varepsilon \leq c_2$, then for any width vector $p$ with $p_0 = d$ and $p_{L+1} = 1$,

$$\sup_{f_0 \in C_\beta^d([0,1],K)} \inf_{f \in F(L,p,s)} \|f - f_0\|_\infty \geq \varepsilon.$$  

A more refined argument using Lemma 10 instead of Theorem 2 yields also lower bounds for $L^2$.

### 4 Examples of specific structural constraints

In this section we discuss several well-studied special cases of compositional constraints on the regression function.

**Additive models:** In an additive model the regression function has the form

$$f_0(x_1,\ldots,x_d) = \sum_{i=1}^d f_i(x_i).$$

This can be written as a composition of functions

$$f_0 = g_1 \circ g_0$$

with $g_0(\mathbf{x}) = (f_1(x_1),\ldots,f_d(x_d))^\top$ and $g_1(\mathbf{y}) = \sum_{j=1}^d y_j$. Consequently, $g_0 : [0,1]^d \to \mathbb{R}^d$ and $g_1 : \mathbb{R}^d \to \mathbb{R}$ and thus $d_0 = d$, $t_0 = 1$, $d_1 = t_1 = d$, $d_2 = 1$. Equation (4.1) decomposes the original function into one function where each component only depends on one variable only and another function that depends on all variables but is infinitely smooth. For both types of functions fast rates can be obtained that do not suffer from the curse of dimensionality. This explains then the fast rate that can be obtained for additive models.

Suppose that $f_i \in C_\beta^d([0,1],K)$ for $i = 1,\ldots,d$. Then, $f : [0,1]^d \xrightarrow{g_0} [-K,K]^d \xrightarrow{g_1} [-Kd,Kd]$. Since for any $\gamma > 1$, $g_1 \in C_\gamma^d([-K,K]^d,(K+1)d)$,

$$f_0 \in \mathcal{G}(1, (d,d,1), (1,d), (\beta, (\beta \vee 2)d), (K+1)d).$$
For network architectures $\mathcal{F}(L,p,s,F)$ satisfying $F \geq (K+1)d$, $\log_2(16d) \log n \leq L \lesssim \log n$, $n^{1/(2\beta+1)} \lesssim \min_i p_i$ and $s \asymp n^{1/(2\beta+1)} \log n$, we thus obtain by Theorem 1,

$$R(\hat{f}_n, f_0) \lesssim n^{-\frac{2\gamma}{2\beta+1}} \log^3 n + \Delta(\hat{f}_n, f_0).$$

This coincides up to the $\log^3 n$-factor with the minimax estimation rate.

**Generalized additive models:** Suppose the regression function is of the form

$$f_0(x_1, \ldots, x_d) = h\left(\sum_{i=1}^d f_i(x_i)\right),$$

for some unknown link function $h : \mathbb{R} \to \mathbb{R}$. This can be written as composition of three functions $f_0 = g_2 \circ g_1 \circ g_0$ with $g_0$ and $g_1$ as before and $g_2 = h$. If $f_i \in C_1^\beta([0,1],K)$ and $h \in C_1^\gamma(\mathbb{R},K)$, then $f_0 : [0,1]^d \xrightarrow{g_0} [-K,K]^d \xrightarrow{g_1} [-Kd,Kd] \xrightarrow{g_2} [-K,K]$. Arguing as for additive models,

$$f_0 \in \mathcal{G}(2, (d,d,1,1), (1,d,1), (\beta, (\beta \lor 2)d, \gamma), (K+1)d).$$

For network architectures satisfying the assumptions of Theorem 1 the bound on the estimation rate becomes

$$R(\hat{f}_n, f_0) \lesssim \left(n^{-\frac{2\beta(\gamma \lor 1)}{2\beta(\gamma \lor 1)+1}} + n^{-\frac{2\beta}{2\beta+1}}\right) \log^3 n + \Delta(\hat{f}_n, f_0). \quad (4.2)$$

Theorem 3 shows that $n^{-\frac{2\beta(\gamma \lor 1)}{2\beta(\gamma \lor 1)+1}} + n^{-\frac{2\gamma}{2\gamma+1}}$ is also a lower bound. Let us also remark that for the special case $\beta = \gamma \geq 2$ and $\beta, \gamma$ integers, Theorem 2.1 of [20] establishes the estimation rate $n^{-\frac{2\beta}{2\beta+1}}$.

**Sparse tensor decomposition:** Assume that the regression function $f_0$ has the form

$$f_0(x) = \sum_{\ell=1}^N a_\ell \prod_{i=1}^d f_{i\ell}(x_i), \quad (4.3)$$

for fixed $N$, real coefficients $a_\ell$ and univariate functions $f_{i\ell}$. Especially, if $N = 1$, this is the same as imposing a product structure on the regression function $f_0(x) = \prod_{i=1}^d f_i(x_i)$.

The function class spanned by such sparse tensor decomposition can be best explained by making a link to series estimators. Series estimators are based on the idea that the unknown function is close to a linear combination of few basis functions, where the approximation error depends on the smoothness of the signal. This means that any $L^2$-function can be approximated by $f_0(x) \approx \sum_{\ell=1}^N a_\ell \prod_{i=1}^d \phi_{i\ell}(x_i)$ for suitable coefficients $a_\ell$ and functions $\phi_{i\ell}$.

Whereas series estimators require the choice of a basis, for neural networks to achieve fast rates it is enough that (4.3) holds. The functions $f_{i\ell}$ can be unknown and do not need to be orthogonal.
We can rewrite (4.3) as a composition of functions \( f_0 = g_2 \circ g_1 \circ g_0 \) with \( g_0(x) = (f_{\ell t}(x_i))_{i, t}, \)
\( g_1 = (g_{ij})_{j=1,...,N} \) performing the \( N \) multiplications \( \prod_{t=1}^{d} \) and \( g_2(y) = \sum_{\ell=1}^{N} a_{\ell} y_{\ell}. \) Observe
that \( t_0 = 1 \) and \( t_1 = d. \) Assume that \( f_{\ell t} \in C_1^d([0, 1], K) \) for \( K \geq 1 \) and \( \max_{\ell} |a_{\ell}| \leq 1. \) Because
of \( g_{1,j} \in C_1^d([-K, K]^d, 2d^2K^d) \) for all \( \gamma \geq d+1 \) and \( g_2 \in C_1^\gamma([-2dK^d, 2dK^d], N(2dK^d+1)) \) for
\( \gamma' > 1, \) we have \([0, 1]^d \xrightarrow{g_0} [-K, K]^N \xrightarrow{g_1} [-2dK^d, 2dK^d]^N \xrightarrow{g_2} [N(2dK^d+1), N(2dK^d+1)]\)
\( f_0 \in \mathcal{G}\left(2, (d, Nd, N, 1), (1, d, Nd), (\beta, \beta d \vee (d + 1), N\beta + 1), N(2dK^d+1)\right). \)
For networks with architectures satisfying \( \log_2(64Nd^2 \log_2 n) \leq L \leq \log n, \ n^{1/(2\beta+1)} \leq \min_i p_i \) and \( s \propto n^{1/(2\beta+1)} \log n, \) Theorem 1 yields the rate
\( R(\hat{f}_n, f_0) \lesssim n^{-\frac{2\beta}{2\beta+1}} \log^3 n + \Delta(\hat{f}_n, f_0), \)
which is unaffected by the curse of dimensionality.

5 Suboptimality of wavelet series estimators

As argued before the composition assumption in (3.1) is very natural and generalizes many structural constraints such as additive models. In this section, we show that wavelet series estimators are unable to take advantage from the underlying composition structure in the regression function and achieve in some setups much slower convergence rates.

More specifically, we consider general additive models of the form \( f_0(x) = h(x_1 + \ldots + x_d) \)
with \( h \in C_1^0((0, d], K). \) Using (4.2), the prediction error of neural network reconstructions
with small empirical risk is then bounded by \( n^{-2\alpha/(2\alpha+1)} \log^3 n. \) The lower bound below shows that wavelet series estimators cannot converge faster than with the rate \( n^{-2\alpha/(2\alpha+d)}. \)
This rate can be much slower if \( d \) is large. Wavelet series estimators thus suffer in this case from the curse of dimensionality while neural networks achieve fast rates.

Consider a compact wavelet basis of \( L^2(\mathbb{R}) \) restricted to \( L^2[0, 1], \) say \((\psi_\lambda, \lambda \in \Lambda), \) cf. [9].
Here, \( \Lambda = \{(j,k) : j = -1, 0, 1, \ldots; k \in I_j\} \) with \( k \) ranging over the index set \( I_j \) and \( \psi_{-1,k} := \phi(-k) \) are the shifted scaling functions. Then for any function \( f \in L^2[0, 1]^d, \)
\( f(x) = \sum_{(\lambda_1, \ldots, \lambda_d) \in \Lambda \times \ldots \times \Lambda} d_{\lambda_1 \ldots \lambda_d}(f) \prod_{r=1}^{d} \psi_{\lambda_r}(x_r), \)
with convergence in \( L^2[0, 1] \) and
\[ d_{\lambda_1 \ldots \lambda_d}(f) := \int f(x) \prod_{r=1}^{d} \psi_{\lambda_r}(x_r) \, dx \]
the wavelet coefficients.

To construct a counterexample, it is enough to consider the nonparametric regression model
\( Y_i = f_0(X_i) + \varepsilon_i, \ i = 1, \ldots, n \) with uniform design \( X_i := (U_{i,1}, \ldots, U_{i,d}) \sim \text{Unif}[0,1]^d \). The empirical wavelet coefficients are
\[
\hat{d}_{\lambda_1 \ldots \lambda_d}(f_0) = \frac{1}{n} \sum_{i=1}^{n} Y_i \prod_{r=1}^{d} \psi_{\lambda_r}(U_{i,r}).
\]

Because of \( E[\hat{d}_{\lambda_1 \ldots \lambda_d}(f_0)] = d_{\lambda_1 \ldots \lambda_d}(f_0) \), this gives unbiased estimators for the wavelet coefficients. By the law of total variance,
\[
\text{Var} (\hat{d}_{\lambda_1 \ldots \lambda_d}(f_0)) = \frac{1}{n} \text{Var} ( Y_1 \prod_{r=1}^{d} \psi_{\lambda_r}(U_{1,r}) ) \geq \frac{1}{n} E \left[ \text{Var} ( Y_1 \prod_{r=1}^{d} \psi_{\lambda_r}(U_{1,r}) | U_{1,1}, \ldots, U_{1,d} ) \right] = \frac{1}{n}.
\]

For the lower bounds we may assume that the smoothness indices are known. For estimation, we can truncate the series expansion on a resolution level that balances squared bias and variance of the total estimator. More generally, we study estimators of the form
\[
\hat{f}_n(x) = \sum_{(\lambda_1, \ldots, \lambda_d) \in I} \hat{d}_{\lambda_1 \ldots \lambda_d}(f_0) \prod_{r=1}^{d} \psi_{\lambda_r}(x_r),
\]
where \( I \subset \Lambda \times \ldots \times \Lambda \) is an arbitrary subset. Using that the design is uniform,
\[
R(\hat{f}_n, f_0) = \sum_{(\lambda_1, \ldots, \lambda_d) \in I} E [ (\hat{d}_{\lambda_1 \ldots \lambda_d}(f_0) - d_{\lambda_1 \ldots \lambda_d}(f_0))^2 ] + \sum_{(\lambda_1, \ldots, \lambda_d) \in I^c} d_{\lambda_1 \ldots \lambda_d}(f_0)^2 \geq \frac{1}{n} \wedge d_{\lambda_1 \ldots \lambda_d}(f_0)^2.
\]

By construction, \( \psi \in L^2(\mathbb{R}) \) has compact support, We can therefore without loss of generality assume that \( \psi \) is zero outside of \([0, 2^q]\) for some integer \( q > 0 \).

**Lemma 2.** Let \( q \) be as above and set \( \nu := \lceil \log_2 d \rceil + 1 \). For any \( 0 < \alpha \leq 1 \) and any \( K > 0 \), there exists a non-zero constant \( c(\psi, d) \) only depending on \( d \) and properties of the wavelet function \( \psi \) such that for any \( j \), we can find a function \( f_{j,\alpha}(x) = h_{j,\alpha}(x_1 + \ldots + x_d) \) with \( h_{j,\alpha} \in C^\alpha([0,d],K) \) satisfying
\[
d_{(j,2^{q+\nu}p_1), \ldots, (j,2^{q+\nu}p_r)}(f_{j,\alpha}) = c(\psi, d) K 2^{-\frac{q}{2}(2\alpha + d)}
\]
for all \( p_1, \ldots, p_r \in \{0, 1, \ldots, 2^{j-q-\nu} - 1\} \).
Theorem 4. If \( \hat{f}_n \) denotes the wavelet estimator (5.1) for a compactly supported wavelet \( \psi \) and an arbitrary index set \( I \), then, for any \( 0 < \alpha \leq 1 \) and any Hölder radius \( K > 0 \),
\[
\sup_{f_0(x) = h(\sum_{i=1}^d x_i), h \in C_1^\alpha([0,2],K)} R(\hat{f}_n, f_0) \gtrsim n^{-2\alpha/2\alpha+d}.
\]

6 A brief summary of related statistical theory for neural networks

This section is intended as a condensed overview on related literature summarizing main proving strategies for bounds on the statistical risk. An extended summary of the work until the late 90’s is given in [38]. To control the stochastic error of neural networks, bounds on the covering entropy and VC dimension can be found in the monograph [1]. A challenging part in the analysis of neural networks is the approximation theory for multivariate functions. We first recall results for shallow neural networks, that is, neural networks with one hidden layer.

Shallow neural networks and cosine expansions: A shallow network with one output unit and width vector \((d, m, 1)\) can be written as
\[
f_m(x) = \sum_{j=1}^m c_j \sigma(w_j^\top x + v_j), \quad w_j \in \mathbb{R}^d, \ v_j, c_j \in \mathbb{R}.
\]
(6.1)

The universal approximation theorem states that a neural network with one hidden layer can approximate any continuous function \( f \) arbitrarily well with respect to the uniform norm provided there are enough hidden units, cf. [18, 19, 10, 29, 43]. If \( f \) has a derivative \( f' \), then the derivative of the neural network also approximates \( f' \). The number of required hidden units might be, however, extremely large, cf. [37] and [36].

The essential idea of the universal approximation theory can be described as follows. Recall the addition theorem \( \cos(u) \cos(v) = \frac{1}{2} (\cos(u + v) + \cos(u - v)) \). Using this together with the fact that any function \( f \in L^2[0,1]^d \) can be expanded in the tensorized cosine basis, we obtain \( f(x_1, \ldots, x_d) = \sum_{(i_1, \ldots, i_d) \in \mathbb{N}^d} a_{i_1 \ldots i_d} \prod_{j=1}^d \cos(i_j \pi x_j) = \sum_j \tilde{c}_j \cos(\tilde{w}_j^\top x) \) for suitable \( \tilde{w}_j \in \mathbb{R}^d \) and \( \tilde{c}_j \in \mathbb{R} \). We can bring this then in the form (6.1) by approximating \( \cos(\cdot) \) through linear combinations of \( \sigma(a \cdot + b) \).

This idea can be sharpened in order to obtain rates of convergence. In [33] the convergence rate \( n^{-2\beta/(2\beta+d+5)} \) is derived. Compared with the minimax estimation rate this is suboptimal by a polynomial factor. The reason for the loss of performance with this approach is that rewriting the function as a network requires too many parameters.
In [4, 5, 22, 23] a similar strategy is used to derive the rate $C_f(d \log n)^{1/2}$ for the squared $L^2$-risk, where $C_f := \int |\omega| |\mathcal{F}f(\omega)|d\omega$ and $\mathcal{F}f$ denotes the Fourier transform of $f$. If $C_f < \infty$ and $d$ is fixed the rate is always $n^{-1/2}$ up to logarithmic factors. Since $\sum_i \|\partial_i f\|_\infty \leq C_f$, this means that $C_f < \infty$ can only hold if $f$ has Hölder smoothness at least one. This rate is difficult to compare with the standard nonparametric rates except for the special case $d = 1$, where the rate is suboptimal compared with the minimax rate $n^{-2/(2+d)}$ for $d$-variate functions with smoothness one. More interestingly, the rate $C_f(d \log n)^{1/2}$ shows that neural networks can converge fast if the underlying function satisfies some additional structural constraint. In a similar fashion, [2] studies abstract function spaces on which shallow networks achieve fast convergence rates.

Results for multilayer neural networks: [24, 15, 26, 25] use two-layer neural networks with sigmoidal activation function and achieve the nonparametric rate $n^{-2\beta/(2\beta+d)}$ up to $\log n$-factors. Unfortunately, the result requires that the activation function is at least as smooth as the signal, cf. Theorem 1 in [6]. It therefore rules out the ReLU activation function.

The activation function $\sigma(x) = x^2$ is not of practical relevance but has some interesting theory. Indeed, with one hidden layer, we can generate quadratic polynomials and with $L$ hidden layers polynomials of degree $2^L$. For this activation function, the role of the network depth is the polynomial degree and we can use standard results to approximate functions in common function classes. A natural generalization is the class of activation functions satisfying $\lim_{x \to -\infty} x^{-k} \sigma(x) = 0$ and $\lim_{x \to +\infty} x^{-k} \sigma(x) = 1$.

If the growth is at least quadratic ($k \geq 2$), the approximation theory has been derived in [34] for deep networks with number of layers scaling with $\log d$. The same class has also been considered recently in [7]. For the approximations to work, the assumption $k \geq 2$ is crucial and the same approach does not generalize to the ReLU activation function, which satisfies the growth condition with $k = 1$, and always produces functions that are piecewise linear in the input.

Approximation theory for the ReLU activation function has been only recently developed in [36, 30, 50, 44]. The key observation is that there are specific deep networks with few units which approximate the square function well. In particular, the function approximation presented in [50] is essential for our approach and we use a similar strategy to construct networks that are close to a given function. We are, however, interested in a somehow different question. Instead of deriving existence of a network architecture with good approximation properties, we show that for any network architecture satisfying the conditions of Theorem [4] good approximation rates are obtainable. An additional difficulty in our approach is the boundedness of the network parameters.
7 Proofs

7.1 Embedding properties of network function classes

For the approximation of a function by a network, we first construct smaller networks computing simpler objects. To combine networks, we make frequently use of the following rules. Recall that \( p = (p_0, \ldots, p_{L+1}) \) and \( p' = (p'_0, \ldots, p'_{L+1}) \).

**Enlarging:** \( \mathcal{F}(L, p, s) \subseteq \mathcal{F}(L, q, s') \) whenever \( p \leq q \) componentwise and \( s \leq s' \).

**Composition:** Suppose that \( f \in \mathcal{F}(L, p) \) and \( g \in \mathcal{F}(L', p') \) with \( p_{L+1} = p'_0 \). For a vector \( \mathbf{v} \in \mathbb{R}^{p_{L+1}} \) we define the composed network \( g \circ \sigma_{\mathbf{v}}(f) \) which is in the space \( \mathcal{F}(L + L' + 1, (p, p'_1, \ldots, p'_{L+1})) \). In most of the cases that we consider, the output of the first network is non-negative and the shift vector \( \mathbf{v} \) will be taken to be zero.

**Additional layers/depth synchronization:** To synchronize the number of hidden layers for two networks, we can add additional layers with identity weight matrix, such that
\[
\mathcal{F}(L, p, s) \subseteq \mathcal{F}(L + q, (p_0, \ldots, p_0 q \times p, s), s + qp_0).
\]

**Parallelization:** Given two networks with the same number of hidden layers and the same input dimension, that is, \( f \in \mathcal{F}(L, p) \) and \( g \in \mathcal{F}(L, p') \) with \( p_0 = p'_0 \). The parallelized network \( (f, g) \) computes \( f \) and \( g \) simultaneously in a joint network in the class \( \mathcal{F}(L, (p_0, p_1 + p'_1, \ldots, p_{L+1} + p'_{L+1})) \).

**Removal of inactive nodes:** We have
\[
\mathcal{F}(L, p, s) = \mathcal{F}(L, (p_0, p_1 \land s, p_2 \land s, \ldots, p_L \land s, p_{L+1}), s).
\]

To see this, let \( f(x) = W_{L+1} \sigma_{v_L} W_L \ldots \sigma_{v_1} W_1 x \in \mathcal{F}(L, p, s) \). If all entries of the \( j \)-th column of \( W_{i+1} \) are zero, then we can remove this column together with the \( j \)-th row in \( W_i \) and the \( j \)-th entry of \( v_i \) without changing the function. This shows then that \( f \in \mathcal{F}(L, (p_0, \ldots, p_{i-1}, p_i - 1, p_{i+1}, \ldots, p_{L+1}), s) \). Because there are \( s \) active parameters, we can iterate this procedure at least \( p_i - s \) times for any \( i = 1, \ldots, L \). This proves \( f \in \mathcal{F}(L, (p_0, p_1 \land s, p_2 \land s, \ldots, p_L \land s, p_{L+1}), s) \).

We frequently make use of the fact that for a fully connected network in \( \mathcal{F}(L, p) \) the number of parameters is
\[
\sum_{\ell=0}^{L} (p_\ell + 1)p_{\ell+1} - p_{L+1}.
\]
7.2 Approximation of polynomials by neural networks

In a first step, we construct a network, with all network parameters bounded by one, which approximately computes \( xy \) given input \( x \) and \( y \). Let \( T^k : [0, 2^{2-k}] \to [0, 2^{-2k}] \),
\[
T^k(x) := (x/2) \wedge (2^{1-2k} - x/2) = (x/2)_+ - (x - 2^{1-2k})_+
\]
and \( R^k : [0, 1] \to [0, 2^{-2k}] \),
\[
R^k := T^k \circ T^{k-1} \circ \ldots \circ T^1.
\]
The next result shows that \( \sum_{k=1}^{m} R^k(x) \) approximates \( x(1-x) \) exponentially fast in \( m \) and that in particular \( x(1-x) = \sum_{k=1}^{\infty} R^k(x) \) in \( L^\infty[0,1] \). This lemma can be viewed as a slightly sharper variation of Lemma 2.4 in [46] and Proposition 2 in [50]. In contrast to the existing results, we can use it to build networks with parameters bounded by one. It also provides an explicit bound on the approximation error.

**Lemma 3.**
\[
|x(1-x) - \sum_{k=1}^{m} R^k(x)| \leq 2^{-m}.
\]

**Proof.** In a first step, we show by induction that \( R^k \) is a triangle wave. More precisely, \( R^k \) is piecewise linear on the intervals \( [\ell/2^k, (\ell+1)/2^k] \) with endpoints \( R^k(\ell/2^k) = 2^{-2k} \) if \( \ell \) is odd and \( R^k(\ell/2^k) = 0 \) if \( \ell \) is even. For \( R^1 = T^1 \) this is obviously true. For the inductive step, suppose this is true for \( R^k \). Write \( \ell \equiv r \mod 4 \) if \( \ell - r \) is divisible by 4 and consider \( x \in [\ell/2^{k+1}, (\ell+1)/2^{k+1}] \). If \( \ell \equiv 0 \mod 4 \) then, \( R^k(x) = 2^{-k}(x - \ell/2^{k+1}) \). Similar for \( \ell \equiv 2 \mod 4 \), \( R^k(x) = 2^{-2k} - 2^{-k}(x - \ell/2^{k+1}) \); for \( \ell \equiv 1 \mod 4 \), we have \( \ell + 1 \equiv 2 \mod 4 \) and \( R^k(x) = 2^{-2k-1} + 2^{-k}(x - \ell/2^{k+1}) \); and for \( \ell \equiv 3 \mod 4 \), \( R^k(x) = 2^{-2k-1} - 2^{-k}(x - \ell/2^{k+1}) \). Together with
\[
R^{k+1}(x) = T^{k+1} \circ R^k(x)
\]
\[
= \frac{R^k(x)}{2} \mathbf{1}(R^k(x) \leq 2^{-2k-1}) + \left(2^{-2k-1} - \frac{R^k(x)}{2}\right) \mathbf{1}(R^k(x) > 2^{-2k-1}).
\]
this shows the claim for \( R^{k+1} \) and completes the induction.

For convenience, write \( g(x) = x(1-x) \). In the next step, we show that for any \( m \geq 1 \) and any \( \ell \in \{0, 1, \ldots, 2^m\} \),
\[
g(\ell 2^{-m}) = \sum_{k=1}^{m} R^k(\ell 2^{-m}).
\]
We prove this by induction over \(m\). For \(m = 1\) the result can be checked directly. For the inductive step, suppose that the claim holds for \(m\). If \(\ell\) is even we use that \(R^{m+1}(\ell 2^{-m-1}) = 0\) to obtain that \(g(\ell 2^{-m-1}) = \sum_{k=1}^{m} R^k(\ell 2^{-m-1}) = \sum_{k=1}^{m+1} R^k(\ell 2^{-m-1})\). It thus remains to consider \(\ell\) odd. Recall that \(x \mapsto \sum_{k=1}^{m} R^k(x)\) is linear on \([((\ell - 1)2^{-m}, (\ell + 1)2^{-m}]\) and observe that for any real \(t\),

\[
g(x) - \frac{g(x + t) + g(x - t)}{2} = t^2.
\]

Using this for \(x = \ell 2^{-m-1}\) and \(t = 2^{-m-1}\) yields for odd \(\ell\) due to \(R^{m+1}(\ell 2^{-m-1}) = 2^{-2m-2}\),

\[
g(\ell 2^{-m-1}) = 2^{-2m-2} + \sum_{k=1}^{m} R^k(\ell 2^{-m-1}) = \sum_{k=1}^{m+1} R^k(\ell 2^{-m-1}) = \sum_{k=1}^{m+1} R^k(\ell 2^{-m-1}).
\]

This completes the inductive step.

So far we proved that \(\sum_{k=1}^{m} R^k(x)\) interpolates \(g\) at the points \(\ell 2^{-m}\) and is linear on the intervals \([\ell 2^{-m}, (\ell + 1)2^{-m}]\). Observe also that \(g\) is Lipschitz with Lipschitz constant one. Thus, for any \(x\), there exists an \(\ell\) such that

\[
|g(x) - \sum_{k=1}^{m} R^k(x)| = |g(x) - (2^m x - \ell)g((\ell + 1)2^{-m}) - (\ell + 1 - 2^m x)g(2^{-m})| \leq 2^{-m}.
\]

\(\square\)

Let \(g(x) = x(1 - x)\) as in the last proof. To construct a network which returns approximately \(xy\) given input \(x\) and \(y\), we use the polarization type identity

\[
g\left(\frac{x - y + 1}{2}\right) - g\left(\frac{x + y}{2}\right) + \frac{x + y}{2} - \frac{1}{4} = xy, \quad (7.4)
\]

cf. also [50], Equation (3).

**Lemma 4.** There exists a network \(\text{Mult}_m \in \mathcal{F}(m+4, (2, 6, 6, \ldots, 6, 1))\), such that \(\text{Mult}_m(x, y) \in [0, 1]\) and

\[
|\text{Mult}_m(x, y) - xy| \leq 2^{-m}, \quad \text{for all } x, y \in [0, 1].
\]

**Proof.** Write \(T_k(x) = (x/2)_+ - (x - 2^{1-2k})_+ = T_+(x) - T_+(x)\) with \(T_+(x) = (x/2)_+\) and \(T_-(x) = (x - 2^{1-2k})_+\) and let \(h : [0, 1] \to [0, \infty)\) be a non-negative function. In a first step we show that there is a network \(N_m\) with \(m\) hidden layers and width vector \((3, 3, \ldots, 3, 1)\) that computes the function

\[
(T_+(u), T_-(u), h(u)) \mapsto \sum_{k=1}^{m+1} R^k(u) + h(u),
\]

21
Figure 2: The network \((T_+ (u), T'_{-1} (u), h(u)) \mapsto \sum_{k=1}^{m+1} R_k(u) + h(u)\).

for all \(u \in [0,1]\). The proof is given in Figure 2. Notice that all parameters in this network are bounded by one. In a next step, we show that there is a network with \(m + 3\) hidden layers that computes the function

\[(x, y) \mapsto \left( \sum_{k=1}^{m+1} R_k \left( \frac{x - y + 1}{2} \right) - \sum_{k=1}^{m+1} R_k \left( \frac{x + y}{2} \right) + \frac{x + y}{2} - \frac{1}{4} \right) \wedge 1.\]

This network computes in the first layer

\[(x, y) \mapsto \left( T_+ \left( \frac{x - y + 1}{2} \right), T'_{-1} \left( \frac{x - y + 1}{2} \right), \left( \frac{x + y}{2} \right)_+, T_+ \left( \frac{x + y}{2} \right), T'_{-1} \left( \frac{x + y}{2} \right), \frac{1}{4} \right).\]

On the first three and the last three components, we apply the network \(N_m\). This gives a network with \(m + 1\) hidden layers and width vector \((2, 3, \ldots, 3, 2)\) that computes

\[(x, y) \mapsto \left( \sum_{k=1}^{m+1} R_k \left( \frac{x - y + 1}{2} \right) + \frac{x + y}{2}, \sum_{k=1}^{m+1} R_k \left( \frac{x + y}{2} \right) + \frac{1}{4} \right).\]

Apply to the output the two hidden layer network \((u, v) \mapsto (1 - (1 - (u - v))_+)_+ = (u - v)_+ \wedge 1.\)

The combined network \(\text{Mult}_m(x, y)\) has thus \(m + 4\) hidden layers and computes

\[(x, y) \mapsto \left( \sum_{k=1}^{m+1} R_k \left( \frac{x - y + 1}{2} \right) - \sum_{k=1}^{m+1} R_k \left( \frac{x + y}{2} \right) + \frac{x + y}{2} - \frac{1}{4} \right) \wedge 1.\]

This shows that the output is always in \([0, 1]\). By (7.4) and Lemma 3, \(|\text{Mult}_m(x, y) - xy| \leq 2^{-m}\).

\(\square\)
Remark 1. Denote by $\log_2$ the logarithm with respect to the basis two and write $\lceil x \rceil$ for the smallest integer $\geq x$.

Lemma 5. There exists a network $\text{Mult}_m^r \in \mathcal{F}((m+5)[\log_2 r], (r, 6r, 6r, \ldots, 6r, 1))$ such that $\text{Mult}_m^r \in [0,1]$ and

$$|\text{Mult}_m^r(x) - \prod_{i=1}^r x_i| \leq 3^r 2^{-m}, \quad \text{for all } x = (x_1, \ldots, x_r) \in [0,1]^r.$$ 

Proof. Let $q := \lceil \log_2 (r) \rceil$. Let us now describe the construction of the $\text{Mult}_m^r$ network. In the first hidden layer the network computes $(x_1, \ldots, x_r) \mapsto (x_1, \ldots, x_r, 1, \ldots, 1)_{2^q-r}$. Next, apply the network $\text{Mult}_m$ in Lemma 4 to the pairs $(x_1, x_2), (x_3, x_4), \ldots, (1, 1)$ in order to compute the vector $(\text{Mult}_m^r(x_1, x_2), \text{Mult}_m^r(x_3, x_4), \ldots, \text{Mult}_m^r(1, 1))$ which has length $2^q - 1$. Now, we pair neighboring entries and apply $\text{Mult}_m$ again. This procedure is continued until there is only one entry left. The resulting network is called $\text{Mult}_m^r$ and has $q(m+5)$ hidden layers and all parameters bounded by one.

If $a, b, c, d \in [0,1]$, then by Lemma 4 and triangle inequality, $|\text{Mult}_m(a, b) - cd| \leq 2^{-m} + |a - c| + |b - d|$. By induction on the number of iterated multiplications $q$, we therefore find that $|\text{Mult}_m^r(x) - \prod_{i=1}^r x_i| \leq 3^q 12^{-m}$. □

In the next step, we construct a sufficiently large network that approximates all monomials $x_1^{\alpha_1} \cdot \ldots \cdot x_r^{\alpha_r}$ for non-negative integers $\alpha_i$ up to a certain degree. As common, we use multi-index notation $x^\alpha := x_1^{\alpha_1} \cdot \ldots \cdot x_r^{\alpha_r}$, where $\alpha = (\alpha_1, \ldots, \alpha_r)$ and $|\alpha| := \sum \alpha_\ell$ is the degree of the monomial. The number of monomials with degree $0 < |\alpha| < \gamma$ is denoted by $C_{r, \gamma}$. Obviously, $C_{r, \gamma} + 1 \leq (\gamma + 1)^r$ since each $\alpha_i$ has to take values in $\{0, 1, \ldots, \gamma\}$.

Lemma 6. Given $\gamma > 0$, there exists a network

$$\text{Mon}_{m,\gamma}^r \in \mathcal{F}((m+5)[\log_2 r], (r, 6r C_{r, \gamma}, \ldots, 6r C_{r, \gamma}, C_{r, \gamma})),$$

such that $\text{Mon}_{m,\gamma}^r \in [0,1]_{C_{r, \gamma}}$ and

$$|\text{Mon}_{m,\gamma}^r(x) - (x^\alpha)_{0 < |\alpha| < \gamma}|_\infty \leq 3^r 2^{-m}, \quad \text{for all } x \in [0,1]^r.$$ 

Proof. This follows from computing all monomials with degree $0 < |\alpha| < \gamma$ in parallel. The claim follows from Lemma 5. □
7.3 Reconstruction of a multivariate function with a multilayer neural network

We follow the classical idea of function approximation by local Taylor approximations that has previously been used for network approximations in [50]. For a vector $a \in [0, 1]^r$ define

$$P^\beta_a f(x) = \sum_{0 \leq |\alpha| < \beta} (\partial^\alpha f)(a) \frac{(x - a)^\alpha}{\alpha!}.$$  (7.5)

Since $a \in [0, 1]^r$ and $f \in C^\beta_r([0, 1]^r, K)$, $|(x - a)^\alpha| = \prod_i |x_i - a_i|^\alpha_i \leq |x - a|^\alpha_\infty$ and by the definition of Hölder balls,

$$|P^\beta_a f(x)| \leq K.$$  (7.6)

By Taylor’s theorem for multivariate functions, we have for a suitable $\xi \in [0, 1]$,

$$f(x) = \sum_{\alpha:|\alpha| < \beta - 1} (\partial^\alpha f)(a) \frac{(x - a)^\alpha}{\alpha!} + \sum_{\beta - 1 \leq |\alpha| < \beta} (\partial^\alpha f)(a + \xi(x - a)) \frac{(x - a)^\alpha}{\alpha!}$$

and so, for $f \in C^\beta_r([0, 1]^r, K)$,

$$|f(x) - P^\beta_a f(x)| = \sum_{\beta - 1 \leq |\alpha| < \beta} \frac{|(x - a)^\alpha|}{\alpha!} |(\partial^\alpha f)(a + \xi(x - a)) - (\partial^\alpha f)(a)|$$

$$\leq K|x - a|^\beta_\infty.$$  (7.7)

We may also write (7.5) as a linear combination of monomials

$$P^\beta_a f(x) = \sum_{0 \leq |\gamma| < \beta} x^\gamma c_\gamma,$$  (7.8)

for suitable coefficients $c_\gamma$. Since $\partial^\gamma P^\beta_a f(x)|_{x=0} = \gamma! c_\gamma$, we must have

$$c_\gamma = \sum_{\gamma \leq \alpha \leq |\alpha| < \beta} (\partial^\alpha f)(a) \frac{(-a)^{\alpha - \gamma}}{\gamma!(\alpha - \gamma)!}.$$  (7.9)

Notice that since $a \in [0, 1]^r$ and $f \in C^\beta_r([0, 1]^r, K)$,

$$|c_\gamma| \leq K/\gamma!.$$  (7.9)

Consider the set of grid points $D(M) := \{x_\ell = (\ell_j/M)_{j=1,...,r} : \ell = (\ell_1, \ldots, \ell_r) \in \{0, 1, \ldots, M\}^r\}$. The cardinality of this set is $(M + 1)^r$. We write $x_\ell = (x_\ell^j)$ to denote the components of $x_\ell$. Define

$$P^\beta f(x) := \sum_{x_\ell \in D(M)} P^\beta_{x_\ell} f(x) \prod_{j=1}^r (1 - M|x_j - x_\ell^j|)_+.$$
Lemma 7. If \( f \in C^\beta([0, 1]^r, K) \), then \( \|P^\beta f - f\|_{L^\infty[0,1]^r} \leq KM^{-\beta} \).

Proof. Since for all \( x = (x_1, \ldots, x_r) \in [0, 1]^r \),

\[
\sum_{x \in D(M)} \prod_{j=1}^r (1 - M|x_j - x_j^f|)_+ = \prod_{j=1}^r \sum_{\ell=0}^M (1 - M|\ell/M|)_+ = 1, \tag{7.10}
\]

we have \( f(x) = \sum_{x \in D(M): \|x - x_d\|_\infty \leq 1/M} f(x) \prod_{j=1}^r (1 - M|x_j - x_j^f|)_+ \) and with \( \ell, j \in \mathbb{N} \),

\[
|P^\beta f(x) - f(x)| \leq \max_{x \in D(M): \|x - x_d\|_\infty \leq 1/M} |P^\beta_{x_d} f(x) - f(x)| \leq KM^{-\beta}.
\]

\[\blacksquare\]

In a next step, we describe how to build a network that approximates \( P^\beta f \).

Lemma 8. For \( M \geq 1 \), there exists a network

\[\text{Hat}^r \in \mathcal{F}(2 + (m + 5)[\log_2 r], r, 6r(M + 1)^r, \ldots, 6r(M + 1)^r, (M + 1)^r), s, 1\]

with \( s = 49r^2(M + 1)^r(1 + (m + 5)[\log_2 r]) \), such that \( \text{Hat}^r \in [0, 1]^{(M+1)^r} \) and

\[
\left| \text{Hat}^r(x) - \left( \prod_{j=1}^r (1/M - |x_j - x_j^f|)_+ \right)_{x \in D(M)} \right|_\infty \leq 3^r2^{-m}, \text{ for all } x = (x_1, \ldots, x_r) \in [0, 1]^r.
\]

Proof. The first hidden layer computes the functions \((x_j - \ell/M)_+\) and \((\ell/M - x_j)_+\) using \(2rM + 1\) units and \(4rM + 1\) parameters. The second hidden layer computes \((1/M - |x_j - \ell/M|)_+ = (1/M - (x_j - \ell/M)_+ - (\ell/M - x_j)_+)_+ = (1/M - |x_j - \ell/M|)_+\) using \(r(M+1)\) units and \(3rM\) parameters. These functions take values in the interval \([0,1]\) and we can apply Lemma 5 to construct a network which computes the products \(\prod_{j=1}^r (1/M - |x_j - x_j^f|)_+\) up to an error that is bounded by \(3^r2^{-m}\). By \(\text{(3.3)}\), the number of parameters of one \(\text{Mult}^r_m\) network is bounded by \(42r^2(1+(m+5)[\log_2 r])\). As there are \((M+1)^r\) of these networks in parallel, this requires \(6r(M+1)^r\) units in each hidden layer and \(42r^2(M+1)^r(1+(m+5)[\log_2 r])\) parameters for the multiplications. Together with the \(7r(M+1)\) parameters from the first two layers, the total number of parameters is thus bounded by \(49r^2(M+1)^r(1+(m+5)[\log_2 r])\). \(\blacksquare\)

In the next step, we construct a network which approximately computes \(P^\beta f\) and apply Lemma 7.
Theorem 5. For any function $f \in \mathcal{C}^\beta_r([0,1]^r,K)$ and any integers $m\geq 1$ and $N\geq (\beta+1)^r \vee (K+1)$, there exists a network $\tilde{f} \in \mathcal{F}(L,(r,12rN,\ldots,12rN,1))$ with depth

$$L = 8 + (m+5)(1 + \lfloor \log_2 r \rfloor)$$

and number of parameters

$$s \leq 94r^2(\beta+1)^{2r}N(m+6)(1 + \lfloor \log_2 r \rfloor),$$

such that

$$\|\tilde{f} - f\|_{L^\infty([0,1]^r)} \leq (2K+1)^{3r+1}N2^{-m} + K2^\beta N^{-\frac{\beta}{r}}.$$

Proof. All the constructed networks in this proof are of the form $\mathcal{F}(L,p,s) = \mathcal{F}(L,p,s,\infty)$ with $F = \infty$. Let $M$ be the largest integer such that $(M+1)^r \leq N$ and define $L^* := (m+5)\lfloor \log_2 r \rfloor$. Thanks to (7.6), (7.9), and (7.8), we can add a layer to the network $\text{Mon}_{m,\beta}^r$ to obtain a network $Q_1 \in \mathcal{F}(1 + L^*,(r,6rC_{r,\beta},\ldots,6rC_{r,\beta},C_{r,\beta},(M+1)^r))$, such that $Q_1(x) \in [0,1]^{(M+1)^r}$ and for any $x \in [0,1]^r$,

$$\left|Q_1(x) - \left(\frac{P_{x,\beta}^L f(x)}{B} + \frac{1}{2}\right)_{x \in \mathcal{D}(M)}\right|_{\infty} \leq 3^r 2^{-m} \tag{7.11}$$

with $B := \lceil 2K \rceil$. By (7.3), the number of non-zero parameters in the $Q_1$ network is bounded by $42r^2C_{r,\beta}^2L^* + (C_{r,\beta} + 1)(M+1)^r$.

Recall that the network $\text{Hat}^r$ computes the products of hat functions $\prod_{j=1}^r (1/M - |x_j - x_j^0|)_+$ up to an error that is bounded by $3^r 2^{-m}$. It requires at most $49r^2N(1 + L^*)$ active parameters. Consider now the parallel network $(Q_1, \text{Hat}^r)$. Observe that $C_{r,\beta} + 1 \leq (\beta+1)^r \leq N$ by the definition of $C_{r,\beta}$ and the assumptions on $N$. By Lemma 8, the networks $Q_1$ and $\text{Hat}^r$ can be embedded into a joint network $(Q_1, \text{Hat}^r)$ with $2 + L^*$ hidden layers, weight vector $(r,12rN,\ldots,12rN,2(M+1)^r)$ and all parameters bounded by one. The number of non-zero parameters in the combined network $(Q_1, \text{Hat}^r)$ is bounded by

$$r + 42r^2C_{r,\beta}^2L^* + (C_{r,\beta} + 1)(M+1)^r + 49r^2N(1 + L^*) \leq 51r^2(C_{r,\beta} + 1)^2N(1 + L^*). \tag{7.12}$$

Next, we pair the $x_\ell$-th entry of the output of $Q_1$ and $\text{Hat}^r$ and apply to each of the $(M+1)^r$ pairs the $\text{Mult}_{m,\beta}$ network described in Lemma 4. In the last layer, we add all entries. By Lemma 4, this requires at most $42(m+5)r^2(M+1)^r + (M+1)^r$ active parameters for the $(M+1)^r$ multiplications and the sum. Using Lemma 4, Lemma 8, (7.11) and triangle inequality, there is a network $Q_2 \in \mathcal{F}(3 + (m+5)(1 + \lfloor \log_2 r \rfloor),(r,12rN,\ldots,12rN,1))$ such
that for any \( x \in [0,1]^r \),
\[
|Q_2 - \sum_{x \in \mathcal{D}(M)} \left( \frac{P_{xK}^t f(x)}{B} + \frac{1}{2} \right) \prod_{j=1}^{r} \left( \frac{1}{M} - |x_j - x_{j,l}| \right) + | \leq 2^{-m} + 3^r 2^{-m} + 3^r 2^{-m}
\]
\[
\leq 3^{r+1} 2^{-m}.
\]
(7.13)

Because of (7.12), the network \( Q_2 \) has at most
\[
94r^2(C_{r,\beta} + 1)^2 N(m + 5)(1 + \lceil \log_2 r \rceil) \leq 94r^2(\beta + 1)^2 N(m + 5)(1 + \lceil \log_2 r \rceil) \quad (7.14)
\]
active parameters.

To obtain a network reconstruction of the function \( f \), it remains to scale and shift the output entries. This is not entirely trivial because of the bounded parameter weights in the network. Recall that \( B = \lceil 2K \rceil \). Notice that the network \( x \mapsto BM^r x \) is in the class \( F(3, (1, M^r, 1, [2K], 1)) \) with shift vectors \( v_j \) are all equal to zero and weight matrices \( W_j \) having all entries equal to one. Because of \( N \geq (K + 1) \), the number of parameters of this network is bounded by \( 2M^r + 2[2K] \leq 6N \). It shows that there is a network in the class \( F(4, (1, 2, 2M^r, 2, [2K], 1)) \) computing \( a \mapsto BM^r(a - c) \) with \( c := 1/(2M^r) \). This network computes in the first hidden layer \( (a - c)_+ \) and \( (c - a)_+ \) and then applies the network \( x \mapsto BM^r x \) to both units. In the output layer both entries are added. This requires at most \( 6 + 12N \) active parameters.

Because of (7.13) and (7.10), there exists a network \( Q_3 \in F(8 + (m + 5)(1 + \lceil \log_2 r \rceil), (r, 12rN, \ldots, 12rN, 1)) \)

such that
\[
|Q_3(x) - \sum_{x \in \mathcal{D}(M)} P_{xK}^t f(x) \prod_{j=1}^{r} \left( 1 - M|x_j - x_{j,l}| \right) + | \leq (2K + 1)M^r 3^{r+1} 2^{-m},
\]
for all \( x \in [0,1]^r \). With (7.14), the number of non-zero parameters of \( Q_3 \) is bounded by
\[
94r^2(\beta + 1)^2 N(m + 6)(1 + \lceil \log_2 r \rceil).
\]

Observe that by construction \( (M + 1)^r \leq N \leq (M + 2)^r \leq (2M)^r \) and hence \( M^{-\beta} \leq N^{-\beta/2r^2} \). Together with Lemma 7, the result follows.

Based on the previous result, we can now construct a network that approximates \( f = g_4 \circ \ldots \circ g_0 \). In a first step, we show that \( f \) can always be written as composition of functions
defined on hypercubes \([0,1]^t_i\). As in the previous theorem, let \(g_{ij} \in C^\beta_{t_i}(a_i, b_i]^{t_i}, K_i)\) and assume that \(K_i \geq 1\). For \(i = 1, \ldots, q - 1\), define

\[
h_0 := \frac{g_0}{2K_0} + \frac{1}{2}, \quad h_i := \frac{g_i(2K_{i-1} \cdots - K_{i-1})}{2K_i} + \frac{1}{2}, \quad h_q = g_q(2K_{q-1} \cdots - K_{q-1}).
\]

Here, \(2K_{i-1}x - K_{i-1}\) means that we transform the entries componentwise by \((2K_{i-1}x_i - K_{i-1})i\). Clearly,

\[
f = g_q \circ \ldots \circ g_0 = h_q \circ \ldots \circ h_0.
\]

Using the definition of the Hölder balls \(C^\beta(D, K)\), it follows that \(h_{0j}\) takes values in \([0,1]\), \(h_{0j} \in C^\beta_{t_0}([0,1]^{t_0}, 1)\), \(h_{ij} \in C^\beta_{t_i}([0,1]^{t_i}, (2K_{i-1})^{\beta_i})\) for \(i = 1, \ldots, q - 1\), and \(h_{qj} \in C^\beta_{t_q}([0,1]^{t_q}, K_q(2K_{q-1})^{\beta_q})\). Without loss of generality, we can always assume that the radii of the Hölder balls are at least one, that is, \(K_i \geq 1\).

**Lemma 9.** Let \(h_{ij}\) be as above with \(K_i \geq 1\). Then, for any functions \(\tilde{h}_i = (\tilde{h}_{ij})_j^T\) with \(\tilde{h}_{ij} : [0,1]^{t_i} \to [0,1]\),

\[
\|h_q \circ \ldots \circ h_0 - \tilde{h}_0 \circ \ldots \circ \tilde{h}_0\|_{L^\infty[0,1]^d} \leq K_q \prod_{\ell=0}^{q-1} (2K_\ell)^{\beta_{\ell+1}} \sum_{i=0}^q \|h_i - \tilde{h}_i\|_{L^\infty[0,1]^{t_i}}^{\beta_i \wedge 1}.
\]

**Proof.** Define \(H_i = h_i \circ \ldots \circ h_0\) and \(\tilde{H}_i = \tilde{h}_i \circ \ldots \circ \tilde{h}_0\). Using triangle inequality,

\[
|H_i(x) - \tilde{H}_i(x)|_\infty \leq |h_i \circ H_{i-1}(x) - h_i \circ \tilde{H}_{i-1}(x)|_\infty + |h_i \circ \tilde{H}_{i-1}(x) - \tilde{h}_i \circ \tilde{H}_{i-1}(x)|_\infty
\]

\[
\leq K_i |H_{i-1}(x) - \tilde{H}_{i-1}(x)|_\infty^{\beta_i \wedge 1} + \|h_i - \tilde{h}_i\|_{L^\infty[0,1]^{t_i}}^{\beta_i \wedge 1}.
\]

Together with the inequality \((y+z)^\alpha \leq y^\alpha + z^\alpha\) which holds for all \(y, z \geq 0\) and all \(\alpha \in [0,1]\), the result follows.

**Proof of Theorem**

It is enough to prove the result for all sufficiently large \(n\). Throughout the proof \(C'\) is a constant only depending on \((q,d, t, \beta, F)\) that may change from line to line. By Theorem 2 and the assumed bounds on the depth \(L\), and the network sparsity \(s\), it follows for \(n \geq 3\),

\[
\frac{1}{4} \Delta_n(\hat{f}_n, f_0) - C' \phi_n \log^3 n \leq R(\hat{f}, f_0)
\]

\[
\leq 4 \inf_{f^* \in \mathcal{F}^{(L, p, s, F)}} \|f^* - f_0\|_\infty^2 + 4 \Delta_n(\hat{f}_n, f_0) + C' \phi_n \log^3 n,
\]

(7.16)

where we used \(\varepsilon = 1/2\) for the lower bound and \(\varepsilon = 1\) for the upper bound. Taking \(C = 8C'\), we find that \(\frac{1}{8} \Delta_n(\hat{f}_n, f_0) \leq R(\hat{f}, f_0)\) whenever \(\Delta_n(\hat{f}_n, f_0) \geq C \phi_n \log^3 n\). This proves the lower bound in (3.4).
To derive the upper bounds in (3.3) and (3.4) we need to bound the approximation error. To do this, we rewrite the regression function $f_0$ as in (7.15), that is, $f_0 = h_q \circ \ldots \circ h_0$ with $h_i = (h_{ij})^\top$, $h_{ij}$ defined on $[0,1]^{t_i}$, and for any $i < q$, $h_{ij}$ mapping to $[0,1]$. We apply Theorem 5 to each function $h_{ij}$ separately. Take $m = \lceil \log_2 n \rceil$ and let $L'_i := 8 + (\lceil \log_2 n \rceil + 5)(1 + \lceil \log_2 t_i \rceil)$. This means there exists a network

$$
\tilde{h}_{ij} \in \mathcal{F}(L'_i, (t_i, 12 t_i N, \ldots, 12 t_i N, 1), s_i)
$$

with $s_i \leq 94 t_i^2 (\beta + 1)^{2 t_i} N (\lceil \log_2 n \rceil + 6)(1 + \lceil \log_2 t_i \rceil)$, such that

$$
\|\tilde{h}_{ij} - h_{ij}\|_{L^\infty([0,1]^{t_i})} \leq (2 Q_i + 1) 3^{t_i + 1} N n^{-1} + Q_i 2^{\beta} N^{-\frac{\beta}{t_i}}, \quad (7.17)
$$

where $Q_i$ is any upper bound of the Hölder constants of $\tilde{h}_{ij}$. If $i < q$, then we apply to the output the two additional layers $1 - (1 - x)_+$. This requires four additional parameters. Call the resulting network $h_{ij}^* \in \mathcal{F}(L'_i + 2, (t_i, 12 t_i N, \ldots, 12 t_i N, 1), s_i + 4)$ and observe that $\sigma(h_{ij}^*) = (h_{ij}^*(x) \vee 0) \land 1$. Since $h_{ij}(x) \in [0,1]$, we must have

$$
\|\sigma(h_{ij}^*) - h_{ij}\|_{L^\infty([0,1]^{t_i})} \leq \|\tilde{h}_{ij} - h_{ij}\|_{L^\infty([0,1]^{t_i})}, \quad (7.18)
$$

If the networks $h_{ij}^*$ are computed in parallel,

$$
h_{ij}^* = (h_{ij}^*)_{j=1,\ldots,d_i+1} \in \mathcal{F}(L'_i + 2, (d_i, 12 d_i + 12 t_i N, \ldots, 12 d_i + t_i N, d_i + 1), d_i + 1(s_i + 4)).
$$

Finally, we construct the composite network $f^* = \tilde{h}_{q1} \circ \sigma(h_{q-1}^*) \circ \ldots \circ \sigma(h_0^*)$ which by the composition rule in Section 7.1 can be realized in the class

$$
\mathcal{F} \left( E, (d_i, 12 \max_i d_i + t_i N, \ldots, \max_i d_i + t_i N, 1), \sum_{i=0}^{q} d_i(s_i + 4) \right), \quad (7.19)
$$

with $E := 3(q-1) + \sum_{i=0}^{q} L'_i$. Observe that there is an $A_n$ that is bounded in $n$ such that $E = A_n + \log_2 n (\sum_{i=0}^{q} \log_2 t_i) + 1$. Using Remark 1 $E \leq \sum_{i=0}^{q} (2 + \log_2 t_i) \log_2 n \leq L$ for all sufficiently large $n$. By (7.1) and for sufficiently large $n$, the space (7.19) can be embedded into $\mathcal{F}(L, p, s)$ with $L, p, s$ satisfying the assumptions of the theorem by choosing $N = \lceil c \max_{i=0,\ldots,q} n^{-\frac{2\beta^*}{t_i} + \frac{1}{t_i}} \rceil$ for a sufficiently small constant $c > 0$ only depending on $q, d, t, \beta$. Combining Lemma 9 with (7.17) and (7.18)

$$
\inf_{f^* \in \mathcal{F}(L, p, s)} \|f^* - f_0\|_{L^\infty}^2 \leq C' \max_{i=0,\ldots,q} N^{-\frac{2\beta^*}{t_i}} \leq C' \max_{i=0,\ldots,q} c^{-\frac{2\beta^*}{t_i} + \frac{1}{t_i}} n^{-\frac{2\beta^*}{t_i} + \frac{1}{t_i}}. \quad (7.20)
$$

For the approximation error in (7.16) we need to find a network function that is bounded in sup-norm by $F$. By the previous inequality there exists a sequence $(\tilde{f}_n)_n$ such that for all sufficiently large $n$, $\tilde{f}_n \in \mathcal{F}(L, p, s)$ and $\|\tilde{f}_n - f_0\|_{L^\infty} \leq 2 C \max_{i=0,\ldots,q} c^{-2\beta^*/t_i} n^{-(2\beta^*/(2\beta^* + t_i))}$.
Define \( f_n^* = \tilde{f}_n(\|f\|_\infty/\|\tilde{f}_n\|_\infty \wedge 1) \). Then, \( \|f_n^*\|_\infty \leq \|f\|_\infty = \|g_0\|_\infty \leq K \leq F \), where the last inequality follows from assumption \((i)\). Moreover, \( f_n^* \in \mathcal{F}(L, p, s, F) \). Writing \( f_n^* - f_0 = (f_n^* - \tilde{f}_n) + (\tilde{f}_n - f_0) \), we obtain \( \|f_n^* - f_0\|_\infty \leq 2\|\tilde{f}_n - f_0\|_\infty \). This shows that (7.20) also holds (with constants multiplied by 8) if the infimum is taken over the smaller space \( \mathcal{F}(L, p, s, F) \). Together with (7.16) the upper bounds in (3.3) and (3.4) follow for any constant \( C \). This completes the proof. \( \square \)

### 7.4 Proof of Theorem 2

Several oracle inequalities for the least-squares estimator are known, cf. \([14, 27, 11, 15, 32]\). The common assumption of bounded response variables is, however, violated in the nonparametric regression model with Gaussian measurement noise. Additionally we provide also a lower bound of the risk and give a proof that can be easily generalized to arbitrary noise distributions. Let \( \mathcal{N}(\delta, \mathcal{F}, \|\cdot\|_\infty) \) be the covering number, that is, the minimal number of \( \|\cdot\|_\infty \)-balls with radius \( \delta \) that covers \( \mathcal{F} \) (the centers do not need to be in \( \mathcal{F} \)).

**Lemma 10.** Consider the \( d \)-variate nonparametric regression model \((1.1)\) with unknown regression function \( f_0 \). Let \( \hat{f} \) be any estimator taking values in \( \mathcal{F} \). Define \( \Delta_n(\hat{f}, f_0, \mathcal{F}) := E_{f_0}[\frac{1}{n} \sum_{i=1}^{n} (Y_i - \hat{f}(X_i))^2] - \arg \min_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} (Y_i - f(X_i))^2 \) and \( \{f_0\} \cup \mathcal{F} \subset \{f : [0, 1]^d \to [0, F] \} \) for some \( F \geq 1 \). If \( \mathcal{N}_n := \mathcal{N}(\delta, \mathcal{F}, \|\cdot\|_\infty) \geq 3 \), then,

\[
(1 - \varepsilon)^2 \Delta_n - F^2 \frac{11 \log \mathcal{N}_n + 19}{n \varepsilon} - 19 \delta F \leq R(\hat{f}, f_0) \leq (1 + \varepsilon)^2 \left[ \inf_{f \in \mathcal{F}} E\left[ (f(X) - f_0(X))^2 \right] + F^2 \frac{14 \log \mathcal{N}_n + 20}{n \varepsilon} + 25 \delta F + \Delta_n \right],
\]

for all \( \delta, \varepsilon \in (0, 1] \).

**Proof.** Throughout the proof we write \( \Delta_n \) for \( \Delta_n(\hat{f}, f_0, \mathcal{F}) \) and \( E = E_{f_0} \). Define \( \|g\|_n^2 := \frac{1}{n} \sum_{i=1}^{n} g(X_i)^2 \). If \( \log \mathcal{N}_n \geq n \) then there is nothing to prove since \( R(\hat{f}, f_0) \leq 4F^2 \). It is therefore enough to show the inequality for \( 1 \leq \log \mathcal{N}_n \leq n \). For any estimator \( \hat{f} \), we introduce \( \hat{R}_n(\hat{f}, f_0) := E[\|\hat{f} - f_0\|_n^2] \) for the empirical risk. The proof is divided into four parts which are denoted by \((I) - (IV)\).

**\((I)\):** We relate the risk \( R(\hat{f}, f_0) = E[(\hat{f}(X) - f_0(X))^2] \) to its empirical counterpart \( \hat{R}_n(\hat{f}, f_0) \) via the inequalities

\[
(1 - \varepsilon) \left( \hat{R}_n(\hat{f}, f_0) - (1 - \varepsilon) \frac{F^2}{n \varepsilon} (8 \log \mathcal{N}_n + 18) - 19 \delta F \right) \leq R(\hat{f}, f_0) \leq (1 + \varepsilon) \left( \hat{R}_n(\hat{f}, f_0) + (1 + \varepsilon) \frac{F^2}{n \varepsilon} (8 \log \mathcal{N}_n + 18) + 19 \delta F \right). \quad (7.21)
\]
(II): For any estimator \( \hat{\theta} \) taking values in \( F \),
\[
|E\left[ \frac{2}{n} \sum_{i=1}^{n} \varepsilon_i \tilde{f}(X_i) \right] | \leq 2 \sqrt{ \frac{\hat{R}_n(\tilde{f}, f_0)(3 \log N_n + 1)}{n} + 6 \delta }.
\]

(III): We have
\[
\hat{R}_n(\tilde{f}, f_0) \leq (1 + \varepsilon) \left[ \inf_{f \in F} E\left[ (f(X) - f_0(X))^2 \right] + 6 \delta + \frac{6 \log N_n + 2}{n \varepsilon} + \Delta_n \right]. \tag{7.22}
\]

(IV): We have
\[
\hat{R}_n(\tilde{f}, f_0) \geq (1 - \varepsilon) \left( \Delta_n - \frac{3 \log N_n + 1}{n \varepsilon} - 12 \delta \right).
\]

Combining (I) and (IV) gives the lower bound of the assertion since \( F \geq 1 \). The upper bound follows from (I) and (III).

(I): Given a minimal \( \delta \)-covering of \( F \), denote the centers of the balls by \( f_j \). By construction there exists a (random) \( j^* \) such that \( \| \hat{f} - f_{j^*} \|_\infty \leq \delta \). Without loss of generality, we can assume that \( f_{j^*} \leq F \). Generate i.i.d. random variables \( X'_i, i = 1, \ldots, n \) with the same distribution as \( X \) and independent of \( (X_i)_{i=1}^n \). Using that \( \|f_j\|_\infty, \|f_0\|_\infty, \delta \leq F \),
\[
|R(\hat{f}, f_0) - \hat{R}_n(\tilde{f}, f_0)| = |E\left[ \frac{1}{n} \sum_{i=1}^{n} (\tilde{f}(X'_i) - f_0(X'_i))^2 - \frac{1}{n} \sum_{i=1}^{n} (\tilde{f}(X_i) - f_0(X_i))^2 \right]|
\leq E\left[ \left| \frac{1}{n} \sum_{i=1}^{n} g_{j^*}(X_i, X'_i) \right| \right] + 9 \delta F,
\]
with \( g_{j^*}(X_i, X'_i) := (f_{j^*}(X'_i) - f_0(X'_i))^2 - (f_{j^*}(X_i) - f_0(X_i))^2 \). Define \( r_j \) in the same way with \( f_{j^*} \) replaced by \( f_j \). Similarly, define \( r_{j^*} := \sqrt{56n^{-1} \log N_n + E^{1/2} [ (f_j(X) - f_0(X))^2 ]} \) and \( r_j^* \).

Notice that \( r_{j^*} \) is a deterministic quantity. If \( T := \max_j \left| \sum_{i=1}^{n} \frac{g_j(X_i, X'_i)}{r_j} \right| \), then
\[
|R(\hat{f}, f_0) - \hat{R}_n(\tilde{f}, f_0)| \leq \frac{r_{j^*}}{n} E[T] + 9 \delta F. \tag{7.23}
\]

Observe that \( E[g_j(X_i, X'_i)] = 0, |g_j(X_i, X'_i)| \leq 4F^2 \) and
\[
\text{Var}(g_j(X_i, X'_i)) = 2 \text{Var}\left( (f_j(X'_i) - f_0(X'_i))^2 \right) \leq E\left[ (f_j(X'_i) - f_0(X'_i))^4 \right] \leq 4F^2 r_j^2.
\]

Bernstein’s inequality states that for independent and centered random variables \( U_1, \ldots, U_n \), satisfying \( |U_i| \leq M \), \( P(\sum_{i=1}^{n} U_i \geq t) \leq 2 \exp(-t^2/[2Mt/3 + 2 \sum_{i=1}^{n} \text{Var}(U_i)]) \), cf. [48].

Combining Bernstein’s inequality with a union bound argument yields
\[
P(T \geq t) \leq 1 \wedge 2N_n \exp\left( - \frac{t^2}{8F^2(t/(3r_j) + n)} \right).
\]
Since for any non-negative random variable with finite expectation, \( E[X] = \int_0^\infty P(X \geq t) dt \), we have for any \( t_0 > 0 \),
\[
E[T] \leq t_0 + \int_{t_0}^\infty 2N_n e^{-\frac{t^2}{16F^2n}} dt + \int_{t_0}^\infty 2N_n e^{-\frac{3r_n}{16F^2}} dt
\leq t_0 + \frac{16nF^2}{t_0} N_n e^{-\frac{\delta^2}{16F^2}} + \frac{32F^2}{3r_j} N_n e^{-\frac{\epsilon^2 n}{2}},
\]
where we used for the second inequality the tail bound \( \int_a^\infty e^{-x^2/2} dx \leq e^{-a^2/2}/a \) which holds for all \( a > 0 \). Recall that \( \log N_n \geq 1 \). With \( t_0 := 4F \sqrt{n} \log N_n \) and the definition of \( r_j \), it follows that \( E[T] \leq 4F \sqrt{n} \log N_n + 6F \sqrt{n} \). Using the triangle inequality with respect to the weighted \( L^2 \)-norm \( E^{1/2}[\|f(X) - g(X)\|^2] \), we find \( r_{j^*} \leq (F \sqrt{56n^{-1} \log N_n}) \vee (R(\hat{f}, f_0)^{1/2} + \delta) \). If \( R(\hat{f}, f_0)^{1/2} \leq F \sqrt{56n^{-1} \log N_n} \) the assertion of the lemma is true since \( 4 \leq (1 + \epsilon)^2/\epsilon \) for \( \epsilon > 0 \). It is therefore sufficient to consider the case \( r_{j^*} \leq R(\hat{f}, f_0)^{1/2} + \delta \). Because of \( \log N_n \leq n \), we can conclude that
\[
\frac{r_{j^*}}{n} E[T] \leq R(\hat{f}, f_0)^{1/2} \left( 4F \sqrt{\frac{\log N_n}{n}} + \frac{6F}{\sqrt{n}} \right) + 10F\delta. \quad (7.24)
\]
Let \( a, b, c, d \) be positive real numbers, such that \( |a - b| \leq 2\sqrt{ac + d} \). Then, for any \( \epsilon \in (0, 1) \),
\[
(1 - \epsilon)(b - d) - \frac{(1 - \epsilon)^2 \epsilon^2}{\epsilon} \leq a \leq (1 + \epsilon)(b + d) + \frac{(1 + \epsilon)^2 \epsilon^2}{\epsilon}. \quad (7.25)
\]
To see this observe that \( |a - b| \leq 2\sqrt{ac + d} \) implies \( a \leq \epsilon a/(1 + \epsilon) + (1 + \epsilon)c^2/4 + (b + d) \). Rearranging yields the upper bound. For the lower bound, we use the same argument and find \( a \geq -\epsilon a/(1 - \epsilon) - (1 - \epsilon)c^2/\epsilon + (b - d) \) which gives \( (7.25) \). With \( a = R(\hat{f}, f_0) \), \( b = E[\|\hat{f} - f_0\|^2] \), \( c = 2F \sqrt{\log N_n/n} + 3Fn^{-1/2} \), \( d = 198F \), we can thus conclude from \( (7.23) \) and \( (7.24) \) the inequality in \( (7.21) \). This completes the proof of (I).

(II): Given an estimator \( \tilde{f} \) taking values in \( \mathcal{F} \), let \( j^* \) be such that \( \|\tilde{f} - f_{j^*}\|_\infty \leq \delta \). By Cauchy-Schwarz inequality,
\[
\left| E\left[ \sum_{i=1}^n \epsilon_i (\tilde{f}(X_i) - f_{j^*}(X_i)) \right] \right| \leq \sqrt{n} E\left[ \left( \sum_{i=1}^n \epsilon_i^2 \right)^{1/2} \|\tilde{f} - f_{j^*}\|_n \right]
\leq \sqrt{n} E^{1/2} \left( \sum_{i=1}^n \epsilon_i^2 \right) E^{1/2} \left[ \|\tilde{f} - f_{j^*}\|_n^2 \right] \leq n\delta. \quad (7.26)
\]
Since \( E[\epsilon_i f_0(X_i)] = E[\epsilon_i f_0(X_i) \mid X_i] = 0 \), we also find
\[
\left| E\left[ \frac{2}{n} \sum_{i=1}^n \epsilon_i \tilde{f}(X_i) \right] \right| = \left| E\left[ \frac{2}{n} \sum_{i=1}^n \epsilon_i (\tilde{f}(X_i) - f_0(X_i)) \right] \right|
\leq 2\delta + \frac{2}{\sqrt{n}} E\left[ (\|\tilde{f}_{j^*} - f_0\|_n + \delta) \chi_{j^*} \right] \quad (7.27)
\]
with

\[ \xi_j := \frac{\sum_{i=1}^n \epsilon_i (f_j(x_i) - f_0(x_i))}{\sqrt{n}||f_j - f_0||_n}. \]

Conditionally on \( (X_i)_i \), we have \( \xi_j \sim \mathcal{N}(0,1) \). With Lemma 11 we obtain \( E[\xi_j^2] \leq E[\max_j \xi_j^2] \leq 3 \log \mathcal{N}_n + 1 \). Using Cauchy-Schwarz,

\[ E \left[ \left( \| \tilde{f} - f_0 \|_n + \delta \right) |\xi_j| \right] \leq \left( \tilde{R}_n(\tilde{f}, f_0)^{1/2} + \delta \right) \sqrt{3 \log \mathcal{N}_n + 1}. \]  

(7.28)

Because of \( \log \mathcal{N}_n \leq n \), we have \( 2n^{-1/2} \delta \sqrt{3 \log \mathcal{N}_n + 1} \leq 4 \delta \). Together with (7.27) and (7.28) the result follows.

(III): For any fixed \( f \in \mathcal{F} \), \( E[\frac{1}{n} \sum_{i=1}^n (Y_i - \hat{f}(X_i))^2] \leq E[\frac{1}{n} \sum_{i=1}^n (Y_i - f(X_i))^2] + \Delta_n \). Because of \( X_i \sim \mathcal{X} \) and \( f \) being deterministic, we have \( E[\| f - f_0 \|_n^2] = E[(f(X) - f_0(X))^2] \). Since also \( E[\epsilon_i f(\sum_{i=1}^n \epsilon_i \hat{f}(X_i)) = \hat{E}[E[\epsilon_i f(X_i)] \hat{X}_i] = 0, \)

\[ \tilde{R}_n(\hat{f}, f_0) \leq E[\| f - f_0 \|_n^2] + E\left[ \frac{2}{n} \sum_{i=1}^n \epsilon_i \hat{f}(X_i) \right] = \Delta_n \]

\[ \leq E[(f(X) - f_0(X))^2] + 2 \sqrt{\frac{\tilde{R}_n(\hat{f}, f_0)(3 \log \mathcal{N}_n + 1)}{n}} + 6\delta + \Delta_n \]

using for the second inequality (II). Applying (7.25) to \( a := \tilde{R}_n(\hat{f}, f_0), b := 0, c := \sqrt{(3 \log \mathcal{N}_n + 1)/n}, d := E[(f(X) - f_0(X))^2] + 6\delta + \Delta_n \), yields (III).

(IV): Let \( \tilde{f} \in \arg \min_{f \in \mathcal{F}} \sum_{i=1}^n (Y_i - f(X_i))^2 \) be a (global) empirical risk minimizer. Observe that

\[ \tilde{R}_n(\hat{f}, f_0) - \tilde{R}_n(\tilde{f}, f_0) = \Delta_n + E\left[ \frac{2}{n} \sum_{i=1}^n \epsilon_i \hat{f}(X_i) \right] - E\left[ \frac{2}{n} \sum_{i=1}^n \epsilon_i \tilde{f}(X_i) \right]. \]

With (II), we find

\[ \tilde{R}_n(\hat{f}, f_0) - \tilde{R}_n(\tilde{f}, f_0) \geq \Delta_n - 2 \sqrt{\frac{\tilde{R}_n(\hat{f}, f_0)(3 \log \mathcal{N}_n + 1)}{n}} - 2 \sqrt{\frac{\tilde{R}_n(\tilde{f}, f_0)(3 \log \mathcal{N}_n + 1)}{n}} - 12\delta \]

\[ \geq \Delta_n - \frac{\varepsilon}{1 - \varepsilon} \tilde{R}_n(\hat{f}, f_0) - \tilde{R}_n(\hat{f}, f_0) - \frac{3 \log \mathcal{N}_n + 1}{n\varepsilon} - 12\delta. \]

Rearranging of the terms leads then to the conclusion of (IV).

\[ \square \]

**Lemma 11.** Let \( \eta_j \sim \mathcal{N}(0,1) \), then \( E[\max_{j=1,\ldots,M} \eta_j^2] \leq 3 \log M + 1 \).

**Proof.** For \( M = 1 \) the result is trivial. Let therefore be \( M \geq 2 \). For \( \eta \sim \mathcal{N}(0,1) \) and \( T > 0 \), we find using integration by parts and \( P(\eta > T) \leq e^{-T^2/2}, \)

\[ E[\eta^2 \mathbb{1}[|\eta| > T]] = (2\pi)^{-1/2} \int_{-T}^{\infty} x^2 e^{-x^2/2} dx = (2\pi)^{-1/2} Te^{-T^2} + (2\pi)^{-1/2} \int_{T}^{\infty} e^{-x^2/2} dx \leq (1 + (2\pi)^{-1/2} T) e^{-T^2/2}. \]
Therefore, \( E[\max_{j=1,\ldots,M} \eta_j^2] \leq T^2 + M(1+(2\pi)^{-1/2}T)e^{-T^2/2} \). Now, choosing \( T = \sqrt{2 \log M - 1} \) and using that \((2\pi)^{-1/2}T \leq \sqrt{e}/(4\pi) + T^2 e^{-1/2}/2 \) gives \( E[\max_{j=1,\ldots,M} \eta_j^2] \leq 3T^2/2 + \sqrt{e} + \epsilon/(4\pi)^{-1} \). With \( \sqrt{e} \leq 2 \) and \( \epsilon \leq \pi \), the result follows.

Next, we prove a covering entropy bound. Recall the definition of the network function class \( \mathcal{F}(L, p, s, F) \) in [2, 3].

**Lemma 12.** If \( V := \prod_{\ell=0}^{L+1}(p_\ell + 1) \), then, for any \( \delta > 0 \),

\[
\log \mathcal{N}(\delta, \mathcal{F}(L, p, s, \infty), \| \cdot \|_\infty) \leq (s + 1) \log \left( 2 \delta^{-1}(L + 1) V^2 \right).
\]

Results of this type have been derived earlier, cf. Theorem 14.5 in [1]. We nevertheless give a full proof of the lemma as we could not find the statement in this form elsewhere.

**Proof.** Given a network function \( f(x) = W_{L+1} \sigma_{V_L} W_L \sigma_{V_{L-1}} \cdots W_2 \sigma_{V_1} W_1 x \) we define for \( k \in \{1, \ldots, L\} \), \( A_k^+ f : [0,1]^d \to \mathbb{R}^{p_k} \),

\[
A_k^+ f(x) = \sigma_{V_k} W_k \sigma_{V_{k-1}} \cdots W_2 \sigma_{V_1} W_1 x
\]

and \( A_k^- f : \mathbb{R}^{p_{k-1}} \to \mathbb{R}^{p_{L+1}} \),

\[
A_k^- f(y) = W_{L+1} \sigma_{V_L} W_L \sigma_{V_{L-1}} \cdots W_{k+1} \sigma_{V_k} W_k y.
\]

Set \( A_0^+ f(x) = A_{L+2}^- f(x) = x \) and notice that for \( f \in \mathcal{F}(L, p) \), \( |A_k^+ f(x)|_\infty \leq \prod_{\ell=0}^{k-1}(p_\ell + 1) \). Composition of two Lipschitz functions with Lipschitz constants \( L_1 \) and \( L_2 \) gives again a Lipschitz function with Lipschitz constant \( L_1 L_2 \). Therefore, the Lipschitz constant of \( A_k^- f \) is bounded by \( \prod_{\ell=k-1}^{L} p_\ell \). Fix \( \epsilon > 0 \). Let \( f, f^* \in \mathcal{F}(L, p, s) \) be two network functions, such that all parameters are at most \( \epsilon \) away from each other. Then, we can bound the absolute value of the difference by

\[
|f(x) - f^*(x)| \leq \sum_{k=1}^{L+1} \left| A_{k+1}^- f \sigma_{V_k} W_k A_{k-1}^+ f^*(x) - A_{k+1}^- f \sigma_{V_k} W_k^* A_{k-1}^+ f^*(x) \right|
\]

\[
\leq \sum_{k=1}^{L+1} \left( \prod_{\ell=k}^{L} p_\ell \right) \left| \sigma_{V_k} W_k A_{k-1}^+ f^*(x) - \sigma_{V_k} W_k^* A_{k-1}^+ f^*(x) \right|_\infty
\]

\[
\leq \sum_{k=1}^{L+1} \left( \prod_{\ell=k}^{L} p_\ell \right) \left( |(W_k - W_k^*) A_{k-1}^+ f^*(x)|_\infty + |v_k - v_k^*|_\infty \right)
\]

\[
\leq \epsilon \sum_{k=1}^{L+1} \left( \prod_{\ell=k}^{L} p_\ell \right) \left( p_{k-1} |A_{k-1}^+ f^*(x)|_\infty + 1 \right)
\]

\[
\leq \epsilon V(L + 1).
\]
By (1.3) the total number of parameters is therefore bounded by $T := \sum_{t=0}^{L}(p_t + 1)p_{t+1} \leq (L + 1)2^{-L} \prod_{t=0}^{L+1}(p_t + 1) \leq V$ and there are \( \binom{V}{s} \) combinations to pick \( s \) non-zero parameters. Since all the parameters are bounded in absolute value by one, we can discretize the non-zero parameters with grid size \( \delta/(2(L+1)V) \) and obtain for the covering number

\[
\mathcal{N}\left(\delta, \mathcal{F}(L, p, s, \infty), \| \cdot \|_{\infty}\right) \leq \sum_{s^* \leq s} (2\delta^{-1}(L+1)V^2)^{s^*} \leq (2\delta^{-1}(L+1)V^2)^{s+1}.
\]

Taking logarithms yields the result.

**Remark 2.** Identity (7.2) applied to Lemma 12 yields,

\[
\log \mathcal{N}\left(\delta, \mathcal{F}(L, p, s, \infty), \| \cdot \|_{\infty}\right) \leq (s + 1) \log \left(2^{2L+5}\delta^{-1}(L+1)p_0^2p_L^2s^{2L}\right).
\]

**Proof of Theorem 3** The assertion follows from Lemma 12 with \( \delta = 1/n \), Lemma 10 and Remark 2 since \( F \geq 1 \).}

### 7.5 Proof of Theorem 3

Throughout this proof, \( \| \cdot \|_2 = \| \cdot \|_{L^2([0,1]^d)} \). By assumption there exist positive \( \gamma \leq \Gamma \) such that the Lebesgue density of \( X \) is lower bounded by \( \gamma \) and upper bounded by \( \Gamma \) on \([0,1]^d\). For such design, \( R(\hat{f}_n, f_0) \geq \gamma \| \hat{f}_n - f_0 \|_2^2 \). Denote by \( P_f \) the law of the data in the nonparametric regression model (1.1). For the Kullback-Leibler divergence we have \( KL(P_f, P_g) = nE[(f(X_1) - g(X_1))^2] \leq \Gamma n \| f - g \|_2^2 \). Theorem 2.7 in [17] states that if for some \( M \geq 1 \) and \( \kappa > 0 \), \( f(0), \ldots, f(M) \in \mathcal{G}(q,d,t,\beta,K) \) are such that

(i) \( \| f(j) - f(k) \|_2 \geq \kappa \phi_n \) for all \( 0 \leq j < k \leq M \)

(ii) \( n \sum_{j=1}^{M} \| f(j) - f(0) \|_2^2 \leq M \log(M)/(9\Gamma) \),

then there exists a positive constant \( c = c(\kappa,\gamma) \), such that

\[
\inf_{\hat{f}_n} \sup_{f_0 \in \mathcal{G}(q,d,t,\beta,K)} R(\hat{f}_n, f_0) \geq c \phi_n^2.
\]

In a next step, we construct functions \( f(0), \ldots, f(M) \in \mathcal{G}(q,d,t,\beta,K) \) satisfying (i) and (ii). Define \( t^* := \inf_{\beta} \left(\frac{1}{(2\beta^* + t^* + 1})\right) \). The index \( t^* \) determines the estimation rate in the sense that \( \phi_n = n^{-\beta^*/(2\beta^* + t^*)} \). For convenience, we write \( \kappa^* := \kappa \beta^*/(2\beta^* + t^*) \), and \( t^* := t^* \). One should notice the difference between \( \beta^* \) and \( \beta^{**} \). Let \( K \in L^2(\mathbb{R}) \cap C^q(\mathbb{R},1) \) be supported on \([0,1]\). It is easy to see that such a function \( K \) exists. Furthermore, define \( m_n := [\rho n^{1/(2\beta^* + t^*)}] \) and \( h_n := 1/m_n \) where the constant \( \rho \) is chosen such that \( nh_n^{2\beta^* + t^*} \leq 1/(72\Gamma \| K \|_2^2) \). For any \( u = (u_1, \ldots, u_{t^*}) \in U_n := \{(u_1, \ldots, u_{t^*}) : u_i \in \} \)
For $\alpha$ with $|\alpha| < \beta^*$, we have $\|\partial^{\alpha} \psi_{u}\|_{\infty} \leq 1$ using $K \in C_{1}^{\beta^*}(\mathbb{R}, 1)$. For $\alpha$ with $|\alpha| = |\beta^*|$, triangle inequality and $K \in C_{1}^{\beta^*}(\mathbb{R}, 1)$ gives
\[
 h_n^{\beta^* - |\beta^*|} \frac{|\psi_u(x_1, \ldots, x_{t^*}) - \psi_u(y_1, \ldots, y_{t^*})|}{\max_i |x_i - y_i|^{\beta^* - |\beta^*|}} \leq t^*.
\]
Hence $\psi_u \in C_{t^*}^{\beta^*}([0, 1]^{t^*}, (\beta^*)^{t^*} t^*)$. For a vector $w = (w_u)_{u \in U_n} \in \{0, 1\}^{2|U_n|}$, define
\[
 \phi_w = \sum_{u \in U_n} w_u \psi_u.
\]
By construction, $\psi_u$ and $\psi_{u'}$, $u, u' \in U_n$, $u \neq u'$ have disjoint support. As a consequence $\phi_w \in C_{t^*}^{\beta^*}([0, 1]^{t^*}, 2(\beta^*)^{t^*} t^*)$.

For $i < i^*$, let $g_i(x) := (x_1, \ldots, x_{d_i})^\top$. For $i = i^*$ define $g_{i^*, w}(x) = (\phi_w(x_1, \ldots, x_{i^*}), 0, \ldots, 0)^\top$.

For $i > i^*$, set $g_i(x) := (x_{i^*+1}, \ldots, 0, \ldots, 0)^\top$. Let $\gamma := \prod_{t=i^*+1}^{q}(\beta_t \land 1)$. We will frequently use that $\beta^{**} = \beta^* \gamma$. Because of $t_i \leq \min(d_0, \ldots, d_{i-1})$ and the disjoint supports of the $\psi_u$,
\[
 f_w(x) = g_q \circ \cdots \circ g_{i+1} \circ g_{i^*, w} \circ g_{i-1} \circ \cdots \circ g_0(x)
 = \phi_w(x_1, \ldots, x_{i^*})^\gamma
 = \sum_{u \in U_n} w_u \psi_u(x_1, \ldots, x_{i^*})^\gamma
\]
and $f_w \in G(q, d, t, \beta, K)$ provided $K$ is taken sufficiently large.

For all $u$, $\|\psi_u\|_2^2 = h_n^{2\beta^* + t^*} \|K\|_2^{2t^*}$. If $\text{Ham}(w, w') = \sum_{u \in U_n} 1(w_u \neq w_u')$ denotes the Hamming distance, we find $\|f_w - f_{w'}\|_2^2 = \text{Ham}(w, w') h_n^{2\beta^* + t^*} \|K\|_2^{2t^*}$. By the Varshamov-Gilbert bound (47, Lemma 2.9) and because of $m_\kappa^{t^*} = |U_n|$, we conclude that there exists a subset $W \subset \{0, 1\}^{m_\kappa^{t^*}}$ of cardinality $|W| \geq 2m_\kappa^{t^*}/8$, such that $\text{Ham}(w, w') \geq m_\kappa^{t^*}/8$ for all $w, w' \in W$, $w \neq w'$. This implies that for $\kappa = \|K\|_2^{t^*}/(\sqrt{8} \rho^{\beta^{**}})$,
\[
 \|f_w - f_{w'}\|_2^2 \geq \frac{1}{8} h_n^{2\beta^*} \|K\|_2^{2t^*} \geq \kappa^2 \phi_n^2 \quad \text{for all } w, w' \in W, \ w \neq w'.
\]
Using the definition of $h_n$ and $\rho$,
\[
n \|f_w - f_{w'}\|_2^2 \leq nm_\kappa^{t^*} h_n^{2\beta^* + t^*} \|K\|_2^{2t^*} \leq \frac{m_\kappa^{t^*}}{t^*} \leq \frac{\log |W|}{9\Gamma}.
\]
This shows that the functions $f_w$ with $w \in W$ satisfy $(i)$ and $(ii)$. The assertion follows. \(\square\)
7.6 Proof of Lemma 1

Proof of Lemma 1. We will choose $c_2 \leq 1$. Since $\|f_0\|_\infty \leq K$, it is therefore enough to consider the infimum over $\mathcal{F}(L, \mathbf{p}, s, F)$ with $F = K + 1$. Let $\tilde{f}_n$ be the empirical risk minimizer and notice that $\Delta_n(\tilde{f}_n, f_0) = 0$. Because of the minimax lower bound in Theorem 3, there exists a constant $c_3$ such that $c_3 n^{-2\beta/(2\beta + d)} \leq \sup_{\theta \in \mathcal{C}^0([0,1],K)} R(\tilde{f}_n, f_0)$ for all sufficiently large $n$. Because of $p_0 = d$ and $p_{L+1} = 1$, Theorem 3 yields

$$c_3 n^{-2\beta/(2\beta + d)} \leq \sup_{\theta \in \mathcal{C}^0([0,1],K)} R(\tilde{f}_n, f_0) \leq 4 \sup_{\theta \in \mathcal{C}^0([0,1],K)} \inf_{f \in \mathcal{F}(L, \mathbf{p}, s, K+1)} \|f - f_0\|_\infty^2 + C(K + 1)^2 \frac{(s + 1) \log(n(s + 1)^L)}{n}$$

for some constant $C$. Given $\varepsilon$, let $n_\varepsilon = \lfloor \varepsilon^{-2(\beta + d)/\beta} \rfloor$. Observe that for $\varepsilon \leq 1$, $n_\varepsilon^{-1} \leq 2\varepsilon^{(2\beta + d)/\beta}$ and $\varepsilon \leq n_\varepsilon^{-1}$. For sufficiently small $c_2 > 0$ and all $\varepsilon \leq c_2$, we can insert $n_\varepsilon$ in the previous inequality and find

$$c_3 \varepsilon^2 \leq 4 \sup_{\theta \in \mathcal{C}^0([0,1],K)} \inf_{f \in \mathcal{F}(L, \mathbf{p}, s, K+1)} \|f - f_0\|_\infty^2 + C_1 \varepsilon^{(2\beta + d)/\beta} s \left( \log(\varepsilon^{-1}s^L) + C_2 \right)$$

for constants $C_1, C_2$ depending on $K, \beta$, and $d$. The result follows using the condition $s \leq c_1 \varepsilon^{-d/\beta}/(L \log(1/\varepsilon))$ and choosing $c_1$ small enough. \qed

7.7 Proof of Lemma 2 and Theorem 4

Proof of Lemma 2. Denote by $r$ the smallest positive integer such that $\mu_r := \int x^r \psi(x)dx \neq 0$. Such an $r$ exists because $\{x^r : r = 0, 1, \ldots\}$ spans $L^2[0, A]$ and $\psi$ cannot be constant. If $h \in L^2(\mathbb{R})$, then we have for the wavelet coefficients

$$\int h(x_1 + \ldots + x_d) \prod_{r=1}^d \psi_{j,k_r}(x_r) dx = 2^{-jd} \int_{[0,2]^d} h(2^{-j} \sum_{r=1}^d x_r + k_r) \prod_{r=1}^d \psi(x_r) dx. \quad (7.29)$$

For a real number $u$, denote by $\{u\}$ the fractional part of $u$.

We need to study the cases $\mu_0 \neq 0$ and $\mu_0 = 0$ separately. If $\mu_0 \neq 0$, define $g(u) = r^{-1}u^{r-1}1_{[1/2]}(u) + r^{-1}(1-u)^r1_{(-1/2, 1]}(u)$. Notice that $g$ is Lipschitz with Lipschitz constant one. Let $h_{j,\alpha}(u) = K^{2^{-j\alpha}} \eta(\{2^{j-q-\nu} u\})$ with $q$ and $\nu$ as defined in the statement of the lemma. For a $T$-periodic function $u \mapsto s(u)$ the $\alpha$-Hölder semi-norm for $\alpha \leq 1$ can be shown to be $\sup_{u \neq v, |u - v| \leq T} |s(u) - s(v)|/|u - v|^\alpha$. Since $g$ is 1-Lipschitz, we have for $u, v$ with $|u - v| \leq 2^{q+\nu-j}$,

$$|h_{j,\alpha}(u) - h_{j,\alpha}(v)| \leq K^{2^{-j\alpha}} 2^{j-q-\nu} |u - v| \leq \frac{K}{2} |u - v|^\alpha.$$
Since \( \|h_{j,\alpha}\|_{\infty} \leq K/2 \), \( h_{j,\alpha} \in C^1_1([0,d], K) \). Let \( f_{j,\alpha}(x) = h_{j,\alpha}(x_1 + \ldots + x_d) \). By definition of the wavelet coefficients, Equation (7.29), the definition of \( h_{j,\alpha} \), and using \( \mu_r = \int x^r \psi(x) dx \), we find for \( p_1, \ldots, p_r \in \{0, 1, \ldots, 2^{j-q-2} - 1\} \),

\[
\begin{align*}
\mathcal{d}_{(j,2^q + p_1) \ldots (j,2^q + p_r)}(f_{j,\alpha}) &= 2^{-jd} \int_{[0,2^q]^d} h_{j,\alpha}(2^{-j} \left( \sum_{r=1}^d x_r + 2^{q+\nu} p_r \right)) \prod_{r=1}^d \psi(x_r) \, dx \\
&= K2^{-jd-j\alpha-1} \int_{[0,2^q]^d} g\left( \left\{ \sum_{r=1}^d x_r / 2^q \right\} \right) \prod_{r=1}^d \psi(x_r) \, dx \\
&= r^{-1}2^{-qr - \nu r - K}2^{-j/2(2\alpha + d)} \int_{[0,2^q]^d} (x_1 + \ldots + x_d)^r \prod_{r=1}^d \psi(x_r) \, dx \\
&= dr^{-1}2^{-qr - \nu r - K} \mu_0^{d-1} \mu_r 2^{-j/2(2\alpha + d)},
\end{align*}
\]

where we used for the last identity that by definition of \( r \), \( \mu_1 = \ldots = \mu_r = 0 \).

In the case that \( \mu_0 = 0 \), we can take \( g(u) = (dr)^{-1}u^d \mathbf{1}_{[0,1/2]}(u) + (dr)^{-1}(1-u)^d \mathbf{1}_{(1/2,1]}(u) \).

Following the same arguments as before and using the multinomial theorem, we obtain

\[
\mathcal{d}_{(j,2^q + p_1) \ldots (j,2^q + p_r)}(f_{j,\alpha}) = \left( \frac{dr}{r} \right) \frac{1}{d-r} 2^{-dqr - dr - \nu r - 1} K \mu_0^d 2^{-j(1+\alpha)}.
\]

The claim of the lemma follows. \( \square \)

**Proof of Theorem 4.** Let \( c(\psi, d) \) be as in Lemma 2. Choose an integer \( j^* \) such that

\[
c(\psi, d)^2 K^2 2^{-j^*(2\alpha + d)} \in [1/n, 2^{2\alpha + d}/n].
\]

This means that \( 2^{j^*} \geq \frac{1}{2} (c(\psi, d)^2 K^2 n)^{1/(2\alpha + d)} \). By Lemma 2, there exists a function \( f_{j^*,\alpha} \) of the form \( h(x_1 + \ldots + x_d) \), \( h \in C^1([0,d], K) \), such that with (5.2),

\[
R(\hat{f}_n, f_{j^*,\alpha}) \geq \sum_{p_1, \ldots, p_d \in \{0,1,\ldots, 2^{j^* - q - \nu - 1}\}} \frac{1}{n} \frac{1}{n} 2^{j^* d - q d - \nu d} \gtrsim n^{-\frac{2\alpha}{2\alpha + 2}}.
\]

\( \square \)
