Least Prime Primitive Roots

N. A. Carella

Abstract: This note presents an upper bound for the least prime primitive roots $g^*(p)$ modulo $p$, a large prime. The current literature has several estimates of the least prime primitive root $g^*(p)$ modulo a prime $p \geq 2$ such as $g^*(p) \ll p^c, c > 2.8$. The estimate provided within seems to sharpen this estimate to the smaller estimate $g^*(p) \ll p^{5/\log\log p}$ uniformly for all large primes $p \geq 2$.

1 Introduction

This note provides the details for the analysis of some estimates for the least primitive root $g(p)$, and the least prime primitive root $g^*(p)$ in the cyclic group $\mathbb{Z}/(p - 1)\mathbb{Z}, p \geq 2$ prime. The current literature has several estimates for the least prime primitive root $g^*(p)$ modulo a prime $p \geq 2$ such as $g^*(p) \ll p^c, c > 2.8$. The actual constant $c > 2.8$ depends on various conditions such as the factorization of $p - 1$, etc. These results are based on sieve methods and the least primes in arithmetic progressions, see [22], [21], [15]. Moreover, there are a few other conditional estimates such as $g(p) \leq g^*(p) \ll (\log p)^6$, see [31], and the conjectured upper bound $g^*(p) \ll (\log p)(\log \log p)^2$, see [3]. On the other direction, there is the Turán lower bound $g^*(p) \geq g(p) = \Omega(\log p \log \log p)$, refer to [4], [29, p. 24], and [24] for discussions. The result stated in Theorem 1 improves the current estimate to the smaller estimate $g^*(p) \ll p^{5/\log \log p}$ uniformly for all large primes $p \geq 2$.

Theorem 1. Let $p \geq 3$ be a large prime. Then the following hold.

1. Almost every prime $p \geq 3$ has a prime primitive root $g^*(p) \ll (\log p)^c, c > 1$ constant.
2. Every prime $p \geq 3$ has a prime primitive root $g^*(p) \ll p^{5/\log \log p}$.

Case (1) explains the frequent occurrence of very small primitive roots for almost every prime; and case (2) explains the rare occurrence of large prime primitive roots modulo $p \geq 2$ on a subset of density zero in the set of primes. The term for almost every prime refers to the set of all primes, but a subset of primes of zero density. The subset of exceptional primes are of the form $p - 1 = \prod_{q \leq \log p} q^{v^q}$, where $q \geq 2$ is prime, and $v \geq 1$. The proof appears in Section 5.

2 Basic Concepts

Let $G$ be a finite group of order $q = \#G$. The order $\text{ord}(u)$ of an element $u \in G$ is the smallest integer $d \mid q$ such that $u^d = 1$. An element $u \in G$ is called a primitive element if it has order $\text{ord}(u) = q$. A cyclic group $G$ is a group generated by a primitive element $\tau \in G$. Given a primitive root $\tau \in G$, every element $0 \neq u \in G$ in a cyclic group has a representation as $u = \tau^v, 0 \leq v < q$. The integer $v = \log u = \log_{\tau} u$ is called the discrete logarithm of $u$ with respect to $\tau$.

2.1 Simple Characters Sums

Let $d \mid q$. A character $\chi$ modulo $q \geq 2$, is a complex-valued periodic function $\chi : \mathbb{N} \rightarrow \mathbb{C}$, and it has order $\text{ord}(\chi) = d \geq 1$ if and only if $\chi(n)^d = 1$ for all integers $n \in \mathbb{N}, \text{gcd}(n, q) = 1$. For $q \neq 2^r, r \geq 2$, a multiplicative character $\chi \neq 1$ of order $\text{ord}(\chi) = d$, has a representation as

$$\chi(u) = e^{i2\pi k \log(u)/d},$$

where $v = \log u$ is the discrete logarithm of $u \neq 0$ with respect to some primitive root, and for some integer $k \in \mathbb{Z}$, see [20, p. 187], [25, p. 118], and [17, p. 271]. The principal character
\( \chi_0 = 1 \mod q \) has order \( d = 1 \), and it is defined by the relation
\[
\chi_0(n) = \begin{cases} 
1 & \text{if } \gcd(n, q) = 1, \\
0 & \text{if } \gcd(n, q) \neq 1.
\end{cases}
\tag{2}
\]

And the nonprincipal character \( \chi \neq 1 \mod q \) of order \( \text{ord}(\chi) = d > 1 \) is defined by the relation
\[
\chi(n) = \begin{cases} 
\omega^{\log n} & \text{if } \gcd(n, q) = 1, \\
0 & \text{if } \gcd(n, q) \neq 1,
\end{cases}
\tag{3}
\]
where \( \omega \in \mathbb{C} \) is a \( d \)-th root of unity.

The Mobius function and Euler totient function occur in various formulae. For an integer \( n = p_1^{v_1} p_2^{v_2} \cdots p_t^{v_t} \), with \( p_k \geq 2 \) prime, and \( v_i \geq 1 \), the Mobius function is defined by
\[
\mu(n) = \begin{cases} 
(-1)^t & \text{if } n = p_1 p_2 \cdots p_t, \text{ all } k \geq 1, \\
0 & \text{if } n \neq p_1 p_2 \cdots p_t, \text{ some } k \geq 1.
\end{cases}
\tag{4}
\]

The Euler totient function counts the number of relatively prime integers \( \varphi(n) = \# \{ k : \gcd(k, n) = 1 \} \). This is compactly expressed by the analytic formula
\[
\varphi(n) = n \prod_{d \mid n} (1 - 1/p) = n \sum_{d \mid n} \frac{\mu(d)}{d}. \tag{5}
\]

**Lemma 1.** For a fixed integer \( u \neq 0 \), and an integer \( q \in \mathbb{N} \), let \( \chi \neq 1 \) be nonprincipal character mod \( q \), then
\[
1. \sum_{\text{ord}(\chi) = \varphi(q)} \chi(u) = \begin{cases} 
\varphi(q) & \text{if } u \equiv 1 \mod q, \\
-1 & \text{if } u \neq 1 \mod q.
\end{cases}
\]
\[
2. \sum_{1 \leq a < \varphi(q)} \chi(au) = \begin{cases} 
\varphi(q) & \text{if } u \equiv 1 \mod q, \\
-1 & \text{if } u \neq 1 \mod q.
\end{cases}
\]

### 2.2 Representation of the Characteristic Function

The characteristic function \( \Psi : G \rightarrow \{0, 1\} \) of primitive element is one of the standard tools employed to investigate the various properties of primitive roots in cyclic groups \( G \). Many equivalent representations of characteristic function \( \Psi \) of primitive elements are possible. The best known representation of the characteristic function of primitive elements in finite rings is stated below.

**Lemma 2.** Let \( G \) be a finite group of order \( q = \#G \), and let \( 0 \neq u \in G \) be an invertible element of the group. Assume that \( v = \log u \), and \( e = \gcd(d, v) \). Then
\[
\Psi(u) = \frac{\varphi(q)}{q} \sum_{d \mid q} \frac{\mu(d)}{\varphi(d)} \sum_{\text{ord}(\chi) = d} \chi(u) = \begin{cases} 
1 & \text{if } \text{ord}(u) = q, \\
0 & \text{if } \text{ord}(u) \neq q.
\end{cases}
\tag{6}
\]
Finer details on the characteristic function are given in [12, p. 863], [20, p. 258], [23, p. 18], [34], et alii. The characteristic function for multiple primitive roots is used in [8, p. 146] to study consecutive primitive roots. In [18] it is used to study the gap between primitive roots with respect to the Hamming metric. In [30] it is used to study Fermat quotients as primitive roots. And in [34] it is used to prove the existence of primitive roots in certain small subsets $A \subset \mathbb{F}_{p^n}$, $n \geq 1$. Many other applications are available in the literature. An introduction to elementary character sums as in Lemmas 1 and 2 appears in [20, Chapter 6].

## 3 Basic $L$-Functions Estimates

For a character $\chi$ modulo $q \geq 2$, and a complex number $s \in \mathbb{C}, \Re(s) > 1$, an $L$-function is defined by the infinite sum $L(s, \chi) = \sum_{n \geq 1} \chi(n) n^{-s}$. Simple elementary estimates associated with the characteristic function of primitive roots are calculated here.

### 3.1 An $L$-Function for Prime Primitive Roots

The analysis of the least prime primitive root mod $p$ is based on the Dirichlet series

$$L(s, \Psi \Lambda) = \sum_{n \geq 1} \frac{\Psi(n) \Lambda(n)}{n^s},$$

where $\Psi(n)\Lambda(n)/n^s$ is the weighted characteristic function of primes and prime powers primitive roots mod $p$. This is constructed using the characteristic function of primitive roots, which is defined by

$$\Psi(n) = \begin{cases} 
1 & \text{if } n \text{ is a primitive root,} \\
0 & \text{if } n \text{ is not a primitive root,}
\end{cases}$$

where $p \geq 2$ is a prime, see Lemma 3 for the exact formula, and the vonMangoldt function

$$\Lambda(n) = \begin{cases} 
\log p & \text{if } n = p^k, k \geq 1, \\
0 & \text{if } n \neq p^k, k \geq 1.
\end{cases}$$

The function $L(s, \Psi \Lambda)$ is zero-free, and analytic on the complex half plane $\{s \in \mathbb{C} : \Re(s) = \sigma > 1\}$. Furthermore, it has a pole at $s = 1$. This technique has a lot of flexibility and does not require delicate information on the zero-free regions $\{s \in \mathbb{C} : 0 < \Re(s) = \sigma < 1\}$ of the associated $L$-functions. Moreover, the analysis is much simpler than the sieve methods used in the current literature – lex parsimoniae.

The nonprincipal partial sum of the previous $L$-function has a mild dependence on the prime $p$, this is made explicit in the next result.

**Lemma 3.** Let $p \geq 2$ be a prime number, and let $\chi_0$ be the principal character modulo $p$. For a real number $x \geq 1$, and a real number $s = \sigma > 1$, the nonprincipal partial sum

$$\sum_{n \leq x} \frac{\Lambda(n)\chi_0(n)}{n^s} = -\frac{\zeta'(s)}{\zeta(s)} - \sum_{k \geq 0} \frac{\log p}{p^{(1+k)s}} + O \left( \frac{\log x}{x^{s-1}} \right).$$

Proof. The principal character $\chi_0(n) = 0$ if and only if $p \mid n$. Otherwise $\chi(n) = 1$. Moreover, the series
\[
\sum_{n \geq 1} \frac{\Lambda(n)}{n^s} = -\frac{\zeta'(s)}{\zeta(s)},
\]  
where $\zeta(s)$ is the zeta function, is absolutely convergent for $\Re(s) = \sigma > 1$. The smaller correction constant
\[
\sum_{n \geq 1} \frac{\Lambda(pn)}{(pn)^s} = \sum_{k \geq 0} \frac{\log p}{p(1+k)s}
\]  
accounts for the missing integers $n \equiv 0 \mod p$. In particular, at $s = 2$, this is
\[
-\frac{\zeta'(2)}{\zeta(2)} - \sum_{k \geq 0} \frac{\log p}{p(1+k)^2} + O \left( \frac{\log x}{x} \right) = \kappa_2(p) + O \left( \frac{\log x}{x} \right),
\]  
where $\kappa_2(p) > 0$ is a constant for any fixed prime $p$.

A formula for computing the constant $-\zeta'(2)/\zeta(2) > 0$ is given in [10, 25.6.15].

Lemma 4. Let $x \geq 2$ be a real number. Let $p \geq 2$ be a prime, and let $\chi \neq 1$ be the nontrivial characters modulo $d$, where $d \mid (p-1)$. If $s = \sigma > 1$ is a real number, then principal partial sum
\[
\sum_{n \leq x} \frac{\Lambda(n)}{n^s} \sum_{1 < d \mid p-1} \frac{\mu(d)}{\varphi(d)} \sum_{\text{ord}(\chi) = d} \chi(n) = O \left( \frac{2^{\omega(p-1)}}{x^{\sigma-1}} \right). 
\]  

Proof. Rearranging the principal partial sum and taking absolute value yield
\[
\left| \sum_{n \leq x} \frac{\Lambda(n)}{n^s} \sum_{1 < d \mid p-1} \frac{\mu(d)}{\varphi(d)} \sum_{\text{ord}(\chi) = d} \chi(n) \right| \leq \sum_{1 < d \mid p-1} \left| \sum_{\text{ord}(\chi) = d, \ n \leq x} \frac{\chi(n)\Lambda(n)}{n^s} \right| \leq \sum_{1 < d \mid p-1} \left| \sum_{\text{ord}(\chi) = d, \ n \leq x} \frac{n^s}{n^s} \right|,
\]  
where $\varphi(d) = \#\{\chi \neq 1 : \chi^d = 1\}$ is the number of nontrivial characters of order $d > 1$. The inner sum is estimated, using Abel summation formula, (discussed in [25, p. 12] and [35], as
\[
\sum_{n \leq x} \frac{\chi(n)\Lambda(n)}{n^s} = \int_1^x \frac{1}{t^s} d\psi_W(t) \ll \frac{1}{x^{s-1}},
\]  
where
\[
|\psi_W(x)| = \sum_{n \leq x} \chi(n)\Lambda(n) \ll x.
\]  

5
Substitute this estimate of the integral back into (15) returns

\[
\sum_{1 < d | p-1} \mu^2(d) \left| \sum_{n \leq x} \frac{\chi(n)\Lambda(n)}{n^s} \right| \ll \frac{1}{x^{\sigma-1}} \sum_{1 < d | p-1} \mu^2(d) \ll O \left( \frac{2\omega(p-1)}{x^{\sigma-1}} \right).
\]

The estimates in (16) and (17) are trivial, but sufficient. Similar and sharper results are proved in [25, Theorem 4.11], and similar references.

4 Prime Divisors Counting Function

For \( n \in \mathbb{N} \), the prime counting function is defined by \( \omega(n) = \# \{ p \mid n \} \). Somewhat similar proofs of the various properties of the arithmetic function \( \omega(n) \) are given in [16, p. 473], [25, p. 55], [9, p. 34], [33, p. 83], and other references.

**Lemma 5.** Let \( n \geq 1 \) be a large integer. Then,

1. Almost every integer \( n \geq 1 \) satisfies the inequality
   \[
   \omega(n) \ll \log \log n.
   \]

2. Every integer \( n \geq 1 \) satisfies the inequality
   \[
   \omega(n) \ll \frac{n}{\log \log n}.
   \]

**Lemma 6.** Let \( n \geq 1 \) be a large integer. Then,

1. Almost every integer \( n \geq 1 \) satisfies the number of squarefree divisors inequality
   \[
   2^{\omega(n)} \ll 2^{\log \log n}.
   \]

2. For every integer \( n \geq 1 \), the number of squarefree divisors satisfies the inequality
   \[
   2^{\omega(n)} \ll 2^{\log n/\log \log n}.
   \]

The Euler constant is defined by the formula \( \gamma = \lim_{x \to \infty} \left( \sum_{n \leq x} \frac{1}{n} - \log x \right) \), and the Mertens constant is defined by the formula \( B_1 = \lim_{x \to \infty} \left( \sum_{p \leq x} \frac{1}{p} - \log \log x \right) \), and \( c > 0 \) is an absolute constant.
Remark 1. The average order of the prime divisor counting function is precisely
\[
\frac{1}{x} \sum_{n \leq x} \omega(n) = \log \log n + B_1 + (\gamma - 1)/\log n + O \left( e^{-c\sqrt{\log n}} \right),
\] (23)
and the standard deviation is \( \ll \sqrt{\log \log n} \), this implies the first statement in Lemma 5. And any integer \( n \geq 1 \) has at most \( \omega(n) \ll \log n/\log \log n \) primes, this can be proved using the product
\[
n = \prod_{p \leq x} p < e^{\sum_{p \leq w} \log p}.
\] (24)
The properties of the distribution of the omega function has been extended to a wide range of subsets of integers, arithmetic functions and number fields, the interested reader should refer to the literature. In particular, \( \omega(p - 1) \) satisfies all the properties stated in Lemmas 5 and 6, see [14] and other more recent publications.

5 The Least Prime Primitive Roots

It is expected that there are estimates for the least prime primitive roots \( g^*(p) \geq g(p) \), which are quite similar to the estimates for the least primitive roots \( g(p) \). This is a very small quantity and nowhere near the currently proved results. In fact, the numerical tables confirm that the least prime primitive roots are very small, and nearly the same magnitude as the least primitive roots, but have more complex patterns, see [27].

Proof. (Theorem 1) Fix a large prime \( p \geq 2 \), and consider summing the weighted characteristic function \( \Psi(n)\Lambda(n)/n^s \) over a small range of both primes and prime powers \( q^k \leq x, k \geq 1 \), see Lemma 2 Then, the nonexistence equation
\[
0 = \sum_{n \leq x} \frac{\Psi(n)\Lambda(n)}{n^s} = \sum_{n \leq x} \frac{\Lambda(n)}{n^s} \left( \frac{\varphi(p - 1)}{p - 1} \sum_{d \mid p - 1} \frac{\mu(d)}{\varphi(d)} \sum_{\text{ord}(\chi) = d} \chi(n) \right),
\] (25)
where \( s > 1 \) is a real number, holds if and only if there are no primes or prime powers primitive roots in the interval \([1, x]\).

Separating the nonprincipal part and the principal part, and applying Lemma 3 and Lemma 4 with \( q = p - 1 \), and \( s = 2 \), yield
\[
0 = \sum_{n \leq x} \frac{\Lambda(n)\chi_0(n)}{n^s} + \sum_{1 < d \mid p - 1} \frac{\mu(d)}{\varphi(d)} \sum_{\text{ord}(\chi) = d} \sum_{n \leq x} \frac{\Lambda(n)\chi(n)}{n^s} = \kappa_2 + O \left( \frac{\log x}{x} \right) + O \left( 2^{\omega(p - 1)} \frac{\log x}{x} \right),
\] (26)
where \( \kappa_2 = \kappa_2(p) > 0 \) is a constant, which depends on the fixed prime \( p \geq 2 \), see (13).
Case I: Restriction to the average integers $p - 1$, with $2^{\omega(p-1)} \ll \log p$. Refer to Lemmas 5 and 6 for more details.

Let $x = (\log p)^{1+\varepsilon}, \varepsilon > 0$, and suppose that the short interval $[2, (\log p)^{1+\varepsilon}]$ does not contain primes or prime powers primitive roots. Then, replacing these information into (26) yield

$$0 = \kappa_2 + O\left(\frac{\log x}{x}\right) + O\left(\frac{2^{\omega(p-1)}}{x}\right)$$

(27)

$$= \kappa_2 + O\left(\frac{1}{(\log p)^\varepsilon}\right) > 0.$$  

Since $\kappa_2 > 0$ is a constant, this is a contradiction for all sufficiently large prime $p \geq 3$.

Case II: No restrictions on the integers $p - 1$, with $2^{\omega(p-1)} \ll p^{A/\log \log p}$. Refer to Lemmas 5 and 6 for more details.

Let $x = p^{5/\log \log p}$, and suppose that the short interval $[2, p^{5/\log \log p}]$ does not contain primes or prime powers primitive roots. Then, replacing these information into (26) yield

$$0 = \kappa_2 + O\left(\frac{\log x}{x}\right) + O\left(\frac{2^{\omega(p-1)}}{x}\right)$$

(28)

$$= \kappa_2 + O\left(\frac{1}{p^{1/\log \log p}}\right) > 0.$$  

Since $\kappa_2 > 0$ is a constant, this is a contradiction for all sufficiently large prime $p \geq 3$. ■

Remark 2. Explanation For the two cases.

1. Case I: The average magnitude of $\omega(\operatorname{ord}_p(\tau)) = \omega(p-1) \ll \log p$. There is an explicit relationship between the order $\operatorname{ord}_p(\tau)$ of the element $\tau \in \mathbb{F}_p$, the number of primes $\omega(\operatorname{ord}_p(\tau)) = \omega(p-1)$, the order of the multiplicative group $\#G = p - 1$, the number of primes $\omega(\#G) = \omega(p-1)$, and the prime $p$. These explicit dependencies lead to the upper limit $x = (\log p)^{1+\varepsilon}, \varepsilon > 0$.

2. Case II. The extreme size of $\omega(\operatorname{ord}_p(\tau)) = \omega(p-1) \ll \log p$. There is an explicit relationship between the order $\operatorname{ord}_p(\tau)$ of the element $\tau \in \mathbb{F}_p$, the number of primes $\omega(\operatorname{ord}_p(\tau)) = \omega(p-1)$, the order of the multiplicative group $\#G = p - 1$, the number of primes $\omega(\#G) = \omega(p-1)$, and the prime $p$. These explicit dependencies lead to the upper limit $x = p^{5/\log \log p}$.

6 Addendum

The same analysis extends to other multiplicative groups $G$ of order $\#G = q$ provided that the order $\operatorname{ord}_q(\tau)$ of the element $\tau \in G$, the number of primes $\omega(\operatorname{ord}_q(\tau))$, the number of primes $\omega(\#G) = \omega(q)$, and the integer $q$ have a explicit nontrivial relationship.
For elements in the multiplicative group \((\mathbb{Z}/p\mathbb{Z})^\times\) such that \(\omega(\text{ord}_p(\tau))\) is a small constant, there is no explicit relationship between the prime \(p\) and \(x\), accordingly, the analysis is very delicate.

### 6.1 Quadratic Nonresidues

In the case of quadratic nonresidues \(n(p) \mod p\), order \(\text{ord}_p(n(p)) = 2\), and the number of primes \(\omega(\text{ord}_p(n(p)) = 1\). Thus, there is no nontrivial explicit relationship between the different parameters. Moreover, there are just two characters: the principal \(\chi_0(n) = 1\) and the quadratic character is \(\chi(n) = \left(\frac{n}{p}\right)\). Using the same analysis as in the proof of Theorem 1, the last equation (28) reduces to

\[
0 = \sum_{n \leq x} \frac{(\chi_0(n) - \chi(n)) \Lambda(n)}{n^2} = \kappa_2(p) + \sum_{n \leq x} \frac{\chi(n) \Lambda(n)}{n^2} + O\left(\frac{\log x}{x}\right). \tag{29}
\]

But, there is no simple expression as in Case I and II above to link the variable \(x = x(p)\) and \(p\) for all primes \(p\), see Remark 2.

The least \(x \geq 1\) is not arbitrary, it depends on the maximal number of consecutive quadratic residues, this made explicit in the decomposition of the \(L\)-series as

\[
\sum_{n \geq 1} \frac{(\chi_0(n) - \chi(n)) \Lambda(n)}{n^2} = \sum_{n \geq 1} \frac{\chi_0(n) \Lambda(n)}{n^2} - \sum_{n \geq 1} \frac{\chi(n) \Lambda(n)}{n^2}. \tag{30}
\]

Assuming the RH, it is \(n(p) \leq x = O(\log^2 p)\), see [1]. Furthermore, the restriction to certain characters \(\chi \mod p\) produces a better bound \(n(p) \leq x = (\log p)^{1.4}\) as proved in [7].

The classical quadratic nonresidue test

\[
a^{(p-1)/2} \not\equiv 1 \mod p \tag{31}
\]

for \(\gcd(a, p) = 1\), and the primitive root test

\[
a^{(p-1)/r} \not\equiv 1 \mod p \tag{32}
\]

for all prime divisors \(r \mid p - 1\), are the same or nearly the same for primes with very few prime divisors \(r \mid p - 1\). In the extreme cases of Fermat primes \(p = 2^{2^m} + 1\) and Germain primes \(p = 2^aq^b + 1\) with \(a, b \geq 1\) and \(q \geq 3\) prime, these tests are the same. Consequently, Theorem 1 for \(\omega(p - 1) \ll \log \log p\) seems to imply \(n(p) \ll \log^{1+\varepsilon} p\).

### 6.2 Average And Conjectures

The average value of a quadratic nonresidue \(n(p) \mod p\) is extremely small

\[
\overline{n(p)} = \lim_{x \to \infty} \frac{1}{\pi(x)} \sum_{p \leq x} n(p) = 2.920050 \ldots, \tag{33}
\]
a general discussion and a proof appear in [28]. But, there exists a subset of primes of zero density that have large nonquadratic residues $n(p) \to \infty$ as $p \to \infty$.

The Vinogradov quadratic nonresidue conjecture states that the least quadratic nonresidue modulo $p$ satisfies $n(p) \ll p^\varepsilon$, with $\varepsilon > 0$ an arbitrary small number, see [19]. Since

$$n(p) \leq g^*(p) \ll p^{5/\log \log p} \ll p^\varepsilon,$$

this is implied by Theorem [1]. In addition, a recent conjecture calls for

$$n(p) \leq x = O((\log p)(\log \log p)),$$

see [13], [32], and similar literature.
