Point-contact spectroscopy of several non-superconducting topological materials reveals a low-temperature phase transition that is characterized by a Bardeen-Cooper-Schrieffer-type of criticality. We find such a behavior of differential conductance for topological surfaces of non-magnetic and magnetic Pb1−y−zSnzMnyTe. We examine a possible contribution from superconducting nanoparticles, and show to what extent our data are consistent with Brzezicki’s et al. theory [arXiv:1812.02168] assigning the observations to a collective state adjacent to atomic steps at topological surfaces.

Introduction. A series of point-contact experiments has revealed the existence of low-energy modes at junctions of metal tips with topological semiconductors and semimetals [1–3]. Surprisingly, despite the absence of global superconductivity in these systems, the features in dI/dV decay critically with temperature and the magnetic field in accord with the Bardeen-Cooper-Schrieffer (BCS) theory. It has, therefore, been concluded that the superconductivity results from tip-induced strain. In the case of Cd3As2 this interpretation appears to be supported by the featureless spectrum in the case of a soft point-contact produced by silver paint [3, 6]. Surprisingly, however, Andreev reflection-type spectra were recently reported for Au/Cd3As2 junctions (with neither a four probe zero-resistance state nor the Meissner effect) [8], as well as for topological semimetals MoTe2 [7] and WC [9] with hard and soft point-contacts [7] of various nonmagnetic and magnetic metals [9]. A timely question then arises about the properties of other materials, such as topological crystalline insulators (TCI) [10–14] in which hard point-contact characteristics reveal zero-bias conductance peaks (ZBCPs) [11].

Here we show, employing a soft point-contact method, that a conductance gap with a broad ZBCP or Andreev-type characteristics develop at junctions of Ag with topological surfaces of diamagnetic, paramagnetic, and ferromagnetic Pb1−y−zSnzMnyTe, where y ≥ 0.67 and 0 ≤ x ≤ 0.10, in which no signs of superconductivity are found. Nevertheless, the temperature dependence of the gap shows a BCS-like critical behavior as a function of temperature T and the magnetic field H with Tc up to 4.5 K and μ0Hc up to 3 T independent of the orientation of the magnetic field with respect to the surface plane. This implies the emergence of a collective low-temperature phase whose appearance is insensitive not only to the magnetic state of the metallic part of the junction, as found previously [10, 11], but also to the magnetic character of the topological material. In order to elucidate the nature of these striking observations we put forward two models.

First, previous studies of the materials in question revealed superconductivity associated with metal nano-precipitates [15] or misfit dislocations at the heterostructure interfaces [16, 17]. Furthermore, studies of Pb/(Pb,Sn)Te junctions point to the presence of Sn diffusion in Pb [18], which rises the question on whether such an effect could generate superconducting Pb or Sn at the interface. It might be also anticipated that strain associated with different thermal expansion coefficients of silver paint and the samples or hard tips could generate misfit dislocations or precipitates. However, a series of auxiliary high-sensitivity magnetization and resistance measurements as well as high-resolution structural investigations of our samples have not revealed the presence of superconducting nanoparticles within our experimental resolution.

Second, a possible origin of a local collective phase at topological surfaces has recently been proposed by Brzezicki, Wysokiński, and Hyart (BWH) [19, 20], who noted that the electronic structure of one-dimensional (1D) states at atomic steps in TCIs, revealed by scanning tunneling microscopy [20, 21], is significantly richer than anticipated previously [20, 22]. According to BWH, these 1D states may show a low-temperature Peierls-like instability leading to the appearance of low-energy excitations associated with topological states at the domains walls of the collective phase. We discuss to what extent our data are consistent with the BWH model and a possible microscopic nature of the collective phase.

Samples. We investigate here single crystals of rock salt Pb1−ySnyTe and Pb1−y−zSnzMnyTe obtained via the self-selecting vapor growth method [12, 24] and the Bridgman technique [25], respectively. Results of electric, magnetic, x-ray, and electron transmission microscopy characterization of the studied samples are presented in the Supplemental Material [26]. We study samples with y = 0, 0.2, 0.67, 0.74, 0.8, and 1, which covers both the topologically trivial and non-trivial range, as the TCI phase occurs for y ≥ 0.30 [14]. According to both angle-resolved photoemission [13, 14, 27] and magnetotransport...
investigations $^{[25]}$, the surface topological cones coexist with bulk states even for high bulk carrier densities specific to these systems. At the same time, the energetic position of the surface-cone neutrality points with respect to the Fermi level depends on the character of the surface states and the degree of surface oxidation, the question under investigations now $^{[20, 30]}$. The search for metal precipitates by x-ray diffraction and electron microscopy, also in the vicinity of dislocations, has not revealed the presence of any nanoclustering within the state of the art resolution $^{[25]}$.

According to the results of magnetization measurements $^{[26]}$, carried out by employing a superconducting quantum interference device (SQUID), non-magnetic compounds show a field-independent diamagnetic susceptibility, enhanced by strong interband polarization in the inverted band structure case. The Mn-doped samples contain a Sn concentration corresponding to the TCI phase and a bulk hole density high enough to populate $12 \Sigma$ valleys. A large density of states (DOS) associated with these valleys makes hole-mediated exchange coupling between Mn ions sufficiently strong to drive the ferromagnetic ordering $^{[25, 31]}$. The Curie temperature $T_{Curie}$, separating the paramagnetic and ferromagnetic phase, is 2.7 and 14 K for the Mn concentration $x = 0.03$ and 0.10, and Sn content $y = 0.67$ and 0.74, respectively $^{[20]}$. These values are consistent with the mean-field $p-d$ Zener model $^{[26, 32, 33]}$.

**Point-contact spectroscopy.** We employ the soft point-contact method $^{[34, 36]}$, in which a 15 µm Au wire is fixed by silver paint. As shown in Fig. 2(a), $dI/dV(V)$ is featureless in the case of the topologically trivial materials PbTe and Pb$_{0.80}$Sn$_{0.20}$Te. However, in the case of the diamagnetic TCI Pb$_{0.20}$Sn$_{0.80}$Te we find at low temperatures $T < T_c$ and magnetic fields $H < H_c$ maxima (ZBCP) centered at $V = 0$ and superimposed on a conductance gap (see also data Ref. $^{[25]}$). As observed in other systems $^{[16, 38, 39]}$, the spectra form vary from contact to contact $^{[26]}$. In the thermal regime they change over time in a jump way as well as can be modified by
current pulses across the point contact \[26\,34\].

Within the point-contact theories \[34\], the enhanced junction conductance at \(T < T_c\) and at \(V \approx 0\), i.e., the presence of ZBCP, can be interpreted in terms of the Andreev reflection (pointing to superconductivity) or to enlarged DOS due to the appearance of, for instance, zero modes at \(T < T_c\). In either of these scenarios current heating at higher bias voltages may result in side minima \[37\]. Within the superconductivity models, such a spectrum is typical for the thermal regime, i.e., when the contact diameter is larger than the inelastic diffusion length \[34\] [Fig. 1(c)]. In the opposite limit, spectroscopic features in magnetic crystals have been detected [Fig. 2(c)]. Importantly, temperature and magnetic field ranges in which these spectroscopic features appear are rather enhanced compared to non-magnetic crystals. This is best seen in Fig. 3 that depicts the contact resistance and a half of the energy distance between conductance maxima, \(\Delta(T, H)\) for all studied samples with high Sn content. Furthermore, according to Fig. 3, \(\Delta(T)\) is quite well described by an interpolation formula of the BCS expression, \(\Delta(T) = Ck_B T_c \left[1 - (T/T_c)^{3.4}\right]^{0.5}\), where \(C\) in our case is more than twofold greater than the BCS value \(C = 1.76\). Similarly, a reasonable account of \(\Delta(H)\) data is obtained by using another interpolation formula suitable for type II superconductors, \(\Delta(T, H) = \Delta(T, H = 0)(1 - H/H_c)^{1/2}\). This description of \(\Delta(T, H)\) holds for the diamagnetic \(Pb_0.3Sn_{0.67}Mn_{0.03}Te\), ferromagnetic \(Pb_{0.16}Sn_{0.74}Mn_{0.10}Te\), and across the paramagnetic—ferromagnetic phase boundary, the case of \(Pb_{0.20}Sn_{0.07}Mn_{0.03}Te\), in which \(T_c > T_{Curie}\). The existence of a transition to another phase is also documented by a kink in the temperature dependence of the differential resistance for \(V \rightarrow 0\) at \(T_c\), as shown in Fig. 3(a).

The accumulated results demonstrate, therefore, the appearance in junctions of the normal metal with diamagnetic, paramagnetic, and ferromagnetic IV-VI TCIs of another phase below \(T_c\) and \(H_c\), which is characterized by an energy gap and excitations residing near its center. The presence of a phase transition rules out the Kondo effect \[35\,36\,37\] and the Coulomb gap \[29\,38\] as the mechanisms accounting for the observed features. Similarly, the absence of the global superconductivity without metal layers [Figs. 4(d) and 2(d)] as well as data in Ref. 26 indicate that unconventional 2D superconductivity associated with surface topological states \[44\] or dislocation arrays \[35\] in TCIs does not appear under our experimental conditions. The absence of 2D superconductivity is also documented by similar values of \(H_c\) for the magnetic field perpendicular and parallel to the surface \[26\].

Role of superconducting precipitates. According to comprehensive structural and SQUID studies, magnetic nanoparticles account for high \(T_{Curie}\) ferromagnetism observed in a number of semiconductors and oxides over the last two decades \[10\]. Similarly to the ferromagnetic case, embedded nanoparticles can show a variety of superconducting characteristics, such as the Meissner effect, which may depend on nanoparticle chemical composition, strain, and size \[13\,17\,18\]. Here, the presence of superconducting precipitates that could give rise to local superconductivity is ruled out, within an experimental accuracy of 0.1 ppm, by high-sensitivity beyond state-of-the-art SQUID magnetometry \[26\,39\]. Furthermore, no precipitates have been revealed by state-of-the-art x-ray diffraction and transmission microscopy measurements \[26\]. Similarly, no indications of superconductivity have been found in topological samples covered entirely by silver paint or containing a deposited silver film \[26\], pointing to the absence of both interfacial superconductivity and superconducting inclusions at the metal/semiconductor interface.

Role of surface atomic steps. Figure 4 presents the surface morphology of our single crystals under ambient conditions, determined by atomic force microscopy (AFM). As seen in Figs. 4(a,b), (001) facets of as grown \(Pb_{0.20}Sn_{0.80}Te\) contain atomically flat 0.5 \(\mu m\) wide terraces, terminated by monoatomic steps. Similarly, Figs. 4(c,d) visualize a (001) surface of cleaved \(Pb_{0.16}Sn_{0.74}Mn_{0.10}Te\) showing larger roughness and multilayer steps. Results in Figs. 1(b,c) and 2(c) were actually taken for these two surfaces, respectively. We claim that a collective low-temperature phase of the carrier liquid occupying 1D topological step states \[19\,23\] may account for the differential conductance spectra reported here. According to AFM micrographs, a single Ag grain extends over a dozen of steps. The magnitude of ZBCP, about 50 to 500\(e^2/h\), is consistent with the fact that several grains participate in the charge transport process. The above interpretation requires the Fermi level of our \(p\)-type samples to reside within the 1D states, whereas tight-binding computations place the 1D band in the gap \[19\,23\]. We note, however, that our experimental method implies the formation of Schottky’s metal-semiconductor junction, which leads usually to the Fermi level pinning in the band gap region at the semiconduc-
tor surface [50]. This effect, together with a considerable width of the 1D band, as predicted by the BWH theory [19], make the partial occupation of the 1D states plausible. The depletion in the bulk carrier density implies also that Mn spins adjacent to the surface will be rather coupled by antiferromagnetic superexchange [51] than by the hole-mediated ferromagnetic interactions dominating in the bulk [25, 26].

However, since the Fermi liquid is unstable in the 1D case, one expects the emergence of a collective state at low temperatures driven by carrier correlation, presumably enhanced by coupling to phonons and localized spins. For a class of electronic instabilities, such as superconductivity and charge/spin density waves, the BCS relation between the gap $2\Delta$ and the critical temperature $T_c$ remains valid within the mean-field approximation. However, because of the dominating role played by thermal and quantum fluctuations of the order parameter, the apparent magnitude of $T_c$ becomes much reduced in the 1D case [52, 53]. This explains the enhanced magnitude of $C$ over the BCS value (Fig. 3) but indicates also that 1D surface states may not support superconductivity with $T_c$ as high as 5 K.

As demonstrated by BWH [19], the 1D states adjacent to the surface atomic step show much more abundant spectrum than anticipated previously [20, 23]. Within this insight, the effects of magnetic instabilities have been considered and the nature of low-energy excitations proposed [19]. In an analogy with the Su–Schrieffer–Heeger model [54], the low-energy modes are associated with domain walls between the regions characterized by the opposite directions of the order parameter for which, as proven, topological invariants differ. These walls, and thus, low energy excitations vanish in the magnetic field with a rate determined by a competition of the carrier–carrier exchange coupling with the Zeeman, spin-orbit, and $sp$–$d$ exchange interactions. Depending on the assumed broadening, the evaluated conductance spectra show a single ZBCP, or a more complex peak structure that reflects the multi-mode excitation spectrum and may resemble Andreev reflection [19].

**Summary and outlook.** Our results on soft point-contact spectroscopy bring into light the existence of a low-temperature phase in lead-tin and lead-tin-manganese tellurides with tin content corresponding to the topological phase, which substantiates the universality of the phenomenum [11, 18, 8, 9]. The findings could be explained by the presence of superconducting nanoparticles, the surface topological states playing only an ancillary role. However, no indications for the formation of nanoparticles have so far been found. At the same time, our experiments do not provide evidence for the presence of superconductivity at the interface between the metal and the TCI. Hence, this phase can be also linked to carriers occupying 1D topological states adjacent to surface atomic steps, which undergo a transition to a collective state at sufficiently low temperatures and magnetic fields. Four microprobe measurements of conductance along individual steps in materials with the Fermi level within the step states are expected to demonstrate whether this collective phase is a 1D superconductor or a 1D gaped insulator with low-energy excitations at the domain walls. Future work will show to what extent the unusual properties associated with the presence of 1D and 0D topological states offer new and hitherto unexplored functionalities.
FIG. 4. AFM images of the studied single crystal surfaces. (a) Naturally grown (001) facet of Pb$_{0.20}$Sn$_{0.80}$Te showing surface steps. (c) Cleaved (001) surface of Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te showing multilayer steps and higher roughness. (b) and (d) depict step height profiles. The obtained values of about 0.3 nm in (b) correspond to a single atomic step (315 pm).

Search for precipitates by x-ray diffraction

For our experiments we prepared dedicated bulk crystals of the highest, currently available, quality. Our SnTe and Pb$_{0.2}$Sn$_{0.8}$Te crystals were grown by self-selecting vapor growth (SSVG) method known to provide large (volume of the order of 1 cm$^3$) single crystals with dominant (001) and additional (111) crystal facets (see photo in Fig. S1). The SSVG growth involves vapor transport in the presence of a small temperature gradient at temperatures slightly below the melting point, and provides IV-VI semiconductor crystals of excellent crystal quality, good chemical homogeneity with a relatively small deviation from stoichiometry, and free from detectable inclusions of foreign crystal phases.

Due to low vapor pressure of Mn, the growth of magnetic Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te crystals requires the application of the Bridgman method, i.e., crystallization from a melt. Although crystalline grains are here much smaller (typical dimension 0.5 mm) they are only slightly mis-oriented (0.06°). The uniformity of both carrier density and ferromagnetic properties point to the homogeneity of the chemical composition.

The crystallographic quality of the samples has been assessed by the state-of-the-art high-resolution x-ray diffraction (HR-XRD) and powder diffraction. The $\omega$, $2\theta/\omega$ scans, and reciprocal space maps (RSM) have been collected for reflection 444 (SnTe and Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te) and 006 (Pb$_{0.20}$Sn$_{0.80}$Te), as shown in Figs. S2, S3 and S4, respectively. For the crystals of SnTe and Pb$_{0.2}$Sn$_{0.8}$Te grown by the SSVG method one finds very sharp diffraction peaks fully accounted for by a single-rock salt crystal phase. The
application of various XRD geometries (as indicated in Figs. S2 and S3) permitted the determination of the RC width parameters of 92 and 74 arcsec for SnTe and Pb0.2Sn0.8Te, respectively. After correcting for diffraction peaks asymmetry and background contribution due to diffusive scattering by native defects (vacancies) present in the crystals we could also evaluate the crystal perfection of (111) and (001) planes as given by the RC width parameter 17-19.5 arcsec. One may notice that this magnitude of the RC parameters are observed for good GaAs (001) crystals.

In the case of Pb0.16Sn0.74Mn0.10Te - the planes (111) were inclined at the angle of 25° to the surface, so that 444 was asymmetrical (the x-ray geometry at a high angle to the sample was used). The Pb0.16Sn0.74Mn0.10Te sample consists of slightly misoriented 0.5 × 0.1 mm² single crystalline grains. The mean grain deviation angle is estimated to be 0.06 ± 0.02°. For an x-ray beam limited by a mask and slit of such dimensions, the single crystal diffraction pattern is observed (Fig. S4).

Wide-angle x-ray power diffraction for used to detect foreign crystallographic phases in the studied samples. The data collected in Figs. S2(d), S3(d), and S4(d) were taken with excellent statistics, peak-to-background ratio 74, and in a broad angular range (20 up to 159°). The positions of all peaks point to the rock salt crystal symmetry (Fm3-m) with no indication for the presence of a secondary phase. The determined lattice parameters are given in the Table II.

Search for precipitates by electron microscopy

Figure S5(a) shows scanning electron microscopy (SEM) image of a lamella prepared of Pb0.16Sn0.74Mn0.10Te for transmission electron microscopy (TEM) studies. A 5 × 2.5 µm defect-free area is presented in Fig. S5(b). The dark wavy features are due to lamella bending. The sharp feature seen at the bottom right corner is caused by mechanical deformation that occurred during the thinning process or by processing of the crystal during previous investigations. Structural defects (mainly small dislocation

Loops) can be found in some regions near the surface of the crystal - no deeper than 2 µm from the surface. No fluctuations of elemental composition or precipitations of other phases are detected. It appears that Pb and Mn atoms substitute the Sn atoms without ordering or segregation that could be detected within our sensitivity. The high-resolution TEM (HRTEM) image (Fig. S6) indicates a perfect cubic lattice visible in [110] zone axis. A quantitative profile of the crystal region containing structural defects (dislocations) near the surface zone obtained by energy dispersive x-ray spectroscopy (EDS) is presented in Fig. S7. No aggregation of particular constituents is detected, as composition fluctuations are within the error bar of the method. The determined atomic concentrations of the constituting elements are in good agreement with results of our SQUID measurements and specifications found in the previous characterization study$^7$.

**Magnetic properties**

According to results of magnetization measurements collected in Fig. S9, non-magnetic compounds show field-independent diamagnetic susceptibility, enhanced by strong interband polarization in the inverted band structure case. The Mn-doped samples contain Sn concentration corresponding to the TCI phase and the hole density high enough to populate twelve Σ valleys. A large density of states (DOS) associated with these valleys makes hole-mediated exchange coupling between Mn ions sufficiently strong to drive the ferromagnetic ordering$^{25, 31}$. As shown in Fig. S9, the Curie temperature $T_{\text{Curie}}$, separating the paramagnetic and ferromagnetic phase, is 2.7 and 14 K for the Mn concentration $x = 0.03$ and 0.10, and the Sn content $y = 0.67$ and 0.74, respectively.

According to the mean-field $p - d$ Zener model$^{32, 33}$

$$T_{\text{Curie}} = x_{\text{eff}} N_0 S(S+1) \beta_{\text{eff}}^2 \rho_F / 12 k_B - T_{\text{AF}},$$

where $x_{\text{eff}} < x$ and $T_{\text{AF}} > 0$ take into account the presence of short-range antiferromagnetic interactions, and $N_0$ is the cation concentration. Important effects of spin-orbit interactions, carrier-carrier correlation, and mixing between anion and cation wave functions are incorporated into an effective $p - d$ exchange integral $\beta_{\text{eff}}$. In or-

FIG. S7. (a) STEM-HAADF (out of zone axis). (b) EDS elemental concentration profile of Sn, Pb, Te, Mn, Pt of the area with near-surface dislocations. Note that atomic, not cation, concentrations are shown.

FIG. S8. TEM scan of large 71x71 nm of Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te crystal. No signs of precipitates or nanoclustering was found in TEM studies.

FIG. S9. TEM scan of large 71x71 nm of Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te crystal. No signs of precipitates or nanoclustering was found in TEM studies.
Order to evaluate its magnitude we take Mn spin $S = 5/2$ and DOS of holes at the Fermi level $\rho_F$ from specific heat measurements for Sn$_{1-x}$In$_x$Te with comparable hole densities [54]. The values of $x_{\text{eff}} = 0.024$ and 0.095 are determined from the Curie constant obtained from our magnetic susceptibility measurements between 100 K and $T_{\text{Curie}}$; $T_{\text{Curie}} = 8xS(S+1)J$, where $J \approx 1$ K (Ref.[51]). For the experimental magnitudes of $T_{\text{Curie}}$ we then obtain $N_0/|\chi_{\text{eff}}| = 0.25 \pm 0.02$ eV, a value at the upper bound of those determined for Mn-doped lead chalcogenides [56].

Search for superconducting precipitates by SQUID magnetometry

We assess the presence of superconducting Pb, Sn, and related precipitates in samples of topological Pb$_{0.20}$Sn$_{0.80}$Te and non-topological Pb$_{0.80}$Sn$_{0.20}$Te, discussed in the main body of the paper, by SQUID magnetometry. We start by discussing results of magnetization measurements for a reference sample Pb$_{0.63}$Sn$_{0.37}$Se. As shown in Fig. S10, two clear diamagnetic steps in the temperature and magnetic field dependencies of magnetization are recorded, quite accurately corresponding to Pb and Sn superconducting transition temperatures 7.2 and 3.7 K as well as critical magnetic fields at 2 K, 700 and 250 Oe, respectively. The presence of magnetic hysteresis points to some pinning. Assuming a spherical shape of precipitates, the field derivative of the magnetic moment $m$ assumes the form,

$$dm_i/dH = -3M_i/8\pi\rho_i,$$

where $M_i$, $\rho_i$, and $dm_i/dH$ are mass, density, and the experimentally established slopes corresponding to $i =$ Pb or $\beta$-Sn. From the experimental slopes $dm_i/dH$, depicted in Fig. S10(b), we obtain precipitation masses of $M_{\text{Pb}} = 1.7 \mu$g and $M_{\text{Sn}} = 14 \mu$g, which lead to the weight fraction of precipitates $f = 0.04\%$, as sample weight is 38 mg.

Neither Pb$_{0.20}$Sn$_{0.80}$Te nor Pb$_{0.80}$Sn$_{0.20}$Te shows such a signal. We assign a large concentration of Sn and Pb precipitates in Pb$_{0.63}$Sn$_{0.37}$Se to the fact that Sn content $y = 0.37$ is close the solubility limit $y \approx 0.40$. In order to test our telluride samples Pb$_{1-y}$Sn$_y$Te with even higher sensitivity and, in particular, to compensate a relatively large bulk diamagnetic signal, a dedicated sample holder has been prepared. As illustrated in Fig. S11(a), 20–40 mm long and 5 mm wide strips of sapphire are glued to the silicon sample holder [49] forming in the holder center a gap of the length of about 5 mm, to which studied samples are inserted [Fig. S11(a)]. As these sapphire strips extend from the gap for about 8 cm each way, by adjusting the mass of measured samples to be inserted into the gap, the total signal can be made field independent (typically down to 2% of the initial slope), provided that both the sample and the sapphire stripe do not contain any magnetic or superconducting inclusions. We use

(b–d) Magnetic moment of Pb$_{1-y}$Sn$_y$Te samples after compensating the diamagnetic signal linear in the magnetic field, $y = 0.20, 0.80$, and 1, respectively. Brighter and darker experimental points correspond to measurements for two sweeping directions of the magnetic field. The evaluated upper limit of the weight fraction of superconducting precipitates is 0.1 ppm [dashed line in (c)].

FIG. S12. Search for superconducting precipitates in silver paint employed for soft point contact spectroscopy deposited on Si. (a) Magnetic moment as a function of temperature. (b) Magnetization vs. magnetic field at 2 K. Data are corrected for substrate diamagnetism.

Resistance and differential conductance of Ag/TCI and Au/TCI interfaces

Our point-contact spectroscopy experiments have been performed by using silver paint. The remaining two contacts are spot-welded into the sample to ensure a good electrical connection. To check properties of the Ag/TCI interface we have deposited a 50 nm layer of Ag using ultra high vacuum e-beam evaporator onto a ferromagnetic Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te sample. Resistance measurements of the Ag/TCI bilayer have been carried out employing a four probe configuration with the current probes spot-welded to the sample and the voltage probes fixed by silver paint to the silver layer. The resistance measurements as a function of temperature [Fig. S11(a)] and bias voltage [Fig. S11(b)] do not exhibit any noticeable superconductivity in the studied temperature and bias voltage ranges. At the same time, in the three contact geometry, with one of the silver paint contacts serving as a current and voltage probe, we detect a ZBCP, as shown in Fig. S11(c). Thus we conclude that the presence of the ZBCP is not accompanied by a superconductivity of the Ag/TCI interface. Furthermore, a point contact spectroscopy experiment is performed by using only spot-
FIG. S13. Search for a magnetic indication of superconductivity in SnTe sample covered entirely by silver paint in an in-plane magnetic field. (a,b) Magnetic moment vs. temperature measured on cooling in a magnetic field of 10 Oe. (c) Magnetization vs. magnetic field at 2 K showing diamagnetism of SnTe.

FIG. S14. Search for resistive indication of superconductivity at Ag/TCI interface. Resistance $R$ of a bilayer of an Ag film deposited onto Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te measured by a four probe method as a function of temperature (a) and bias voltage (b). Inset presents the low-temperature range of the $R(T)$ dependence. No superconductivity is detected down 1.4 K. (c) Differential conductance measured in a three probe configuration showing a zero-bias conductance peak measured across the soft-point contact at the Ag/TCI interface.

FIG. S15. Differential conductance of Au welded contacts to TCI. Spectrum does not show any signatures of zero-bias anomaly or a gap.

Additional data on point contact spectroscopy

Figure S16 supplements data presented in the Fig. 2 in the main text. Figure S17 presents dependence of the gap, interpreted as a differential conductance minimum, on temperature (a) and the magnetic field (b) in the thermal regime. This is to support the data presented in the Figs. 3(b,c) in the main text. Figure S18 shows how spectroscopic features vanish as a function of temperature. First, the zero-bias peak decreases as a function of temperature, leaving clear gapped spectrum at 1.5 K. Similarly, the magnetic field quenches zero-bias peak as depicted in Fig. S19.

Magnetic anisotropy of differential conductance

In order to probe magnetic anisotropy of the point-contact spectra, differential conductance of the Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te sample has been measured for various fields perpendicular and parallel to the sample surface. As seen in Fig. S20 there is some anisotropy in the welded contacts. No features in differential conductance are found, as show in Fig. S15. This indicates that no ZBCP appears if the interface is damaged by the welding process.
FIG. S16. (a) Evolution of the spectra for Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te as a function of magnetic field in the thermal regime. (b) Temperature evolution of conductance spectra for Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te in the intermediate regime.

FIG. S17. Gap dependence $\Delta$ on temperature (a) and magnetic field (b) evaluated from the conductance minima from the differential conductance spectra presented in Figs.1 and 2 in the main manuscript. The red open circles on the panel (b) correspond to in-plane applied magnetic field.

peak heights but no noticeable differences in the width of the spectra. A minor magnitude of magnetic anisotropy reemphasizes that the observed low temperature phase has no global 2D character.

Effect of current pulses

In most cases freshly prepared silver paint contacts reveal zero-bias conductance peak in topologically non-trivial samples. However, some of the contacts stopped working after temperature sweeps or showed no structure during initial measurements. We have found, as could be expected for phenomena relying on properties of surface steps, that characteristics of differential conductance spectra in topological samples can be modified by current pulses, as shown in Fig. S21(a). A typical pulse sequence consists of 1 ms pulses with amplitude 100 mA, with the repetition rate of 10 Hz. Such a sequence does not awake any structure in conductance of non-topological Pb$_{0.80}$Sn$_{0.20}$Te [Fig. S21(b)].

AFM scans after point-contact spectroscopy studies

Figure S29 presents the AFM image of the (011) surface obtained by a wire-saw cut and subject to a series of etchings. As seen surface roughness are significantly

FIG. S18. The figure illustrates slices of Fig.1(b) from the main manuscript. It shows how ZBCP vanish as a function of temperature leaving clear gap structure. At 2.4 K spectrum is featureless.

FIG. S19. ZBCP quenched as a function of magnetic field in point contact spectroscopy of Pb$_{0.20}$Sn$_{0.8}$Te.

FIG. S20. Differential conductance spectra at various perpendicular and in-plane magnetic fields at 50 mK for Pb$_{0.16}$Sn$_{0.74}$Mn$_{0.10}$Te sample.
FIG. S21. Effect of current pulses on differential conductance characteristics in topological and non-topological samples. (a) In topological samples pulses can restore a peak structure in the case of contacts that have been initially featureless. (b) Differential conductance remains featureless in non-topological samples.

FIG. S22. Various point contact spectra obtained by applying small 1 ms current pulses across the contacts for $\text{Pb}_{0.16}\text{Sn}_{0.74}\text{Mn}_{0.10}\text{Te}$. The pulse height varied from 10 mA to 50 mA depending on the contact resistance.

FIG. S23. AFM image of wire saw cut (011) surface of the $\text{Pb}_{0.16}\text{Sn}_{0.74}\text{Mn}_{0.10}\text{Te}$ single crystal after series of etchings and measurements. This surface shows multilayer steps and a relatively high roughness.

larger compared to the freshly grown or cleaved surfaces, whose AFM images are presented in Fig. 4 of the main text.
